THE great Exhibition, held in 1851, resulted in a large profit which was well invested, and the income has for many years been awarded as scholarships to research students. The results prove that it was one of the best investments ever made. John Cunningham McLennan, among many other men ultimately distinguished in science, received such an award, and it enabled him to join the Cavendish Laboratory at Cambridge from his home in Ontario after his graduation at the University of Toronto. Under the guidance of Sir J. J. Thomson, the Cavendish was enjoying a burst of discovery in connexion with the electron and the ionisation of gases. Young McLennan quickly caught fire, and on his return to Toronto as a demonstrator in physics, at the age of thirty-two, he published a paper in the *Transactions of the Royal Society* (**195**, 1899) in which he proved that the ionisation of gases due to electrons in motion was similar in type to that due to Röntgen rays or the radiations from uranium.

At the same time that Rutherford and H. L. Cooke at McGill were discovering the penetrating radiation, supposedly and mainly from the radioactive substances in the ground, McLennan and E. F. Burton were finding, independently, similar results at Toronto. The later expansion of this subject into cosmic radiation was not then suspected. McLennan also carried out many experiments on the 'natural ionisation' in closed vessels, tracing the effects to minute quantities of radioactive materials, such as polonium in the walls, or radon in the enclosed air. By exposing sealed ionisation electroscopes over the ice on Lake Ontario, he definitely proved that the penetrating radiation over land was greater than over water, and this showed that a large part of the penetrating radiation came from the radium which Lord Rayleigh proved to be widely distributed in small quantities throughout primary and secondary rocks and sediments.

With immense energy, McLennan worked with others to raise funds for building that great physical laboratory at the University of Toronto which now so happily bears his name. Moreover, he secured abundant equipment with excellent apparatus especially for spectroscopy. One of his early successes was the discovery of the single line spectra of zinc, cadmium and magnesium and the deduction of their ionisation potentials. This was a sequel to the work of Frank and Hertz, who had obtained the single line spectrum for mercury. Electrons projected with low voltages in a discharge tube will excite a single line, but at a higher critical voltage the usual many-lined spectra appear.

During the War, McLennan came to England and took an intensely active part in the research work of the Admiralty in connexion with the anti-submarine campaign. His view was that a professor was co-equal in rank with an admiral, and he reported directly to the First Sea Lord. Thus, in certain magnetic work, he insisted on the speedy isolation of a submarine in a dock at Portsmouth with a view to a magnetic survey and the determination of its magnetic moment, hitherto an unknown quantity. At the same time, he organised the extraction of helium from natural gases near Calgary, and obtained a considerable quantity intended for airships and balloons, but actually used after the War for experimental purposes. During the greater part of 1919 he was scientific adviser to the Admiralty.

After the War, McLennan returned to Toronto and continued with enthusiasm and success his work on spectroscopy, for which he was awarded a Royal Medal of the Royal Society in 1927, and the following year he had the honour of giving the Bakerian Lecture to the Society on "The Aurora and its Spectrum". The brilliancy of the aurora is shown by the spectroscope to be due to nitrogen, and the lower limit of the height of the discharge has been proved by Størmer to be about eighty miles above the earth's surface. On any clear night it had been proved by Lord Rayleigh, Vegard and others that there is also present in the spectrum a notable green line (5377) the cause of which gave rise to much controversy. In the Bakerian Lecture (*Proc. Roy. Soc.*, A, **120**, 1928) McLennan described how he and G. M. Shrum had proved in the laboratory that the green line was due to *oxygen*, suitably mixed with argon, which when in a metastable state, as Frank had shown in similar cases, is capable of transferring its energy to a different type of gas.

McLennan next determined with characteristic energy to instal at Toronto a cryogenic laboratory capable of liquefying air, hydrogen and helium. In this difficult undertaking he received advice and plans from Onnes at Leyden and financial support from the National Research Council of Canada, and

the scheme was quickly brought to a successful issue, so that new avenues of research work were opened to his numerous students. The relations between supra-conductivity and magnetism both in elements and alloys were investigated, and such work is continuing under the able guidance of E. F. Burton, who succeeded McLennan on his retirement three years ago.

Prof. H. E. Armstrong wrote to *The Times* on October 12: "In McLennan we lost no mere scientific worker, but a man of the most admirable social gifts, indeed a man to fall in love with. It was a sight for the gods to see him beam with enthusiasm and joy, in his Royal Institution lecture, at his helium super-cooled ring in which the current put into it in Leyden in the afternoon continued to circulate. He had nursed it over from Holland by air."

In the *Proceedings of the Royal Society*, McLennan wrote more than fifty papers, in forty of which his research students collaborated. Perhaps it would not be invidious to name those who contributed two or more papers—D. S. Ainslie, H. J. C. Ireton, H. Grayson-Smith, A. B. McLay, A. R. McLeod, G. M. Shrum. All this work, carried out at high pressure, sometimes led to stress and strain, and McLennan was always impatient with fools—sometimes with others—and though he could not suffer them gladly, his kindly, friendly nature usually restored sunshine after storm. He was a man who thought, spoke, wrote and lectured very clearly, and he was insistent on essential things. He was of a composite nature, greatly preferring friendship, but quite ready for a fight, and he fought hard. In the autumn of life his character was gentler and more mellow, and he was spared its winter. To his many friends and students he showed, time and again, the most thoughtful, unwearying kindness. A great factor in his life was the wise help and comfort of his able and interesting wife Elsie Monro, eldest daughter of William Ramsay, of Bowland, Scotland. Her death, two years ago, left him rather a desolate man, although he wore a brave face.

Of his work in England since his retirement Lord Rutherford writes of McLennan authoritatively: "Largely through his influence, the Union Minière of Brussels generously lent 5 gm. of radium to make a thorough investigation of the effects of mass radiation on cancerous growths. A committee was formed to control this great experiment, presided over by the president of the Royal Society supported by the presidents of the Royal College of Physicians and Royal College of Surgeons, and representatives of the Medical Research Council and the Department of Scientific and Industrial Research. This work, which is still in progress, is being carried out at the Radium Institute. McLennan threw himself whole-heartedly into this new line of work, and personally supervised every detail of the scheme. He spent much of his time at the Institute, and characteristically established the friendliest relations not only with the staff but also with the patients under examination. His services to this investigation in radium beam therapy are indeed great, and his sudden removal is an irreparable loss. Warm-hearted and impulsive, his vitality, his boyish enthusiasm and transparent simplicity of nature, endeared him to all those who came closely into contact with him. His sudden end in the full tide of his activities is a great loss to science and humanity."

McLennan was born on April 14, 1867, and died of heart failure on his way from Paris to Calais on October 9, at the age of sixty-eight years. He received many and well-deserved honours. In 1924, he was president of the Royal Society of Canada and two years later was awarded the Flavelle Medal by that Society. He was elected a fellow of the Royal Society in 1915, and in the current year he received his knighthood. A. S. EVE.

Prof. Henry Briggs, O.B.E.

PROF. HENRY BRIGGS, who died in London on August 26 at the age of fifty-two years, had become, after a distinguished career, an authority on many subjects related to the scientific side of coal-mining. As head of the Department of Mining at Heriot-Watt College and Hood professor of mining at the University of Edinburgh, his influence amongst all students of mining technology was widely felt. In particular, mining engineers looked to Prof. Briggs for advice and information, based on his own original researches, on mine ventilation, on surveying and on the nature of coal. Latterly, he had interested himself in the subject of the production of oil from coal and carbonaceous materials, and had been appointed chairman of the Oil from Coal Committee of the Scottish National Development Council. He was a member of many scientific and technical societies, a member of council of the Institution of Mining Engineers and a fellow of the Royal Society of Edinburgh.

Briggs received his early education at Bradford whence, with a National Scholarship, he went to the Royal School of Mines and obtained the associateship with honours. He received his practical training in mining at collieries in Yorkshire, Cumberland and Wales and, previous to his appointment (in 1919) to the chair of mining at Heriot-Watt College, was, successively, demonstrator at the Royal School of Mines (and research assistant to Sir Clement le Neve Foster) and lecturer in mining at the University of Birmingham. His earlier research work included studies of mine rescue apparatus, and he was the inventor of an oxygen-breathing apparatus; during the War he carried out a number of investigations for the Trench Warfare Committee.

All Briggs's work showed originality of outlook and clarity of thought, and all his writings, with which he took particular pains, were lucid and literary. He had a keen and somewhat mordant wit which rendered his participation in discussions of controversial subjects highly effective; albeit he was constructive in his criticism. The coal-mining industry will feel his loss. R. V. WHEELER.

News and Views

Billingham Hydrogenation Plant

THE formal opening on October 15 by Mr. Ramsay MacDonald of the coal hydrogenation petrol plant of Imperial Chemical Industries, Ltd., at Billingham-on-Tees, marks the start of a completely new British industry. Reference to the present position of commercial hydrogenation of coal has already been made in these columns (NATURE, April 6, 1935, p. 538). The Billingham plant is the first in the world to make petrol on a commercial scale from bituminous coal. It was originally intended to produce 100,000 tons a year of petrol from coal. It was later decided to increase the capacity to 150,000 tons, the extra 50,000 tons to be made either from coal or creosote oil and low-temperature tar. The first section was ready in January, 1935. Creosote oil was used as the starting material, and the first petrol was made in February. The first coal unit was started in June, and the output is expected to reach the designed figure before the end of this year. The normal rate of production is 410 tons or 123,000 gallons of petrol a day. 40,000 tons of petrol have already been made, of which 27,000 tons have been shipped to the oil companies for distribution. The coal consumption is estimated as 4 tons of coal to 1 ton of petrol produced.

THE raw coal is cleaned to less than $2\frac{1}{2}$ per cent of ash and is ground up with oil previously made in the process to make a 50 per cent coal-in-oil 'paste'. This is injected against the working pressure of 250 atmospheres and mixed with hydrogen. The mixture is heated up to reaction temperature, and liquefaction of coal takes place at 450° C. A small heavy oil fraction containing the unconverted coal (5 per cent by weight) and ash is treated for oil recovery, and the coke residue is used as a fuel. The major part of the coal is transformed into lighter oils which are vapourised, and are recovered on cooling the gaseous products leaving the converters. The crude oil so obtained is distilled into heavy oil, middle oil and petrol. Heavy oil is further hydrogenated, in plant exactly similar to that used for the hydrogenation of coal, to give middle oil and petrol. Middle oil resulting from these two steps is further hydrogenated in vapour phase converters, in which the vapourised light oil and hydrogen are passed over a solid catalyst. The crude vapour phase product is distilled, the residual middle oil being separated from petrol and treated again. The whole of the coal is thus transformed into a small solid consumable residue, gas and petrol. Creosote oil and low temperature tars, although they play no essential part in the main process of making oil from coal, are conveniently treated along with the coal. The final petrol, after a simple purification, is pumped to storage tanks beside the River Tees, from which it is shipped by steamers.

Mr. Ramsay MacDonald's Tribute

IN his opening address, Mr. Ramsay MacDonald said that a little more than a generation ago, oil was displacing coal as a source of power, and chemists began to wonder whether it was not possible to 'resurrect' coal. The German chemists were the pioneers and among them stands conspicuously the name of Dr. Bergius. In 1921 he explained his ideas to the Department of Scientific and Industrial Research, and in 1923, under his influence, experiments were begun by the Fuel Research Station. "At that time, fortunately for the chemical industry, Sir Alfred Mond was living. . . . This country does not yet know what debt it owes to Sir Alfred Mond's vision. The result then was that the Government gave a subsidy to enable the necessary research to be prosecuted." In 1927 the experiments were taken over by the Imperial Chemical Industries; that secured that they would be conducted on the scale, and with the expenditure, necessary for their success. As a result of these experiments, the Government again came in. On July 17, 1933, Mr. MacDonald announced in the House of Commons that the Government would guarantee a preference to all British-produced motor spirit; and in March 1934 Parliament passed the Hydrocarbon Production Act. "Few announcements have had such far-reaching results. The immediate effect was that Sir Harry McGowan, that man of vision and energy, announced that Imperial Chemical Industries would at once proceed to erect a plant, and we are here within a year and a half to open it."

Sir Harry McGowan's Reply

SIR HARRY MCGOWAN, on behalf of Imperial Chemical Industries, Ltd., thanked Mr. Ramsay MacDonald for his address. He said that the opening of the Billingham plant has brought to a practical commencement an enterprise which has engaged the attention of his firm for many years. "We began at Billingham in 1927 on a very small scale indeed. For two and a half years research continued on a moderate scale, and by then it was clear that to achieve success a bold expansion policy was essential. Notwithstanding the discouraging business conditions of 1930 and 1931, we launched in those years an extended programme of work at a heavy annual cost. . . . In the end we spent more than a million pounds on this research." During this period active encouragement was given by H.M. Government and interest was displayed in the work by the Fuel Research Board. Similar activities were proceeding abroad though from slightly different angles. The German I.G. was at work on brown coal, the Standard Oil Company of New Jersey was occupied with petroleum oil, and the Shell Group were not inactive. "In 1931 we effected with these three companies a pooling of all interests in the hydrogenation process,

including a provision for a complete exchange of information, which promoted a more rapid advance by bringing us into immediate touch with every development of major importance." The construction of this plant marks the culmination of eight years' work. "The chemists, engineers, metallurgists, draughtsmen, and workers may all be proud when they look at this plant. To name them is impossible, but without being invidious I desire to single out Mr. Kenneth Gordon, who has been in charge of the research work and construction of the plant, and also my colleague Colonel Pollitt, who was the inspiration of our earliest efforts."

Tercentenary of Wilhelm Schickard (1592–1635)

ON October 23, 1635, in the middle of the Thirty Years' War, Wilhelm Schickard, a famous German orientalist and astronomer, died of the plague at Tübingen. Schickard was born on April 22, 1592, at Herrenberg, Württemberg. He was educated for the church, and at an early age became known for his knowledge of Hebrew. At the age of twenty-seven years he was appointed to the chair of Hebrew at Tübingen, and in 1631 was made professor of astronomy. He was also an inspector of schools at Stuttgart. In some of his least-known books are to be found early observations on the aurora, an account of the comet of 1623 which caused considerable commotion on its appearance, and his views on the refraction of light and the theory of the rainbow. He was known to both Kepler and Gassendi, and the latter, after he had observed at Paris the transit of Mercury of 1631 predicted by Kepler, wrote to Schickard: "The crafty god had sought to deceive astronomers by passing over the sun a little earlier than was expected, and had drawn a veil of dark clouds over the earth in order to make his escape more effectual. But Apollo, acquainted with his knavish tricks from his infancy, would not allow him to pass altogether unnoticed. To be brief, I have been more fortunate than those hunters after Mercury who have sought the cunning god in the sun. I found him out, and saw him, where no one else had hitherto seen him." Gassendi, in another letter of the same year, gave an account to Schickard of his fruitless efforts to see the transit of Venus.

Work of the Meteorological Office

THE annual report of the Director of the Meteorological Office for the year ended March 31, 1935 (London: H.M. Stationery Office. 9*d*. net), records a further big increase in the amount of information supplied to the public and to aviators, in accordance with a tendency that has been much in evidence for several years. The Aviation Services, for example, report a total increase of 18,747 in inquiries and of 2,404 in weather reports passed to aircraft in flight; in the British Climatology Division 2,348 general or scientific inquiries were dealt with, this figure including 178 legal inquiries, representing nearly a six-fold increase as compared with 1924–25 and nearly a doubling of the volume of inquiries in the past five years. While the main work of the Meteorological Office during the year under review has been on the same lines as in previous years, certain changes of organisation have been completed. Since the reorganisation after the War, there have been separate divisions for forecasts and aviation, but as experience has shown that this arrangement is not the best from the point of view of efficiency, the two divisions have been combined since October 1, 1934, control of the single large division by a single head, with two senior officers as deputies, being aimed at eventually. The Naval Division has for years been working in co-operation with the Admiralty towards the creation of a weather forecasting service within the Fleet which shall be self-contained but not independent of the State Meteorological Service; that objective has been attained with the expectation of its being in full operation by the end of 1936. Other important changes include a restriction of the responsibility of the Meteorological Office in the matter of gale warnings to the issue of the warning telegrams, the Board of Trade being responsible, as from September 1, 1934, for the exhibition of the warnings and the supply and maintenance of warning cones for that purpose; and the taking over by the Ministry of Agriculture and Fisheries and the Fishery Board of Scotland of the supervision of the stations of the Fishery Barometer and Barograph Service as from January 1, 1935.

THE fusion of the two branches of the Meteorological Office formerly known as the Forecast and Aviation Divisions, referred to above, does not involve any radical change in the system of dealing with weather forecasts and reports in connexion with aviation. Nevertheless, there have been some developments of the existing system. Consequent upon the increased practice by pilots of following direct compass courses on flights from Great Britain to the Continent, it was found necessary to alter the position of auxiliary weather reporting stations formerly established to serve the old Continental air routes. This has led to the closing down of the auxiliary weather reporting stations at Farningham, Deal, North Foreland and Sandgate, and the opening of new stations at Leatherhead, Crowborough and Bexhill, and to an increase in the personnel of the meteorological station at Manston Aerodrome to make practicable the issue of reports throughout the twenty-four hours. Another development was the installation at Croydon Airport of a 'ceiling projector'. This is a searchlight arranged to send a powerful beam of light vertically upwards, which enables the height of low cloud over the airport to be measured at night. The measurements are made at the meteorological station itself, and cloud heights are supplied in response to requests from pilots flying at night. Stations newly established within the period under review included one at Abingdon to meet the requirements of Central Area Headquarters of the Royal Air Force, and another similar station at the new Royal Air Force station at Mildenhall (Suffolk). Both these stations have personnel capable of obtaining information about the state of the upper atmosphere and making forecasts. These additions brought the number of local forecasting centres in Great Britain up to twenty-five.

River Bank Protection

FOR the Inland Navigation Section of the Sixteenth International Congress of Navigation, Brussels, 1935, Dr. Brysson Cunningham prepared a report on "The Estuarial Embankments of the River Thames". Of the origins of these walls little is definitely known and, in his "History of the Port of London", Sir Joseph Broodbank inclines to the view that their construction was a gradual and piecemeal process undertaken locally with the purpose of reclaiming for agriculture the valuable lands along the banks of the river, and probably initiated by immigrants from Flanders familiar with work of this kind. As he also says, "The builders in carrying out their object would not trouble themselves as to the effect their work had on the stream nor did they realise that they were, in fact, performing a mighty service in providing for London one of its greatest assets as a Port". Records of repairs and alterations have been traced back to the time of Edward II, and about that time Commissions of Sewers—using the word in its original sense—began to be appointed to exercise jurisdiction in several localities. Until 1930, when the Land Drainage Act established Catchment and Drainage Boards to take over their duties, these Commissions acted under the authority of an Act of 1531 to protect the lands from being flooded either by inundation or accumulation of superfluous waters. As consultant engineer to two of these bodies entrusted with portions of the Thames Embankments, Dr. Brysson Cunningham was able to advise the Congress as to the nature of the problems presented, and gave an account of the construction, maintenance, repair and renewal of these walls. Altogether, the earthworks on both sides of the river below London Bridge have a total length of approximately 120 miles and give protection to 64 square miles of low-lying marshland. Being 4–5 feet above Ordnance Datum while H.W.O.S.T. level is 10–13 feet, these extensive lands would, without protection, become permanently flooded. In the report, the several inimical agencies are described and, by maps, sections and diagrams, the methods and materials used to ensure adequate defence are fully exhibited.

Research on Combustion

No one is better qualified than Prof. W. A. Bone to give an account of "Fifty Years of Combustion Research"—the title of his William Young Memorial Lecture, delivered to the North British Association of Gas Managers on September 12. The account gives a readable and comprehensive story mainly of the work due to the late Prof. H. B. Dixon and his school, and not least of Prof. Bone himself and his pupils. The lecture included some of the more recent observations on the combustion of gases at very high initial pressures, with activation of nitrogen, the description of some of the curious phenomena such as the 'spin' of the flame head in the detonation wave—observations calling for remarkable achievements in high-speed photography. The existence recently observed of double ranges of ignition temperatures of gases with an intervening 'inert' zone of temperature emphasises the complexity of the process of ignition. The 'chain theory' which has been so extensively used to account for combustion phenomena is held to be not 'mere moonshine' but to merit critical reception when capable of being harmonised with experiment. Prof. Bone closes with the insistence on the necessity of perpetual experimentation, for as Priestley said, "Speculations without experiments have always been the bane of natural philosophy".

Chemical and Physical Society, University College

THE Chemical and Physical Society, now the senior Society of University College, London, opened its sixtieth session on October 15. Before a large and distinguished gathering Dr. Henry Forster Morley, a founder-member and third president of the Society, unveiled oak panels bearing the names of the former presidents, many of whom were actually present. It was unfortunate that Sir Oliver Lodge, who was president of the Society in its first two years, was unavoidably absent on this occasion. The unveiling itself, in accordance with the principles of the Society, was performed electrically by means of an engraved silver switch, which was afterwards formally presented to Dr. Forster Morley. Mr. C. F. Goodeve, this year's president, who was in the chair, then introduced the other speakers, among whom were the Provost, who accepted the panels on behalf of the College, and Prof. A. W. Porter and Prof. M. W. Travers, who made a few interesting remarks about the earlier presidents. The secretary, Mr. R. H. Leach, thanked the many friends of the Society for their assistance, financial and otherwise.

Preservation of Cliff Scenery

IN a paper to Section E (Geography) of the British Association at Norwich on September 5, Dr. Vaughan Cornish directed attention to the menace afforded by private enclosure to the best of the cliff scenery of England and Wales. Of the 1,800 miles of coast line, about five hundred are cliff land, of which more than three hundred miles are in Devon, Somerset and Cornwall. For the most part, the cliff edge is still accessible to the pedestrian, but too often the landward side has been enclosed and thus the full enjoyment of the view is impaired. Dr. Cornish calculates that 40,000 houses would line the whole of the five hundred miles, and believes that with the present rate and spread of building it will not be many years before much of the cliffs will be enclosed. He advocates the public acquisition under the Town and Country Planning Act, supplemented if possible by other funds, of a strip of land 110 yards wide along all the cliffs. This would amount in all to 20,000 acres and the purchase figure would be approximately £2,000,000. Thus, for a relatively small cost the finest scenic treasures of the country would be preserved.

Fossil Human Occipital Bone from Thames Gravels

DURING the recent meeting of the British Association at Norwich, Mr. Alvan T. Marston exhibited to Section H (Anthropology) a complete human

occipital bone which he had found in the middle gravels of the 100-ft. terrace of the Thames at Swanscombe, Kent. The bone was associated with Acheulean flint implements, and is mineralised in the same way as the bones of the Pleistocene mammals occurring with it. The fossil was submitted to the Geological Survey, and Mr. Henry Dewey confirmed the determination of its geological age. Mr. Marston now writes that he has made an endocranial cast of the specimen and has consulted Sir Grafton Elliot-Smith, who expresses the opinion that "the exceptional size and form of the visual territories upon the two hemispheres of the endocranial cast, even if they suggest left-handedness, are definitely Simian and point to a much more primitive stage than *Eoanthropus*". The bone differs considerably from the occipital of *Eoanthropus*, and further discoveries to reveal the characters of the skull to which it belongs will be eagerly awaited.

Ancient Ruins in East Africa

AN archæological reconnaissance with the view of further investigation has been made recently by Dr. L. S. B. Leakey on two sites in East Africa. Of these, one, the ruins of Gedi, an ancient city of considerable extent, sixty-five miles north of Mombasa, is already scheduled under the Ancient Monuments Preservation Ordinance; the other is the large assemblage of stone-built dwelling-places and tombs at Engaruka in the Great Rift Valley in Tanganyika, to which attention was directed as a new discovery in June last of Mr. T. E. Wetherell. The ruins at Gedi, though situated at no more than fifty yards from the Mombasa-Malindi road at their nearest point, are so obscured by a tangle of tropical vegetation as almost to escape notice. Trees of considerable size growing on or in the ruined structures afford some gauge of the antiquity of the ruins. According to Dr. Leakey's report (*The Times*, October 11) future investigation will reap a rich harvest. Town walls, buildings and tombs alike afford evidence of at least two, and possibly three, distinct periods of construction. The materials used consist of dressed blocks of coral, built up with a hard mortar and plastered to a smooth surface. In places, where the dressing is unplastered, as on the arches over doors and windows, it is extremely fine. It is Dr. Leakey's opinion that the ruins may be those of an Arab or Persian settlement of considerable antiquity, the first settlement possibly dating so far back as the beginning of the Christian era.

DR. LEAKEY'S investigations at Engaruka confirm previous reports of the extent of the site, though the limits at present are unknown. He estimates that the buildings in the North and South Ruins on the slope number five to seven thousand; and there are further structures in addition to the tomb mounds below in what he terms the Valley Ruins. The ruins are not entirely a new discovery, as recently reported. They had been visited by Dr. Hans Reck on his way to Oldoway in 1913, when he excavated one or two mounds; and more recently a little digging has been done by British administrative officials. Dr. Leakey carried out one or two exploratory excavations of mounds and buildings, but failed to obtain any material, either skeletal or cultural, which throws light on the dating of the site. It is evidently not of high antiquity. The buildings are entirely of dry stone-walling, without mortar, and show no real skill in stone building. Inquiry among the Masai elicited the tradition that the ruins had been abandoned about one hundred years ago when the Masai drove out the ancestors of the present-day Wambulu. A further tradition of a Portuguese leader or king at Engaruka may, it is thought, afford an explanation of how a people who do not now build in stone, nor live in towns or even villages, came to erect these stone structures in such numbers.

Linguistic Research in Kashmir

IT is reported that Colonel D. L. R. Lorimer, whose studies in Indo-Iranian linguistics are well known, accompanied by Mrs. Lorimer, has recently returned to Srinagar from an expedition of linguistic research among the mountain tribes of Hunza and the area to the north, upon which he has been engaged during the last fifteen months. The chief object of the expedition was to extend and complete Colonel Lorimer's studies of Burushaski, the language of the Burusho of Hunza; but he has also devoted attention to Wakki, a language of the Iranian group spoken in Wakkan and also by Wakkan settlers in northern Hunza. Colonel Lorimer, it is stated in a dispatch from Srinagar in *The Times* of October 9, has succeeded in obtaining a record of a language, Boma, hitherto unknown, spoken by a tribe of musicians and metal workers who have been settled in Hunza for many generations. According to their own tradition, they are a people of Badakhshari origin, who at some period were transferred to the rule of the Mir of Hunza for services he had rendered the ruler of Badakhshan. They have remained an exclusive group and still do not intermarry with the Burusho, although they, like the other peoples of Hunza, are Moslems. Hence while they speak Burushaski fluently, they have retained their cultural and linguistic individuality intact. Their language, which is said not to resemble the Badakhshani of their traditional place of origin, appears to be more closely related to the Sanskritic than to the Iranian members of the Indo-Iranian linguistic group. If this be confirmed by further study, it would agree with the character of other languages of the so-called Dards of Hunza. Colonel Lorimer is now about to return to England for the purpose of studying the large amount of ethnographical and linguistic material he has collected among the less well-known mountain peoples of the area.

Marine Research at Millport

THE report for 1933–34 of the Scottish Marine Biological Association, Millport, shows that much work has been done during the year. The director, Mr. R. Elmhirst, has studied specially the conditions under which shore algæ live, and subdivides the

littoral area into three natural algal belts correlated with the run of the tide. This tidal flow theory also fits closely to the observed distribution of various animal species inhabiting the sandy and muddy areas of the tidal zone. Mr. A. C. Stephen, following up his previous reports on molluscan ecology, has found that in 1933 the density of population of *Tellina tenuis* was far in excess of any previously met with, on an average 8214 per square metre. This was largely composed of a very abundant spat. The closely related *T. fabula* was also very successful in its spatting, but the conditions were evidently not so favourable for the common cockle, *Cardium edule*, very little spat of this species occurring. Dr. Orr, Dr. Marshall and Dr. Nicholls, in continuing their co-operative work on the plankton with special reference to *Calanus*, have shown that the success or failure of a brood depends on the presence or absence of diatoms during the early stages of development. A study of the chemical composition of *Calanus* showed that the fat content followed the changes in weight, and that the protein content also followed in general the changes in weight. Spent females were rarely found, which indicates that they die soon after spawning. An unusual occurrence was noted in the behaviour of Stage V *Calanus* on one occasion, when they swarmed actually on the surface of the water for two or three days, remaining in the upper few metres nearly all the time and only showing a tendency to seek deeper water during the darkest part of the night, which is a complete reversal of the normal migration. This subject is undergoing further investigation.

Public Health in England and Wales, 1934–35

THE sixteenth annual report of the Ministry of Health, 1934–35, has recently been issued, and deals under six sections with the whole subject of the public health and its administration in England and Wales (Cmd. 4978. H.M. Stationery Office, 1935. 5*s*. 6*d*. net.). Sir Kingsley Wood, the Minister of Health, in his introduction, contrasts mortality rates for the years 1910 and 1933. Thus, the death rates per 1,000 living for these two years were, respectively, 13·2 and 9·3; the infant mortality rates were 105 and 64, the death rates per million from pulmonary tuberculosis were 988 and 639, and for typhoid fever, 53 and 5. Maternal mortality, however, in spite of the development of maternity services in recent years, has not yet begun to fall. Statistics of vaccination show a slight but steady decline, from 42·6 per cent of total births in 1928 to 37·0 in 1933. Samples of food and drugs analysed during 1934 numbered 140,583, a small increase over the previous year, of which 7,451 or 5·3 per cent were reported against. It is mentioned that in some districts there are signs of revival and expansion of canal traffic, and there is evidence that motor traction of canal boats is continuing to develop, for many motor-propelled boats are on order, such boats being notable for improvements in design as regards ventilation and sanitation compared with the old type of boat.

Destructive Earthquakes in 1935

IN a recent number of the *Matériaux pour l'Étude des Calamités* (No. 35, 82–86; 1935), M. Charles Bois continues his record of destructive earthquakes. During the first six months of this year, there were 16 such earthquakes, four of them resulting in considerable loss of life, namely, the Persian earthquake of April 11 (480 deaths), the Formosa earthquake of April 20 (3,065), the Caucasian earthquake of May 1 (600) and the Quetta earthquake of May 30 (40,000). The latter number is probably too high, the latest estimate being about 30,000. On the other hand, the number of deaths (2,000) given by M. Bois for the Bihar earthquake of January 15, 1934 (NATURE, 136, 472, September 21, 1935), is too low, the number given in the official report on the earthquake being more than 10,000.

Third World Power Conference

THE third World Power Conference will be held in Washington, U.S.A. on September 7–12, 1936. This will be the third plenary meeting of the World Power Conference, the first plenary meeting having taken place at Wembley in 1924, and the second at Berlin in 1930. There have, in addition, been a number of sectional meetings. The Chemical Engineering Congress of the World Power Conference, to be held in London next June, ranks as one of these series of sectional meetings. The general subject to be discussed at the Third World Power Conference is "National Power Economy". Among the aspects to be treated are the following: physical and statistical bases; technical, economic and social trends; organisation of fuel industries and of gas and electric utilities; public regulations; national and regional planning; conservation of fuel and water resources; rationalisation of distribution; national power and fuel policies. The second Congress of the International Commission on Large Dams of the World Power Conference will be held in Washington at the same time. Further particulars regarding the plenary meeting of the World Power Conference and the second International Congress on Large Dams will be issued in due course. British participation will be organised by the British National Committee of the World Power Conference, 36 Kingsway, London, W.C.2.

Work of the Medical Research Council

IN a pamphlet by Miss Norah Dacre Fox, issued by the London and Provincial Anti-Vivisection Society, an attempt is made to criticise the work carried out under the Medical Research Council. Reference is made to the dominating influence of the late Sir Walter Fletcher, to vested interests, to a suppressed report, etc. It is stated: "The public is the Master, the Medical Research Council its servant. Is it not entitled to assert itself and to require from those it remunerates so lavishly, an account of this stewardship?" Needless to say, an account of this stewardship is available to all who desire it in the annual report and in the numerous research reports issued by the Council.

Announcements

PROF. JOHN A. RYLE, regius professor of physic in the University of Cambridge, and Prof. Matthew J. Stewart, professor of pathology in the University of Leeds, have been appointed members of the Medical Research Council in succession to the Right Hon. Lord Dawson of Penn, and Prof. A. E. Boycott.

AT the annual dinner of the Institute of Fuel, held on October 9, the Melchett Medal was presented to Mr. Harry R. Ricardo for his work on internal combustion engine operation and its relation to fuel.

AT the annual general meeting of the Association of British Chemical Manufacturers, Dr. E. F. Armstrong was elected president in succession to Sir Christopher Clayton.

THE new auxiliary laboratory of the British Electrical and Allied Industries Research Association will be opened by H.R.H. The Duke of Kent at Perivale, Middlesex, on October 22, at 3 p.m.

The eleventh annual Norman Lockyer Lecture of the British Science Guild will be given by Sir Josiah Stamp, who has chosen as his subject "The Calculus of Plenty". The lecture is to be delivered in the Goldsmiths' Hall (by permission of the Goldsmiths' Company) on Wednesday, November 13, at 4.30 p.m.

DR. E. L. HIRST will deliver a lecture on "The Chemical Nature of Vitamins" before the University of Durham Philosophical Society on November 1 at 6.30. The meeting will be open to the public.

SIR WALTER LANGDON-BROWN will deliver the fifth Victor Horsley Memorial Lecture in University College Hospital Medical School, Gower Street, W.C.1, on November 19 at 5 p.m. The subject of the lecture will be "The Integration of the Endocrine System". Admission to the lecture will be free.

IT has been decided to hold the Huxley Lecture at the Imperial College of Science and Technology in alternate years only, and in the other years to hold lectures commemorating other distinguished men who have served on the staff of the College. The first of the new series of lectures will be held on May 4, 1936, at 5.30 p.m., and will be given by Prof. G. T. Morgan. The lecture will be called "The Hofmann Memorial Lecture".

THE second Hinchley Memorial Lecture of the Institution of Chemical Engineers will be delivered by Sir Harold Hartley on October 25, at 6.30, in the Lecture Theatre of the Institution of Civil Engineers, Great George Street, S.W.1. The subject of the lecture will be "Our National Coal Resources". The lecture is open to non-members, for whom tickets can be obtained from the Assistant Secretary, Abbey House, Westminster, S.W.1.

THE first Italian congress on alimentation, organised by the National Medical Syndicate, the committee for the study of the problems of alimentation and the National Research Council, will be held in Rome on October 23–26. At the inaugural meeting, Prof. Filippo Bottazzi will speak on the organisation of scientific research in the service of the national food supply, and Prof. Eugenio Morelli will discuss the work of the doctor in alimentary propaganda.

PROF. BERNARDO A. HOUSSAY, of the Institute of Physiology, Buenos Aires, has been appointed a member of the Permanent International Committee of the Physiological Congresses. The names of the other members of the Committee were given in NATURE of October 12 in the article on the recent Congress held in the U.S.S.R. (see p. 573). Prof. Houssay's election is a welcome acknowledgment of the value of the work of the growing schools of physiology in South America.

MESSRS. ALLEN AND UNWIN, LTD., announce the early publication of "Coral Gardens and Their Magic" by Prof. Bronislaw Malinowski; also "How Animals Develop" by C. H. Waddington, which affords a short account of the science of embryology.

MESSRS. W. Watson and Sons, Ltd., 313 High Holborn, W.C.1, have recently circulated a new issue of part 6 of their microscope catalogue, dealing with microscopes and accessories for polarising purposes, which will be sent gratis to those interested. Two new models have been introduced, the 'Service', 'School of Mines', and 'Advanced' petrological models have been re-designed, and the last two can now be supplied with horse-shoe, instead of tripod, foot if preferred. A demonstration set has also been designed for school purposes in order to demonstrate the phenomena of polarised light, and other new patterns of apparatus are figured and described.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A lecturer in mining in the University of Leeds—The Registrar (Oct. 22).

An examiner in the Aeronautical Inspection Directorate—The Secretary (S.2.d.), Air Ministry, Kingsway, W.C.2 (Oct. 26).

An assistant engineer in the Chief Engineer's Department of the London County Council—The Clerk to the Council, County Hall, S.E.1 (Oct. 28).

A lecturer in electrical engineering and a lecturer in mathematics and electrical engineering in the South-East London Technical Institute—The Education Officer, County Hall, S.E.1 (Oct. 28).

A junior scientific officer and an assistant (III) at the Building Research Station, Garston—The Establishment Officer, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (Oct. 30).

A lecturer in mathematics in the Edinburgh Training Centre—Prof. Godfrey H. Thomson, Director of Studies, Moray House, Edinburgh, 8 (Oct. 30).

A lecturer in mathematics in the Saltley Church of England Training College for Schoolmasters, Birmingham—The Principal (Nov. 1).

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 647.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

'Autogenous' Strains of '*Culex pipiens*' (Diptera, Culicidæ)

IN a letter published in NATURE of January 5, 1935 (**135**, 34), we directed attention to the discovery, at Hayling Island (Hampshire), of a 'strain' of the mosquito *Culex pipiens* exhibiting certain abnormal characteristics (notably the ability of the females to lay fertile eggs upon a blood-free diet) which Roubaud has designated by the adjective 'autogenous'. Such autogenous strains of *C. pipiens* had previously been recorded only from France[1], Germany[2], Greece[3], Hungary[3] and Malta[3]. Roubaud, who considered his autogenous strain and the ordinary ('anautogenous') strain to be morphologically identical[4], indicated their biological differences by naming them respectively *Culex pipiens autogenicus* and *Culex pipiens pipiens*[5].

We find that, in three different stages of development, the Hayling autogenous strain of *C. pipiens* can be morphologically distinguished from the anautogenous strain. The adults are recognisable by the lighter colour of the thorax, by the greater average number of hairs on the lobes of the 9th tergite, and by the shortness of the male palps; the larvæ, by their much lower siphonal index and by the greater average number of branches in the siphonal tufts; and the eggs, by their greater width relatively to their length. The female adults (as already noted in the case of other autogenous strains) also differ from the anautogenous ones by reason of the fierceness with which they attack human beings.

Our investigations prior to March 8 last are fully described in an article about to appear in *Parasitology* (**27**, No. 4), the editor of which journal, Prof. D. Keilin, has very kindly given us permission to refer in this letter to the two subsequent developments summarised below.

(1) In our *Parasitology* article we allude to the (hitherto unexplained) fact that females of *C. pipiens*, although regarded in England as being chiefly 'bird-biters', occasionally exhibit 'man-biting' proclivities in residential districts. We have made the suggestion (supported by evidence provided by the examination of man-biting adults captured in a London hotel in the year 1930) that, in all such cases, an autogenous strain of *C. pipiens* has been concerned. Opportunities of confirming the validity of this assumption have recently been furnished by infestations of man-biting *C. pipiens* in (*a*) a block of flats in Westminster and (*b*) a row of cottages in Hull. Both from a blood-filled female (caught in a bedroom) in the first case, and from larvæ collected near the infested buildings (by kindness of the Medical Officer of Health for Hull, Dr. Gebbie) in the second case, we have established, and are maintaining, an autogenous strain.

(2) We are now rearing autogenous strains derived from Hayling, London, Hull, France and Greece—the last two by kindness of Prof. Roubaud and Dr. P. Tate respectively. We are indebted to Dr. Tate also for larval and adult specimens of the Hungarian and Maltese strains. We find that all these strains resemble one another, but differ from the anautogenous *C. pipiens* in the following respects. In the larvæ, the siphonal index lies between 3·8 and 4·3; in adults of both sexes, the thorax is light-coloured; in male adults, the first division of the mesosome is unusually broad and the combined length of the first four segments of the palp does not exceed the overall length of the proboscis; in female adults, the venter is, both medianly and laterally, devoid of dark scales.

In regard, however, to the chætotaxy of the larval siphon and of the 9th tergites, the seven strains differ noticeably from one another. In the Hungarian strain, for example, the 'tuft-branch' count is low and the 'tergite-hairs' count high; in the Hayling strain, both counts are high; and in the London strain, they are both low. A remarkable characteristic of the Greek strain is the large proportion of larvæ (about 40 per cent) which have three siphonal tufts instead of four.

It appears, therefore, that Roubaud's original (French) *C. pipiens autogenicus* is but one of a number of autogenous strains, all of which differ very markedly from the anautogenous *C. pipiens*, and also—to a lesser but quite obvious extent—from one another. In view of this fact we submit the suggestion that some specific name other than *pipiens* should be adopted to designate both the present and later-discovered members of this autogenous, short-siphoned, short-palped group: varietal names (preferably of geographic import) being appended whenever the recognition of definite morphological or biological differences renders such action desirable. In favour of reviving the specific name *domesticus*, Germar, for this purpose there is a great deal to be said.

Gorilla Skulls in the Bristol Museum

In the course of rearrangement of the study collections in the Department of Zoology, it has recently been discovered that the Bristol Museum and Art Gallery possesses the three gorilla skulls (Reg. Nos. Ab 1993, 1994, 1995) from which Prof. (afterwards Sir Richard) Owen first described this animal to the Zoological Society of London in a paper read on February 22, 1848. This was published in *Trans. Zool. Soc.*, 3, pp. 381–422 (1849) and Plates LVIII–LXIII as "Osteological Contributions to the Natural History of the Chimpanzees (Troglodytes, Geoffroy) including the description of the skull of a large species (Troglodytes Gorilla, Savage) discovered by Thomas S. Savage M.D. in the Gaboon Country, West Africa". One of the skulls (Ab 1993) is figured in Plates LXI–LXIII and, as related on p. 391, they were procured in December 1847.

In a later paper by the same author in *Trans. Zool. Soc.*, 4, pp. 75–77 (1862), a detailed description is given of another skull (Ab 1996), and it is figured in Plates XXVI–XXVIII. The bisection of the skull was carried out under Prof. Owen's direction as mentioned on p. 77.

Casts of these four skulls were presented to the Museum of the Royal College of Surgeons in 1848, and appear as Nos. 5180–5183 in "Descriptive Catalogue of the Osteological Series. Vol. II. Mammalia Placentalia" (1853) where, on pp. 803–805, there are descriptions, including a further detailed one of Ab 1996.

Some more notes are given on p. 9 of a later "Catalogue of Specimens illustrating Osteology and Dentition of Vertebrated Animals, Part II. Mammalia other than Man" (1884) by W. H. Flower and J. G. Garson.

In addition to the above, there are in the collections another skull of a male presented at the same time (1848) as Ab 1996, and a mounted adult male and its skeleton received in 1865.

Details of these specimens are as follows:

(1) Skull of adult male, without mandible, procured by Capt. George Wagstaffe at the Gaboon River, West Africa, in December 1847. Brought to England by Capt. Wagstaffe, ship *Jno. Cabot*. Donor: Mr. S. Stutchbury, August 3, 1848. Reg. No.: Ab 1993.

(2) Skull of mature male, without mandible, same history and donor as No. 1. Reg. No.: Ab 1994.

(3) Skull of adult female, without mandible, same history and donor as Nos. 1 and 2. The top of the cranium has been divided from the rest of the skull. Reg. No.: Ab 1995.

(4) Skull of adult male without mandible, from River Danger (=Muni River), West Africa. Donor: Capt. Harris, ship *Englishman*, August 3, 1848. (This skull was bisected vertically and longitudinally later.) Reg. No.: Ab 1996.

(5) Skull of male, without mandible, from River Danger, West Africa. Donor: Mr. Townsend, ship *Englishman*, August 3, 1848. Reg. No.: Ab 1997.

(6) Mounted specimen of adult male from Gaboon River, West Africa. Donor: Mr. A. Gordon, of Gaboon, December 30, 1865. Reg. No.: A 4890.

(7) Complete skeleton of No. 6. The height of the animal was 5 ft. 5 in. Reg. No.: A 4837.

Ring Deposits on Glass by Positive Ray Bombardment

Positive rays of hydrogen were passed through a hole of 2 mm. diameter and 6 mm. long in the centre of a cathode of brass faced with an aluminium plate. A glass window kept perpendicular to the beam, eleven centimetres behind the front face of the cathode, showed formations of deposits with well-defined rings after the tube was worked at different cathode falls corresponding to a maximum of 25,000 volts D.C., current 1·7 m. amp. The total time of exposure was about twenty-five hours. On examination by transmitted light of the place where the rays fell directly, it was found to be transparent. The rings were brown. The first ring is sharp and circular, with a thickness of 0·5 mm. and a diameter of 8 mm. The second ring is also quite circular, of the same thickness as the first, but not quite concentric with it. The diameter of this ring is about 16 mm. only; two-fifths of the third ring is visible, the diameter is 24–30 mm., but it is nearly concentric with the second ring.

The deposits have been observed by previous workers, but not the rings. Von H. Raether[1] examined similar deposits by electron diffraction, and concluded that they must be due to carbon formed from the decomposition of the hydrocarbons present in the discharge tube and produced from grease or at wax joints. The rings cannot be due to interference. The phenomenon presents many interesting features as a closer extended study with excellent photographic results has revealed, and will be reported in detail elsewhere.

Spectra of SeO and SeO_2

In continuation of earlier work[1] on SO_2, the emission bands of SeO and the absorption bands of SeO_2 have been analysed. The former consist of a long $v'=0$ progression and a short $v'=1$ progression. The origin of the system cannot be definitely located but the $v'=0$ progression can be expressed by the following formula

$$\nu = 30433 - (882\ v'' - 6\ v''^2).$$

Considerations of intensity distribution lead us to 33167 cm.$^{-1}$ as ν_0 and $\omega''=910$ cm.$^{-1}$, and the energy of dissociation of unexcited SeO will therefore be 4·17 volts. The vibrational frequency of the excited state ω' is 513 cm.$^{-1}$

The analysis of the spectrum of SeO_2 indicates two modes of vibration ω_2 and ω_3 both in the ground and in the excited state, the deforming vibration ω_1 being absent. The frequencies of the symmetric valence vibration are $\omega_2''=901$ and $\omega_2'=663$ cm.$^{-1}$; those of the antisymmetric valence vibration are $\omega_3''=1189$ and $\omega_3'=790$ cm.$^{-1}$. The origin of the system lies at 32560 cm.$^{-1}$.

The theoretical selection rule for $\Delta v_{\text{antisym.}}$ of Herzberg and Teller[2] is found to be completely valid.

The close correspondence of the two energies of excitation, ω'' and ω', ω' and ω_2'' of SeO and SeO_2 respectively, indicate strong localisation of the bonds.

This is corroborated by the atomic heat of formation of selenium dioxide, which has been calculated as $Se+O+O=SO_2+8{\cdot}9$ volts, which is almost double the energy of dissociation of SeO.

The *L*-Emission Spectrum of Argon

OF the X-spectra of rare gases, the *K*-series of xenon and that of krypton have been measured[1], and from their absorption spectra the *K*-edge of argon[2], krypton[3] and the *L*-edge of xenon[3] are known. For the *L*-absorption edge of Xe, as well as for the *K*-edge of argon[4], a fine structure also has been found.

In the region of the long wave-lengths, no results obtained by direct measurements have been obtained hitherto. The values for absorption edges have been obtained by the method of magnetic spectra.

By studying with our ionic tube the reversed absorption edges of silver, bromine and potassium in the region of long wave-lengths[5] (which we will publish later on), we have found that if either N_2 or air has been let into the tube, the *K*-series of N_2 has occurred. Sometimes, there also appeared the absorption edge of nitrogen[6]. The absorption edge of N_2 appeared especially when the same pressure had been maintained in the spectrograph as in the ionic tube. Such a regulation and maintenance of the pressure in the spectrograph—which is possible by the application of the ionic tube—is important in the region of the long wave-lengths, where it is impossible to cover the slit. (The gas, which is let into the tube by means of a fine regulating glass valve[7], streams through the slit into the spectrograph, from which it is exhausted.) We have tried to obtain spectra of the rare gases mentioned with the arrangement described above, where the said ionic tube offers a very efficient source of the long X-rays[8]. It is now possible to operate with this tube with a tension of only 600 v. at 250–300 ma. The pressure in the tube under the given conditions is about 0·1 mm. Hg.

When argon is let in the above-mentioned way into the tube, the *L*-series of argon is obtained. As electrodes we have used aluminium with the deposit of lithium borate on the anticathode. For control, if H_2 has been let in instead of argon, only *K*-lines of boron (in 8 orders), *K*-lines of lithium and the *K*-absorption edge of carbon in the first and the second orders have been obtained. But when argon is let in, besides the expected argon lines, we have obtained also new lines, which are observed when H_2 has been the discharge gas. These new lines have been found to belong simply to the elements calcium, sodium and silicon, which elements have been sputtered on the anticathode from some parts of the tube by the presence of argon. The *L*-series of argon have been measured with reference to the lines of boron[9], and the following values have been obtained

	λ	ν/*R*	ν/*R* cal.
L_e	56·1	16·2	16·29
$L\eta$	56·7	16·1	16·13

The observed values (measured in the second order) agree well with those calculated by interpolation of the data from Siegbahn and Magnusson[10]. We have not succeeded hitherto in obtaining a distinct character of the absorption edge of argon. The short wave limit of these lines is 54·0 A., which differs from the value given by Holweck (50·1 A.) and by Turner (50·7 A.) by about 3 A. Our results show that, with certain modifications of our arrangement, such a pressure is obtainable that we can expect the above mentioned absorption edges of argon, as well as of other gases, in the region of long wave-lengths.

Dipole Moments of Ethyl and *Iso*-amyl Borates and Triphenyl Phosphate

SOME months ago we commenced an examination of the dipole moments of esters of inorganic acids. Otto[1] has now published the dipole moments of *n*-butyl borate and *n*-amyl borate as 0·77 D and 0·79 D, respectively, at 25°, in benzene. We have found that ethyl and *iso*-amyl borates have moments of 0·75 D and 0·81 D, respectively, at 20°. The values for *n*- and *iso*-amyl borates are, therefore, in good agreement, and there seems to be a slight increase in the moment in ascending the series of alkyl groups. Triphenyl phosphate has, we find, a moment of 2·79 D.

The borates were fractionated several times, and the triphenyl phosphate recrystallised twice from petrol ether. As the borates are extremely easily hydrolysed, great care was necessary to avoid exposure to air. The dielectric constants were measured by the apparatus previously used[2], except that a glass dielectric cell containing platinum plates, the inlet and outlet tubes of the cell being fitted with ground glass caps, was employed. Benzene was the solvent and all the measurements were at 20° C.

The results were:

Compound	B. Pt.	d_4^{20}	n_D^{20}	P_{∞}	P_E	μ
Ethyl Borate	119·2°/756 mm.	0·8635	1·3741	50·5 c.c.	38·63 c.c.	0·75 D
Iso-amyl Borate	256·1°/761 mm.	0·8514	1·4156	94·3	80·20	0·81 D
Triphenyl phosphate	49·8° (M.Pt.)			252·5	87·41[3]	2·79 D

Work is in progress on other esters, and the results will be discussed when the measurements have been completed.

Structure and Oxidation of Nitrogenous Substances

IT has been reported elsewhere[1] that organic nitrogen in plant materials, soil organic matter and extracted proteins undergoes partial oxidation to nitrate on treatment with a mixture of sulphuric and chromic acids. It has since been found that the proportion of total nitrogen recovered as ammonia is constant for each substance, provided the oxidation is completed under conditions of reduced pressure and moderate temperature[1], and sufficient of the substance be taken to contain more than 20 mgm. of nitrogen. Of the fraction not recovered as ammonia, a portion is oxidised to nitrate and the rest is lost in gaseous form, probably as nitrogen or nitrous oxide. The 'oxidation constants' bear definite relationship to the structure of the compound.

While, in the case of compounds having nitrogen atoms attached to different carbon atoms, full recovery of nitrogen is obtained in the form of ammonia and nitrate, a definite portion is lost in gaseous form with compounds having two or more nitrogen atoms linked to the same carbon atom. The proportion of ammonia recovered from some typical groupings are as follows: –NH–CO–NH– group, 2/3 of total nitrogen; $CH\begin{matrix}N< \\ N-\end{matrix}$ group, 4/5; guanidine group, 4/11; creatine group, 2/3. The hydroxylamine derivatives are almost quantitatively oxidised to nitrate, while the nitrogen in hydrazine derivatives is almost completely lost in gaseous form.

Chlorides present as impurity in commercial samples and as hydrochlorides of bases tend to increase the proportion of nitrate formed at the cost of ammonia, and should be removed by precipitation with Ag_2SO_4. The possible significance of these 'oxidation' constants in relation to the structure of complex substances, for example, proteins, is under examination.

Phonemes

THE terminological confusion which has long plagued linguistic study has latterly been particularly acute in the matter of the phoneme. The recent communication[1] of Prof. E. W. Scripture does not appear likely to improve the situation.

Prof. Scripture proposes to apply the term 'phoneme' to "one of a group of similar sounds". Hitherto, the term has been used as referring to the group itself, as including the various similar (that is, only slightly different) sounds which were regarded then as 'members of a phoneme'. Prof. Scripture's proposal leaves unspecified the group itself; and it is precisely the inclusive, aggregational property which is most important. Prof. Scripture would call the *t* of *tip* a phoneme, and the *t* of *pit* another phoneme; but he has no name to apply to the group which includes these and all other *t*'s.

This departure from the small measure of agreement which has been reached on the phoneme might be justified, of course, if Prof. Scripture could adduce valid evidence of the usefulness of this innovation. But there is patently no advantage in shifting the application of a term from a group to an individual member of the group. The essential problem is the determination of the group[2]. Only if Prof. Scripture has some new and more successful procedure for sorting all the sounds of a language into definite and mutually exclusive categories can his proposal be considered seriously.

Prof. Scripture believes "that phonemes do exist", and thus takes his stand with those who hold that a phoneme is (or corresponds to) an observable physical reality of some order. This reality Prof. Scripture finds in sound-track recordings. His position thus corresponds in certain essential respects to that which Bloomfield developed more fully in his "Language". But Prof. Scripture does not indicate how the "group of sounds" are to be determined, aside from a casual assurance that "On comparing the records we find that groups of similar speech sounds can be formed". Thus far, I know of no evidence from the laboratory that records of *tip* and *pit* will show physical peculiarities to justify grouping together the *t*s or the *p*s on the basis of positive similarity. For to group together the *t*s on this basis presupposes not only the discovery of positive similarities as among various kinds of *t*s but also the determination of some physical peculiarities associated only with *t*s. The group can be established on a laboratory basis only by the discovery of characteristics which are constantly present for this group, and never present for any other group.

Prof. Scripture cannot be unaware of the objections raised to Bloomfield's essentially similar proposal, and it is impossible that his suggestion in NATURE should have been made jocosely or irresponsibly. One can only conclude that he has discovered a method for the determination of positive, exclusive physical properties of the various members of a phoneme (in his terminology, the various phonemes of a group). The announcement of his discovery will be welcomed as a partial solution of this vexing phonetic-phonological problem.

Still unsolved, however, will be the problem of differing phonemic distributions of similar sounds in different languages. Recordings of an American pronouncing *battle* and an Englishman pronouncing *barrel* would show a high order of similarity in the intervocalic consonant, which belongs definitely in a *t*-group for the American and in an *r*-group for the Englishman.

[1] NATURE, **136**, 261, Aug. 17, 1935.
[2] Cf. *Language Monograph*, **16**, 17–32.

IN a collection of sound film registrations I find quite a number of regions that resemble the one reproduced in Fig. 1. Such a region consists of a series of bits of vibration with many peaks of different heights and periods of repetition and several vibratory movements of less sharp character, all of them beginning strong and fading to zero. Each bit of vibration can be characterised by its duration and by the systems of peaks and less sharp movements with their heights, periodicities and decrements. An entire region will be characterised not only by all the measurements for the individual bits but also by the numbers for their differences and order of sequence. Every region will have a more or less similar, but yet different, set of numbers for each of its characteristics.

For the group formed from the similar cases there will be for each characteristic an average value a, an average variation v and a limit of variation l. For the whole set of i characteristics there will be the averages $a_1, a_2, \ldots, a_i$, the average variations $v_1, v_2, \ldots, v_i$, and the limits of variation l_1 $l_2, \ldots, l_i$. The term 'phoneme' might be used to indicate: (1) the whole group of speech sounds with

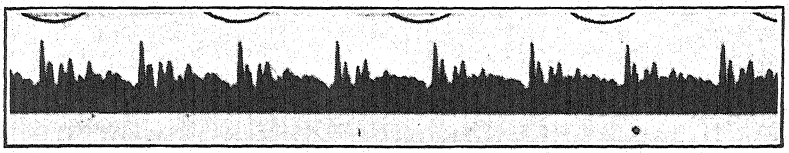

FIG. 1. A few waves of the sound track of the vowel in a film record of 'hatch'.

characteristics specified in this way, or (2) a speech sound defined with averages of these characteristics, or (3) a speech sound that may be any one of the group with these characteristics. The choice depends on convenience and accuracy. If we say that a person pronounced the word indicated in print by *hatch* with the phoneme æ, we do not mean that he used a whole group or an average; we can only mean that he used one of a group. If, however, we say that the speech of a person or a dialect is characterised by the use of the phoneme æ, any one of the three meanings is appropriate.

The essential point is that a new and successful method does exist for accurately and minutely specifying and sorting all the sounds of a language into definite and mutually exclusive categories, namely, the measurement of records of speech. This method transforms phonetics and linguistics from indefinite disciplines into exact sciences. It must be understood that science deals only with observables (Heisenberg) and that our knowledge is limited to the numbers obtained from the observables (Eddington and others). The entities that produce these numbers are not only unknowable but are also unmeasurable (Dirac). A statement that a speech sound consists of a certain set of measurement-numbers is a scientific fact that can be used. A statement that it is like the sound of *t* in *tip* conveys no definite information unless the measurement-numbers are given. If we mean anything else than these measurement-numbers we are claiming knowledge of the unknowable.

Mechanism of Glyoxalase Activation by Glutathione

WE have investigated the specific co-glyoxalase action of glutathione, discovered by Lohmann[1]. Giršavičius and Heyfetz[2] have shown that the spontaneous combination of glutathione and methyl glyoxal in aqueous solution leads to a state of equilibrium; formation and dissociation of the compound proceed, in not too acid solution, with great rapidity. The dependence of the velocity of the enzymic reaction on the initial concentrations of glutathione and methyl glyoxal (Platt and Schroeder[3]) and of their compound (unpublished work of ours) leads to the conclusion that of the three substances—free glutathione, free methyl glyoxal, and the compound—it is the latter that is the true substrate of glyoxalase action (though one of the other two may also be playing a part).

It is a striking fact that although widely differing reaction velocities are obtained when different initial concentrations of glutathione and of methyl glyoxal are used, yet *at all concentrations and velocities* the reaction proceeds linearly (zero order) until almost complete exhaustion of the methyl glyoxal. To shed some light on this fact, unusual in enzyme kinetics, we followed the changes in free sulphydryl in the course of the reaction. The lactic acid production by the enzyme was determined by gradual titration with alkali, the hydrogen ion concentration of the buffer-free solution, which contained an indicator, being kept constant. From time to time, samples were strongly acidified and rapidly titrated with iodine in presence of starch. We expected a gradual reappearance of the glutathione originally bound to methyl glyoxal. The results actually obtained are shown in Fig. 1. The greater part of the initially present free glutathione (less than half of the total; the rest is combined with methyl glyoxal) rapidly disappears after addition of the enzyme. The amount of free —SH group of the glutathione remains at a low value during most of the reaction; finally, as the reaction comes to an end and its velocity begins to fall, all the —SH, including that originally combined, rapidly reappears again. All the while the acid production proceeds at a steady rate.

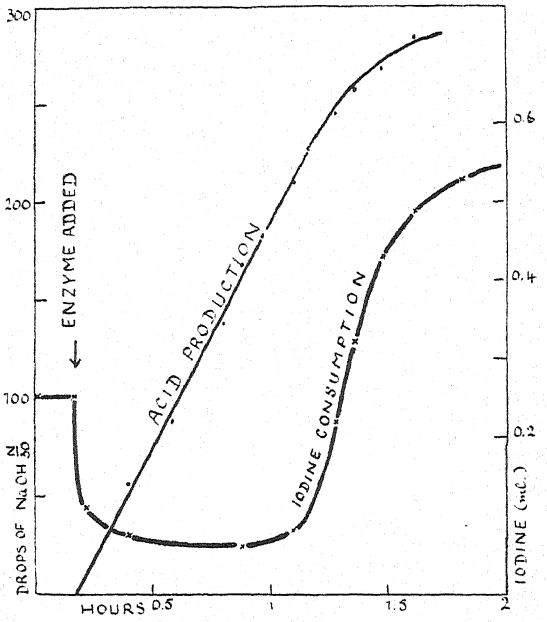

FIG. 1.

We have not yet investigated how the glutathione is 'hidden' during the reaction. A more complete combination with methyl glyoxal under the action of the enzyme (less than 0·5 mgm. of a purified preparation in 1 mol.) would appear to be ruled out by the chemical equilibrium involved. A dismutative reaction, with intermediate formation of other substances than lactic acid, is contradicted by the observation of Ariyama and Kobayashi[4] that lactic acid production is equal to loss of methyl glyoxal throughout the reaction.

Whatever the actual chemical reactions involved, it can be stated in general terms that the glutathione first combines by means of its —SH group with the substrate, methyl glyoxal, and then, as the enzyme-catalysed reaction develops, enters into some further transformations, again involving its —SH group. This observation seems of interest for the role of sulphydryl compounds in biochemical catalysis generally.

Blood Group Inheritance

WE agree with Prof. Haldane's view[1] that the existence of a fourth allelomorph underlying the inheritance of blood groups (equivalent to the theory proposed by us[2]) cannot be regarded as proved until tested in some such way as he suggests. The published statistics of many investigators, collected by Lattes[3], do not give sufficient information about individual families for the points raised by Prof. Haldane to be dealt with immediately.

Of the alternative theories suggested, mutation is discounted for the reason Prof. Haldane surmised: it would need to occur about ten times as frequently in $AB \times O$ matings as in the other cases where anomalous offspring have been recorded. The hypothesis of trisomy is unsatisfactory in that while it explains the occurrence of AB offspring from $AB \times O$ matings, it fails to account for the O offspring, which according to Lattes[4], Furuhata[5] and Bauer[6] are not less frequent. (Each type comprises about 5 per cent of the total progeny.)

Effect of Vitamin C (Ascorbic Acid) on the Growth of Plants

REFERRING to the letter from Miss Synnöve v. Hausen[1], I gladly acknowledge the priority of her paper, the existence of which was unknown to me when publishing mine on the same subject. Such coincidences are frequent in research work. More important, however, than similar questions of priority is the fact that our experiments have resulted, in a new field of research, in mutual confirmation, although worked out independently and with different methods.

There is yet another point which I wish to stress, and that is: the new proof given of the great utility of the 'correspondence' columns of NATURE in giving early news in the field of research and in bringing together research workers who would not otherwise know of each other's work. This is particularly the case with publications in languages which are read by relatively few people outside the countries in which they are used.

Zinc and Plant Metabolism

RECENT investigations by Reed and Dufrénoy[1] on the condition known in *Citrus* culture as 'mottle-leaf' are of great interest to the plant physiologist apart from their practical value to the industry. Results obtained from field treatments in conjunction with microchemical examination have suggested that zinc plays an important role in controlling the oxidation-reduction equilibrium of the leaf cells. Application of zinc, either through the soil or in the form of a spray to the foliage, leads to rapid recovery from the 'mottled' condition, associated with profound cytological changes including the production of chlorophyll.

During a visit to California in the early part of this year, I was fortunate in seeing these experiments. The contrast between the yellow-leaved control trees and those that had been sprayed a few months previously with zinc sulphate solution and were now bearing dark green, healthy foliage was truly striking. There can be no question as to the efficacy of the treatment, surprising though it may be that effective amounts of zinc can be absorbed by leaves with a cuticle so thick as that of *Citrus*.

It would be regrettable if these investigations, through their publication in a periodical mainly devoted to agricultural science, should escape the attention they deserve from plant physiologists who may have no direct contacts with applied work.

Prevention of Clogging of Strainers in Rearing Aquatic Organisms

WALTON SMITH has recently[1] described apparatus which overcomes several difficulties in rearing marine larvæ in flowing water, one special point being the waxing of the bolting silk strainers to retard clogging. I encountered the clogging in rearing *Metriocnemus longitarsus*, Goet. (Diptera, Chironomidæ) larvæ in flowing water, the overflow strainer being rapidly stopped up by the algal food and dejecta.

A 500 c.c. distilling flask was provided with a rubber bung through which passed a short 4 mm. bore glass tube as inlet, its inner end closed with a strainer, as these larvæ attempt to leave their vessel. A second piece of tube was bent to an appropriate angle and one limb cut off very short. The short limb was fixed tightly into the inner end of the delivery tube of the flask by a rubber

ring and the long limb projected into the body of the flask, but not directly below the inlet tube. Its lower end was just clear of the surface when the flask was half-filled with water and was closed by a fine strainer, thin cotton cloth being used as the larvæ nibbled bolting silk and so escaped. A rubber connexion between the inlet tube and a cistern was supplied with a screw clamp to regulate the flow, which fell in heavy drops.

The wave caused by the drop made contact with the outlet strainer and ejected an equal amount of water while the suction of the falling wave kept the strainer from clogging. The drip was adjusted to renew the water in the flask every four hours, but a faster renewal is possible just so long as the 'make and break' system persists. As tap-water served my purpose, the cistern was kept supplied from a gently running tap, four flasks working from a single main lead, and, provided that air locks were not allowed to form in this lead, the apparatus ran smoothly for an indefinite length of time.

X-Ray Examination of the Effect of Removing Non-Cellulosic Constituents from Vegetable Fibres

IN a recent letter by W. T. Astbury, R. D. Preston and A. G. Norman in NATURE of September 7, p. 391, it is stated that "Miles Thomas and Hewitt report a diminished *intensity* in photographs of purified fibres; but we have not observed such an effect".

The results obtained for sisal, in this laboratory, confirm their statement that *no* diminished intensity is observable in photographs of *purified* fibres. On the contrary, the process of purification leads to an improved definition.

Any ambiguity which may have existed on this point is much to be regretted, but it may be easily explained and removed.

Fibres which have been chlorinated by the use of moist chlorine gas, and the so-formed chloro-compounds not removed, were designated "chlorinated fibres". It is these fibres which give a photograph of diminished intensity. There is full agreement as to there being no diminished intensity in photographs of purified fibres.

JOSEPH HEWITT.

University College,
Leicester.

Points from Foregoing Letters

CERTAIN strains of mosquitoes (*Culex pipiens*) originally found on the Continent can lay fertile eggs without a previous meal of blood and have been termed 'autogenous'. J. F. Marshall and J. Staley bring evidence that certain man-biting mosquitoes in Great Britain are females of such autogenous strains: they describe the morphological differences between autogenous mosquitoes from various countries and the original non-autogenous variety and suggest that the specific name *C. domesticus* be revived for the autogenous strain.

The original gorilla skulls upon which Richard Owen based his first description of that animal in 1848 have been discovered in the Bristol Museum and Art Gallery. H. Tetley gives their origin and history.

The formation of brown ring deposits on glass by bombardment with positive rays (protons) is reported by Prof. B. Dasannacharya, V. T. Chiplonkar and L. G. Sapre. Similar deposits, but not ring-shaped, have been observed before and ascribed to the decomposition of hydrocarbon impurities.

Dr. R. K. Asundi, M. Jan-Khan and Prof. R. Samuel have increased the small number of completely analysed spectra of polyatomic molecules by an analysis of the SeO_2 bands. They have also analysed the SeO bands, and find a close correspondence between the constants of these two molecules, which indicates strong localisation of the bonds.

The direct measurement of the *L*-series of the X-ray spectrum of the rare gas argon, by means of their new ionic tube, is reported by M. Bačkovský and Prof. V. Dolejšek. The observed values agree well with those calculated by interpolation of the data from Siegbahn and Magnusson.

E. G. Cowley and Prof. J. R. Partington have determined the dielectric constants of several esters of inorganic acids (ethyl and *iso*-amyl borates and triphenyl phosphate) and have calculated their molecular dipole moments.

Experiments by Dr. C. N. Acharya show that, when nitrogenous substances are oxidised by a mixture of chromic and sulphuric acids, the amount of ammonia formed bears a definite proportion to the total nitrogen present, depending on the structure of the compound. Of the residual nitrogen, a part is converted into nitrate, and the rest lost in gaseous form. Dr. Acharya gives the values of 'oxidation constants' for different types of nitrogenous compounds.

If the term 'phoneme' is to be applied to one only of a group of similar sounds then, asks W. F. Twaddell of Prof. Scripture, what name is to be given to the group itself? Further, is there sufficient evidence from sound-track profiles to justify grouping together the *p*'s or *t*'s in such words as '*pit*' and '*tip*'? Prof. Scripture answers that it is a matter of convenience whether the term phoneme is used for a group of similar sounds or for a single member of the group. The essential part, he insists, is that the phoneme shall be defined in quantitative terms based upon film-tracks or similar records, and not upon references to undefinable and unrecorded sounds such as '*t*' in '*tip*'.

In the fermentation of certain sugars to lactic acid, methyl glyoxal is considered to be an intermediary product, it being changed to lactic acid by an enzyme in presence of the sulphur compound, glutathione. From the rate at which lactic acid is produced and from other evidence, J. Giršavičius and P. A. Heyfetz conclude that the glutathione first combines by means of its $-SH$ group with methyl glyoxal, and then, as the enzyme-catalysed reaction develops, enters into a further transformation, again involving its $-SH$ group.

Prof. Neilson Jones directs attention to recent work by Reed and Dufrénoy showing that spraying with zinc sulphate prevents 'mottle leaf' in *Citrus*, and points out that zinc is apparently an essential element in the production of chlorophyll.

Research Items

Recent Cave Exploration in Britain

AT the recent Norwich meeting of the British Association, reports of two committees of Section H (Anthropology) dealt with explorations of caves in Britain which have been subsidised by the Association. Of these, the report on the work carried out in Kent's Cavern, Torquay, indicates that during the past year a stage of excavation has been reached which promises well for future results, though at an enhanced expense. The work of the past year, which was resumed in October, 1934, and continued until the end of May, 1935, was directed to the centre of the Vestibule at the north entrance, which has been the scene of operations of the last three seasons. It proved most remunerative in the quantity and size of the animal relics, among them being the tibia of an Irish elk, believed to be the largest ever found in the cave, a very long rib of a rhinoceros, a well preserved tooth of a mammoth, and the whole of the incisors of a horse. These bones were remarkably free from the gnawing of carnivores. Probably they had dropped between the interstices of the large fragments of rock, with which the floor had then been covered, and thus escaped the further attention of the hyænas by which they had been brought to the cave. In the Creswell Caves of Derbyshire, which have now been under exploration by Mr. A. Leslie Armstrong on behalf of the Association Committee for some years, a section showing the stratification of the deposits in the cave has been prepared for permanent preservation. It is announced that application has been made to the Office of Works for the cave to be preserved and maintained as an ancient monument. In the meantime, Mr. Armstrong has begun work on the deposits at the entrance of the cave, with the view of penetrating to the two Mousterian levels underlying the superficial levels which were all that were examined by the Rev. Magins Mello in 1875. Valuable additions have been made to the fauna and artefacts from Mother Grundy's Parlour. It is now proposed to excavate the Boat House Cave.

Influence of Illumination on Work-Efficiency

A JOINT report of the Industrial Health Research Board and the Illumination Research Committee gives the result of an investigation by H. C. Weston into the relation between illumination and efficiency in work (H.M. Stationery Office, 1935. 4*d*. net). This report describes the first experiment, and deals with the illumination necessary for different sizes of work. Eighteen men were given sheets of paper on which were printed rows of incomplete circles. The gap in each circle pointed a different way, and each of the several sheets had different sized circles and gaps. The men had to cancel the circles in which the gap pointed a certain way. The same tests were given in six different degrees of illumination. Conditions were controlled so that there was no chance of memorising, no violent change in illumination, the minimum fatigue, and full allowance for individual variations. The results were judged according to the speed and accuracy of the subjects' discrimination alone. They show that although the smallest size could never be seen as easily as the largest, the right illumination obtained the maximum performance for each size. A change in size among the smaller and the larger sizes necessitated less alteration in illumination than a change among the intermediate ones. The range of illumination found necessary in the test is easily obtainable in practice.

Adaptation in *Artemia salina*

THE report submitted to Section D at the Norwich meeting of the British Association by the Committee, of which Prof. R. A. Fisher was chairman and Dr. F. Gross secretary, appointed to investigate the progressive adaptation to new conditions in *Artemia salina* (diploid and octoploid, parthenogenetic and bisexual), describes some highly suggestive experiments. Treatment of different races of *Artemia salina* with sodium arsenite showed a considerable difference in susceptibility between the diploid bisexual and the octoploid parthenogenetic forms. Of the latter, several lines showed 100 per cent survival of nauplii, when tested for twenty-four hours at the age of 1–4 days with 0·6 per cent of an $N/10$ solution of sodium arsenite, whereas in the bisexual races even the 50 per cent point of survival lies well under 0·5 per cent poison. In the bisexual races, parallel families showed consistently different degrees of resistance, although, as shown in the report, there were irregularities in the response of different broods of the same parentage, the cause of which has not yet been established. As regards the question whether there was any increase in resistance due to treatment and selection, comparisons were made which indicate in both a parthenogenetic line and in bisexual strains, a higher percentage of surviving nauplii after one and two generations treatment. "In both cases it is difficult to avoid the conclusion that the strength of poison needed to produce a given death-rate has been increased by at least 10 per cent., and probably more for the bisexual material."

Crabs from the Dutch East Indies

DR. ISABELLA GORDON has described in detail a collection of crabs from the Dutch East Indies ("Résultats Scientifiques du Voyage aux Indes Orientales Néerlandaises de LL.AA.RR. le Prince et la Princesse Léopold de Belgique". *Mémoires du Musée royal d'histoire naturelle de Belgique*. Hors Série, **3**, Fasc. 15. 1934. Crustacea Brachyura). The material includes several uncommon and interesting forms. The genus *Phymodius* is revised and *P. monticulosus* separated from *P. ungulatus* as a distinct species. The sub-family *Eumedoninae* in the family *Parthenopidae*, and the genus *Xenocarcinus* are also revised. The text-figures in this work are good and, especially in the drawings of the male pleopods, show an extraordinary amount of different types. These male pleopods in many genera are found to be of much specific importance and are a valuable diagnostic character, differing as they do very appreciably in those forms in which they are used for systematic work. Further reports in the same series recently published include the Rhizocephala and the Stomatopod larvæ.

After-Ripening and Germination of Rose Seeds

THE propagation of garden roses by budding good varieties upon stocks raised from seed is likely to find extensive application in the near future. Rose seeds are, however, rather difficult to germinate, but a paper by Dr. M. A. H. Tincker (*Roy. Hort. Soc. J.*, 60, Pt. 9, Sept. 1935) shows that suitable storage conditions before planting will render propagation from seed much easier. Achenes from the rose hips should be scattered in layers in damp sand within a plant pot which is then sunk in ashes in the open. This process is known as 'stratification', and if the seeds remain under these conditions from early November to the beginning of March, subsequent germination is hastened considerably. The paper reports a number of trials of unsuitable methods, the results of which are, nevertheless, illuminating. Storage at low or cool temperatures, for example, did not hasten germination; the seeds apparently require fluctuations in temperature and moisture content such as are provided by stratification.

A Virus Disease of Wallflowers and Stocks

GARDENERS are now familiar with the pathological condition of the tulip known as 'breaking', and it is interesting to note that wallflowers and stocks are subject to a similar malady ("Colour Changes in Wallflowers and Stocks" by Dr. Kenneth Smith, *Gard. Chron.*, 112, Aug. 10, 1935). The cause of the trouble is a virus disease of cauliflower and broccoli. This produces a mottling of diffuse yellow patches on the leaves, and such plants serve as sources of infection for wallflowers and stocks, the aphid *Myzus persicæ* being the transmitting agent. The last-mentioned floral crops have mottling of the leaves, but their flowers are also streaked with white or yellow—a most conspicuous and bizarre effect. Control measures are routine spraying of young plants with a wash to kill the aphids, the destruction of any infected plants, and the separation of the culinary members of the Cruciferæ from the beds with wallflowers and stocks.

Nevada Earthquake of 1934

EARTHQUAKES of moderate intensity are very rarely accompanied by superficial fault-displacements, and thus the account given by Messrs. E. Callaghan and V. P. Gianella of the earthquake of January 30, 1934, in the Excelsior Mountains, is of much interest (*Bull. Amer. Seis. Soc.*, 25, 161; 1935). The shock was of intensity 8 or 9 (modified Mercalli scale) and its epicentre lay in about lat. 38·2° N., long. 118·6° W. Numerous faults traverse the mountain area, and, along one of them on the southern slope and directed N. 66° E., a rupture occurred, about 4,500 ft. in length, with a scarp 5 in. in maximum height, showing that the summit area of the range had subsided with reference to the southern side.

Wind Records in Open Sea

"WIND Records from the Bell Rock Lighthouse", by A. H. R. Goldie, is the title of Geophysical Memoir No. 63 of the Meteorological Office (H.M. Stationery Office. 2*s*. 6*d*.). A Dines anemograph was erected at the Bell Rock in 1929, fourteen feet above the dome of the lighthouse, and 130 ft. above the mean level of the sea; the position, twelve miles from that part of the east coast of Scotland in the neighbourhood of Arbroath, is unique for its representation of open-sea conditions. Nevertheless, the detailed analysis of records obtained in the first two years during which the instrument was working, and their comparison with similar records obtained on the very exposed island of Tiree, suggest that the Scottish mainland is not without its influence on the structure of the wind, even at that distance. The absence for a great distance in all directions of any objects except the sea waves that might cause gustiness by mechanical friction leads one to expect low figures for the 'gustiness'—defined as the difference between the average wind speed in gusts and in lulls divided by the mean speed. The analysis showed that gustiness is greater in winter than in summer, an effect attributed by the author to the greater lapse-rate of temperature in winter. The memoir contains a section dealing with wind waves and squalls which is of particular interest in view of the work done at Cardington on the cell structure of squalls. There appears to be very strong evidence that wave-like fluctuations of wind speed at Bell Rock are nearly always associated with marked horizontal stratification of the atmosphere, while squalls of the type where the wind speed increases very suddenly with a veer of direction and falls off gradually (a feature of the convexional cells found at Cardington) are associated with a steep lapse-rate of temperature.

A Device for Stream Field Study

IN a paper communicated by the Structural Research Laboratory of the Royal Technical College, Copenhagen (Ingeniørvidenskabelige Skrifter. *A*, Na. 39: A New Device for Direct Stream Field Studies and its Application: with an Appendix on the Pressure Distribution on a Triangular Prism. By Paul Neményi. Pp. 23. Copenhagen: G. E. C. Gad. 3.00 kr.), Paul Neményi describes a new device which he has designed for stream field studies, and gives details of its application to the determination of wind pressures on buildings. Recent investigations have shown that with small roof slopes there is a partial vacuum on the windward side, and that when the slope becomes steeper this condition changes somewhat abruptly to pressure. The results obtained from experiments made in the Ahlborn Channel being to an unknown extent influenced by capillary phenomena, it was thought desirable to check and correct these by constructing a closed channel with measuring arrangements to give the direction of the stream, the total velocity pressure and the static pressure. The wind channel is horizontal, and across it is placed a horizontal tube having an almond-shaped section with a single hole in the symmetry axis of the central section. This tube can be raised from bottom to top of the wind channel, and can also be turned through any angle so that the pressure and its direction can be taken at any height in the central plane of the channel. The paper provides an illustration and description of the channel and measuring apparatus, and proceeds to describe a number of typical experiments made on models representing solid and perforated walls and buildings, and on a triangular prism. Diagrams show the pressure distributions obtained in these experiments both in the form of contour maps and cross-sections for various directions of the wind relative to the surfaces. These diagrams exhibit very clearly the surprisingly high negative pressures which occur locally near roof edges. At one point, for example, the negative pressure was found to be 326 per cent of the normal velocity pressure.

Radio Research in Australia

THE Radio Research Board, which was set up some years ago under the Commonwealth of Australia Council for Scientific and Industrial Research, continues to carry out considerable research into several of the fundamental problems of radio communication. The results of some of this work have recently been described in a series of ten scientific papers published in Melbourne in three reports of the Radio Research Board. A foreword to these reports states that the co-operation of several bodies in Australia has greatly assisted the work of the Board. In particular, the Postmaster General's Department contributed half the cost of the investigations during the financial year 1928–29, and three-quarters of this cost in the succeeding years. The Universities of Sydney and Melbourne have provided the necessary laboratory facilities for the location of the staff conducting the work, while the Department of Defence has also assisted with the loan of apparatus and in other ways. It is to be noted that several of the authors of the papers received their early research training in Great Britain with the Radio Research Board organisation under the Department of Scientific and Industrial Research.

The first report of the series under review contains four papers[1], of which one "On the Rotation of the Plane of Polarisation of Long Radio Waves" has been previously published in the *Proceedings of the Royal Society*, 1934. The other three have also been published previously in the *Journal of the Institution of Engineers, Australia*. Two of these papers deal with the development of a radio field intensity measuring set for medium broadcast frequencies, and its use in the exploration of the field around some Australian broadcasting stations. As a result of this work data have been obtained on the effective conductivity of several types of ground, and the resulting attenuation accompanying the propagation of waves over this ground. At the same time, measurements were made on the intensities of indirect or downcoming waves at various distances, and on the general noise level due to atmospheric disturbances, with the view of determining the effective service range of certain broadcasting stations. The last paper in this series describes the development of a frequency recorder for the rapid and continuous measurement of audio frequencies, as required in an extension of the frequency-change method of determining the heights of reflecting layers in the ionosphere.

Report No. 7 contains a group of four papers describing investigations into the propagation of medium frequency electric waves in the ionosphere[2]. Each of these papers has already been published in Great Britain during 1934 or 1935.

The last of the reports[3] so far received contains two hitherto unpublished papers describing the study of atmospherics and their interference effect in radio reception in Australia. The first of these describes a series of observations of the directions and intensities of atmospherics carried out with two visual cathode ray direction-finders installed at the ends of a base line 570 miles long and operating on a wave-length of 3,000 metres. The sites selected for these instruments, at Canberra and Toowoomba respectively, were considered to be particularly suitable for obtaining data on sources of atmospherics in Queensland. With the aid of a short wave radio communication link, simultaneous visual observations were made over a period of four months, December 1933–March 1934. The results are illustrated in the paper by maps showing the distribution of the sources of atmospherics during this summer period, and also lines of equal mean intensity of disturbance produced by each source.

The location of these atmospherics sources shows a very satisfactory correlation with the reports of thunderstorms obtained from the ordinary meteorological records, and thus strongly confirms the previous deduction that the majority of, if not all, atmospherics in Australia originate in lightning flashes. An important inference made by the authors on this portion of the work is that for thunderstorm warnings for aircraft, the cathode ray direction-finder is much preferable to ordinary meteorological methods.

The shapes of the iso-intensity lines referred to above for daytime observations were found to be satisfactorily explained by the effect of the topography of the ground on the propagation of the electric disturbance constituting the atmospheric. After making allowance for this effect, both the day and night observations agree in indicating that all the sources were of the same mean intensity within reasonable limits; in other words, the average power in a particular wave-band radiated by lightning flashes is sensibly constant. The distances at which the sources were located ranged up to about 2,500 miles from the observing stations.

The last paper in this series discusses the effect of atmospheric disturbances on broadcast reception conditions in Australia. The equivalent power of the radiation emitted by an average lightning flash is calculated, and the activity and distribution of lightning flashes in thunderstorms in various parts of Australia has been obtained from the meteorological records. With the aid of these data, the interference of atmospherics with the reception of broadcasting on different wave-lengths and at various field intensities has been calculated. Under the conditions considered in the paper, it is concluded that the proportional time of interference with the normal 4,000 hours of broadcasting per annum is very small. In the foreword to this report (No. 8) it is pointed out that some matters in this paper, such as the standards of reception assumed, may not be generally accepted by other experts on this subject.

National Smoke Abatement Society

MEETING AT BRISTOL

THE annual conference of the National Smoke Abatement Society was held in Bristol on September 20–21 under the presidency of Dr. H. A. de Voeux. Dr. A. G. Ruston summarised the work done with the late Prof. J. B. Cohen on the damage caused by smoke in the West Riding of Yorkshire. Animal, as well as vegetable, life suffers. Land exposed to acid atmosphere becomes deficient in lime, and cows grazing on such land yield milk also deficient in lime.

Dr. R. Lessing reviewed sources of atmospheric pollution, and advocated systematic surveys. The generation of electricity in large units, while diminishing total pollution, has resulted in the localised emission of exceptionally large quantities of acid flue gases, often in thickly populated areas. The concentration of fuel burning has the advantage of facilitating efficient utilisation and also the scientific treatment of the flue gases. Within a few years, two processes have been elaborated for the desulphurisation of flue gases, in the Battersea and Fulham Power Stations. The Fulham process has the advantage of producing no liquid effluent. Dr. Lessing estimates that both processes, when in full operation, will reduce the sulphur acids passed annually into the London atmosphere by 40,000 tons. The London gas companies already recover, during gas purification, sulphur equivalent to 55,000 tons of acid. It may be estimated that the public utilities will eventually recover or remove 20 per cent of the sulphur present in the coal burnt in London.

Large power stations emitting flue gases at a high velocity may be an important source of grit and dust, which is an insidious but noxious polluting agent. Fortunately, the washing process also takes care of the grit and dust at the same time. Central heating of large buildings, institutions, blocks of flats is leading to analogous conditions of local atmospheric pollution on a smaller scale.

Hitherto, efforts to diminish atmospheric pollution have been due mainly to idealists possessing knowledge and vision but impotent to alter actual conditions. Those wielding political power, local and national, have been indifferent. Commercial interests have been passively or actively resistant. Conditions, however, change. Already it is recognised that smoke endangers air traffic, and may render a site ineligible for aerodromes. A recent report of an investigation conducted at Pittsburgh expressed the view that "Smoke is a major obstacle to the popularisation of aviation". Atmospheric pollution is largely responsible for the movement of urban population to the country, and this promotes 'ribbon development'. Smoke may make a district unsuitable or unattractive for new industries. The realisation of this by local authorities and chambers of commerce ought to engender a more active interest in ameliorative measures.

Problems of Administration and Management

PROBLEMS of amalgamation and decentralisation were discussed at Norwich on September 9 by the Department of Industrial Co-operation of the Economic Science and Statistics Section of the British Association. Mr. L. Urwick opened the discussion with a paper on executive decentralisation with functional co-ordination in which he emphasised the necessity for a technical approach to questions of organisation. After discussing the nature of responsibility, and its relation to authority and power, he pointed out that reasons of time and space as well as psychological factors were important influences making for decentralisation. The steady and inevitable growth of functional specialisation made imperative the clear distinction between executive and administrative or policy-making responsibility, as well as the co-ordination of functional methods, and the reconciliation of these two tendencies was the central problem in modern business organisation. Failure to recognise the nature of the difficulty might easily involve the failure of a business combination. When a new duty arose, Mr. Urwick insisted that the only ultimate solution was to define that duty and assign it to individuals, properly selected and suitably trained. He regarded it as inevitable that business organisation should evolve towards a true system of 'staff' positions and relationships as distinct from either 'line' or 'functional' positions, and organised staff training was accordingly essential.

Mr. T. G. Rose described some examples of decentralisation problems in small undertakings, particularly of the management difficulties arising with a head office in London and works in the provinces, or in financial control from London while management and manufacturing activities are carried on in the provinces, or again in the decentralisation of management in a group of rationalised small firms.

Dr. K. G. Fenelon discussed problems of centralisation and decentralisation in the management and administration of combines. A choice between these two alternatives in practice has usually been made on an empirical basis, and frequently following an initial centralisation, a complete reorganisation had been undertaken to achieve decentralisation on a scientific basis. Such a task of reorganisation involves the careful study of each of the different functions and activities and the determination of the most suitable organisation for each. This reorganisation accordingly involves three stages: first the bringing of all the threads into the hands of the central management for the study of the problems and procedure of the different units; secondly, comparative analysis of the varying activities, leading to standard practice; and thirdly, the evolution of a process of decentralisation to give new elasticity.

Dr. Fenelon stressed the extent to which effective decentralisation depended not only on careful study

and preparation but also on getting the personnel to co-operate with one another and to think and act with enthusiasm. Centralisation of administration, that is, control of policies and centralisation of the management of each of the chief functions, did not always in practice go together. Improved management methods had greatly facilitated the centralisation of administrative control, and an economic research department or a statistical department frequently gave specialised assistance. The chief danger of administrative centralisation lies in pushing it to a point at which the initiative of local executives is destroyed and the organisation becomes unresponsive to variations in local conditions and the demands of local markets.

Administration and management, however, cannot be kept entirely distinct. It is essential to provide that a managerial staff shall be consulted in the formulation of policies, their active consent obtained and their interest aroused, and Dr. Fenelon referred to the advantages of the wise use of committees, and a budgetary system. With regard to the control of particular functions, the extent of centralisation or decentralisation should be determined by the nature of the function, and the relative importance of technical knowledge, personal contacts with customers, etc. Considering types of organisation, Dr. Fenelon referred to methods of co-ordination, through a system of committees, and to the use of staff on the lines advocated by Major Urwick. He suggested that in any industry there was a definite size of organisation beyond which smaller returns on capital and organisation were obtained. Moreover, success or failure was often determined by the willingness or otherwise of the chief executives to delegate authority and by the closeness of the attention given to the form of organisation and to the principles of administration.

Fourth Imperial Entomological Conference

THE fourth Imperial Entomological Conference, which was summoned on behalf of the Imperial Institute of Entomology and attended by twenty-seven delegates, each representing a different Dominion, Colony or other area of the British Empire, was held in London on September 19–27. The delegates were received by Sir Charles J. Howell Thomas, chairman of the Executive Council, and devoted the remainder of the first morning to the appointment of committees concerned with questions affecting the future policy and activities of the Imperial Institute of Entomology. Afterwards, four mornings or afternoons were devoted to meetings of committees and a final business meeting, and five to public meetings at which papers were read and discussed. Visits were paid to Rothamsted Experimental Station, the Forest Products Research Laboratory, Princes Risborough, the Parasite Laboratory of the Imperial Institute of Entomology at Farnham Royal, and the Stored Products Research Laboratory, Slough. At Farnham Royal, much interest was taken in a cinematograph film shown by Dr. K. R. S. Morris, illustrating work on the collection in central Europe and Sweden of parasites of pine sawflies (*Diprion*) for export to Canada.

By the courtesy of the president and council of the Royal Entomological Society of London, the public meetings of the Conference were held in the meeting room of the Society at 41 Queen's Gate; the delegates were also given every facility to use the Society's library.

The papers read and discussed were: locusts and grasshoppers, by Dr. B. P. Uvarov; termites, by Mr. F. P. Jepson; cotton-stainers and their control, by Mr. W. Allan; sheep blowflies, by Dr. G. D. Morison; the biological control of insect pests, by Dr. W. R. Thompson; pests of stored products, by Prof. J. W. Munro; the need for forest entomologists, with special reference to the pinhole borer problem, by Dr. R. C. Fisher; and plant viruses and their insect vectors, by Dr. K. M. Smith.

It is impossible here to give even an outline of the contents of all these papers, but mention may be made of two, selected as typical examples. That by Mr. Jepson attracted great interest, as it was realised that it dealt with problems on the practical aspects of which much work is required and relatively little has been done. Authorities on termites are few, and most of them are primarily interested in the systematic branch of the subject. Mr. Jepson opened by indicating the enormous damage caused by termites to crops, forest trees and all structures in which timber is employed in the tropics and subtropics, and estimated the annual losses as several millions of pounds sterling in the Empire alone. He then devoted the main part of his paper to a very valuable account of the methods found effective in his experience for the construction of buildings of various types in order to render them proof against invasion by soil-nesting termites, the principle underlying all of them being the insertion between the superstructure and the soil of a barrier of concrete that the insects cannot pass through or round. In his experience (and this was confirmed by speakers in the discussion that followed), Government engineers are usually not inclined to welcome advice on the construction of termite-proof buildings, and great damage to or destruction of valuable buildings constantly results. In addition to excluding subterranean termites, however, it is further necessary, in many countries, to guard against the establishment of drywood termites in the timber of buildings. As these gain admittance in the winged state, the only solution is to use timber that is naturally immune or has been rendered so by artificial treatment. Owing to the contamination of food by the fæcal pellets of these insects, which occurs when they infest roof-timbers, food-safes, etc., the varied protozoan and bacterial fauna of their intestines deserves further study. In Ceylon, it is usually in houses attacked by them that cases of sprue develop, and there is reason for suspecting that the contamination of human food by their solid excrement is in some manner associated with the causation of this disease.

As a result of this paper and the discussion that

followed, a Committee on Termites was appointed, and the Conference adopted consequent resolutions in which it emphasised the heavy losses caused by termites and the lack of knowledge on them, and recommended the accumulation of data on the financial losses to buildings, agriculture and the forest industry, the identity and habits of the species involved, and methods of control. It also recommended that this matter be taken up with the Governments concerned with the view of providing for a thorough investigation of the whole problem.

In contrast to the above, Dr. Uvarov's paper was a report of progress on a subject on which a large amount of co-ordinated study has been carried on for several years. The possibility of preventing outbreaks of locusts is based on the fact that the swarming phase is produced from the solitary one under certain peculiar combinations of external conditions that occur at times in definite and relatively restricted areas. Once it is produced, the swarms spread over immense regions, and the invasion develops in spite of all efforts to stem it. As a result of the extensive international organisation of which the Imperial Institute of Entomology is the centre, records of the movements and breeding of swarms over the infested area of Africa and south-western Asia are analysed, and from the data thus obtained field investigations are made to locate the centres in which the outbreaks arise, with the view of studying the ecological factors concerned in their commencement and the possibility of preventing it. It has thus been shown that the recent outbreak of the tropical migratory locust, which spread gradually over the greater part of Africa, originated in one or two restricted areas on the Middle Niger, and that the red locust similarly originated in a very few areas in Northern Rhodesia and Tanganyika Territory. Work on the desert locust has not progressed so far, but outbreak centres have been discovered on the coasts of the Sudan and of Baluchistan, and it is almost certain that none exists in the inner deserts of Africa. It will therefore be seen that the international investigations have provided a foundation for a preventive anti-locust policy, by which the outbreak centres can be kept under supervision and incipient outbreaks suppressed.

The discussion that followed afforded evidence that similar outbreak centres are characteristic of the principal injurious grasshoppers of North America and Australia.

Timber in the Box-Making and Coal-Mining Industries*

IN 1931, the Forestry Commissioners appointed an Inter-Departmental Committee to inquire into the possibility of making better use of the timber supplies of Great Britain. An interim report was submitted by this Committee in 1933, and recommended a series of detailed inquiries into the demand for timber for certain specific purposes. A first report dealt with the demand for timber for box and packing-case manufacture in Great Britain, whilst a second, now before us, deals with the demand for timber in coal-mining in England and Wales.

In the first report it was stated that there were two distinct sections of the industry, the box and packing-case makers on one hand, and the shook-using firms who merely assemble the component parts of the boxes already prepared, on the other.

So far as was observed, the timber used for shooks is invariably imported, and there was no evidence that home-grown timber could economically take its place either in character or quality. In the box and packing-case industry, home-grown timber, chiefly spruce and fir, is being extensively used in Scotland, and its suitability for many kinds of boxes is widely admitted in other areas, subject to various provisos. The Scottish firms are using it for mineral-water boxes and beer boxes, for the larger and heavier sizes of fish boxes, for soap boxes, for machinery cases, and cases for shipping rope and generally for any type of box in which light weight and a specially dressed appearance are not essential.

"The fact," says the report, "that, within the limits of the present enquiry, 20 per cent of the timber used by box making firms throughout Scotland, and over 40% of the timber used by those in Aberdeen, is home-grown, is emphatic evidence that home-grown timber could be used more largely than it is in other areas if adequate supplies were available in good condition, and if the cost of transport did not make the price prohibitive." Even in Scotland, a number of criticisms of home-grown timber were made. Perhaps the chief, which certainly restricts its use for the finer and lighter types of packing-cases, is the question of the excessive quantity and size of the knots. The presence or absence of knots in home-grown or any other timber is purely a question of good sylviculture, which, with properly grown and tended plantations, should right itself in the future.

With the interest of the State in afforestation schemes during the past fifteen years, and the creation of State plantations extending to more than 250,000 acres, and with another 100,000 acres of privately owned woods, it is obviously desirable that outlets should be found to absorb the increasing supplies of material which will become available.

In the report on the demand for timber in coal-mining, the report shows that the cost of mining timber annually consumed in Great Britain is about £6,000,000, and represents approximately a cost of 7*d*. on every ton of coal put on the market. Of this quantity, some 2¼ million loads were imported in 1934. It is said that an increase in the proportion supplied from native sources is possible immediately, and it can be substantially supplemented in the future from plantations at present immature.

The chief need is an effective scheme for marketing the home-grown supplies, and steps towards the attainment of this end have been taken in the formation of a Home-grown Timber Marketing Association under the chairmanship of Lord Clinton.

Educational Topics and Events

CAMBRIDGE.—Dr. J. A. Ryle has been appointed regius professor of physic in succession to Sir. W. Langdon Brown, who retired on September 30.

At Trinity College, H. Cary Gilson, N. M. V. Rothschild and H. W. Melville have been elected to fellowships.

At Pembroke College, Dr. G. B. B. M. Sutherland has been elected to a fellowship and appointed lecturer and director of studies in physical sciences.

GLASGOW.—The King has been pleased to approve the appointment of Dr. Edward Hindle to be regius professor of zoology in the University of Glasgow, in succession to Prof. John Graham Kerr, who has resigned.

OXFORD.—Prof. H. S. Jennings, professor of zoology and director of the zoological laboratories at Johns Hopkins University since 1910, has succeeded Dr. A. H. Compton of Chicago as George Eastman visiting professor and fellow of Balliol College. Prof. Jennings is an authority on the behaviour of lower organisms and on genetics.

Prof. G. H. Hardy of Cambridge has been elected an honorary fellow of New College, of which for many years he was a fellow.

Mr. B. V. Rollin (in physics) and Mr. G. J. Whitrow (in mathematics) have been elected to Harmsworth senior scholarships at Merton College.

Science News a Century Ago

H.M.S. *Beagle* Crosses the Pacific

UNDER the date October 20, 1835, Darwin records: "The survey of the Galapagos Archipelago being concluded, we steered towards Tahiti and commenced our long passage of 3,200 miles". He says that, during the voyage, "We passed through the Low or Dangerous Archipelago, and saw several of those most curious rings of coral land, just rising above the water's edge, which have been called Lagoon Islands. A long and brilliantly-white beach is capped by a margin of green vegetation; and the strip looking either way, rapidly narrows away in the distance, and sinks beneath the horizon. From the mast-head a wide expanse of smooth water can be seen within the ring. These low hollow coral islands bear no proportion to the vast ocean out of which they abruptly rise; and it seems wonderful, that such weak invaders are not overwhelmed by the all-powerful and never-tiring waves of that great sea, miscalled the Pacific."

The Horticultural Society

A MEETING of the Horticultural Society took place on October 20, 1835, in the rooms of the Society in Regent Street. "The tables which are usually covered with a gorgeous profusion of rare and beautiful shrubs and plants," said *The Times*, "presented an unexpected wintry meagreness of appearance. The Secretary explained that the severe frosts of the previous two nights had materially interfered with the intended display, the thermometers suspended against the walls of the Society's gardens at Chiswick had, on both nights, been as low as 27 of Fahrenheit. . . . There were a few exotic plants, principally from the gardens of Mr. Rolleson, of Tooting. . . . From the Society's gardens was a stove plant of the Orchideous tribe, which was deemed a great curiosity. It was a native of Surinam and was almost unknown in this country. The flower petals were of a dark colour, and the more closely examined, the more beautiful appeared their markings. They had an agreeable fragrance, somewhat partaking of the combined odours of the moss rose and the honeysuckle. . . . From a nobleman's grounds at Catterick, in Yorkshire, had been sent a plate of the veritable old English golden pippin, as a proof that the species was not, as generally supposed, extinct."

Sir James South and Christ's Hospital Boys

THOUGH among many of his contemporaries Sir James South (1785–1867) was perhaps as well known for his litigious character as for his astronomical work at Campden Hill, a kindly act of his was the subject of a letter from "Præceptor" in *The Times* of October 22, 1835. "On Tuesday last," the writer said, "Sir James South invited 50 of the scholars of Christ's Hospital, together with the masters and officials of the establishment, to view the comet at his observatory at Kensington. The evening proving unfavourable for the purpose, Sir James devoted the time to an explanation of his various instruments of observation . . . and afterwards set his youthful auditors to give each a practical proof of his attention to what he had heard, with the results of which he expressed himself very much pleased. He then treated them with a plentiful supper, and on their departure gave them another invitation, that they might not be disappointed of their view of the comet." A second visit was paid next day, the comet was seen and Sir James South in his drawing room delivered a lecture "on the methods by which individuals, however humble, may overcome the early difficulties that may obstruct their path in the attainment of scientific knowledge. . . ."

Lyell, Agassiz and Deshayes

IN the course of a long letter to Sedgwick, Lyell on October 25, 1835, said of Agassiz: "His knowledge of natural history surprises me the more I know of him, and he has that love of imparting it, and the power of doing it with clearness, which makes one feel one is getting on, and that one has caught his enthusiasm. I feel this also strongly when in company with Deshayes, who continues steadily to cultivate his own branch, and that under somewhat discouraging circumstances. . . . As it is my wish to propose the Wollaston medal this year to Deshayes, I wish you would have a talk with Agassiz when he is with you about the matter, for I believe there is no one in London who has seen so much of Deshayes, and knows so well his acquirements and the difficulties he has over-come as Agassiz. I am sure that if we could draw Deshayes over here, he would make a grand reform in our Museums, like Agassiz, and that he would discover rich mines of hidden treasure. . . ." G. P. Deshayes (1797–1875) at this time was teaching privately and devoting his leisure to zoological and conchological studies. From 1839 until 1842 he lived in Algeria. After his return he gave private courses on geology and palæontology and in 1869 was appointed to a chair in the Muséum d'Histoire Naturelle. The Wollaston Medal of the Geological Society of London was awarded to him in 1870.

Societies and Academies

BRUSSELS

Royal Academy of Sciences (*Bull. Classe Sci.*, 21, No. 7, July 1935). P. BURNIAT: A normal surface of bigenus one in linear space of four dimensions. O. ROZET: Surfaces of coincidence. O. ROZET: The canonical pencil of a surface. ST. GOLAB: The rectifiability of curves in centro-affine plane geometry. YVONNE DUPONT: Th. De Donder's thermodynamic synthesis applied to the transverse Nernst and Ettingshausen effects (3). Bridgman's relation is deduced without using the unnecessarily restricted hypothesis of previous papers. J. L. DESTOUCHES: Operatorial kinetics. B. ROSEN and M. DÉSIRANT: Researches on the molecular spectrum of selenium vapour (2). The paper discusses the $^1\Sigma \rightarrow {}^1\Sigma$ band system and its fluctuations and deduces the value 1·9 volts for the energy of dissociation of the Se_2 molecule. M. H. WUYTS and MISS A. LACOURT: A new synthesis of sulphur derivatives of indol. A sulphur derivative of indol was obtained by the action of hydrochloric acid in methyl alcohol on methylthiohydrazide. L. VERLAINE: The analytical character of perception in the macaque. Experimental methods and the precautions necessary in investigating the sense of perception in this monkey are discussed. R. VANDERWALLE: Contribution to the study of the mechanism of the action of heat in anti-smut disinfection of the seeds of cereals. A critical discussion of suggested explanations and a description of inoculation experiments with a micromanipulator.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Sunday, October 20

BRITISH MUSEUM (NATURAL HISTORY), at 3 and 4.30.—M. A. Phillips: "Mammals".*

Monday, October 21

BRITISH MUSEUM (NATURAL HISTORY), at 11.30.—M. Burton: "Bahamas Sponge Fishery".*

Tuesday, October 22

EUGENICS SOCIETY, at 5.15.—(in the rooms of the Linnean Society, Burlington House, Piccadilly, W.1).—H. Brewer: "Eutelegenesis—Objections and Criticisms Considered".*

UNIVERSITY COLLEGE, LONDON, at 5.30.—Dr. Pol Gerard: "Comparative Histo-Physiology of the Vertebrate Nephron" (succeeding lectures on October 24 and 25).*

HALLEY STEWART TRUST LECTURE, at 6.—(in the Memorial Hall, Farringdon Street, E.C.).—Sir James Jeans.*

Wednesday, October 23

ROYAL SOCIETY OF MEDICINE (SECTION OF COMPARATIVE MEDICINE), at 5.—Prof. J. C. G. Ledingham: "The Comparative Study of Clinically Allied Viruses: some unsolved Problems of Edward Jenner" (Presidential Address).

Thursday, October 24

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—J. M. Kennedy: Inaugural Address.

HALLEY STEWART TRUST LECTURE, at 6.—(in the Memorial Hall, Farringdon Street, E.C.).—Sir William Bragg.*

NORTH EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (TEES-SIDE BRANCH), at 7.30—(at the Cleveland Scientific and Technical Institution, Middlesbrough).—Address by P. A. R. Leith (chairman).

Chr. F. Christensen: "By Air and Sea to the Antarctic Whaling Grounds" (Cinematograph Film).

Friday, October 25

GEOPHYSICAL MEETING (ROYAL ASTRONOMICAL SOCIETY), at 4.30.—Discussion on "Geodesy in India" to be opened by Capt. G. Bomford. Speakers: Sir Gerald Lenox-Conyngham, G. H. Tipper and Dr. J. de Graaff Hunter.

KING'S COLLEGE, LONDON, at 5.30.—Dr. Paul Dienes: "Intuitionist Logic and the Foundations of Mathematics" (succeeding lectures on November 1 and 8).*

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Colonel A. E. Davidson: Presidential Address.

INSTITUTION OF CHEMICAL ENGINEERS, at 6.30.—Sir Harold Hartley: "Our National Coal Resources" (Second Hinchley Memorial Lecture).

ROYAL SOCIETY OF MEDICINE (SECTION OF EPIDEMIOLOGY AND STATE MEDICINE), at 8.15.—Surgeon-Capt. S. F. Dudley: "On the Biological Approach to the Study of Epidemiology" (Presidential Address).

No. 3443 SATURDAY, OCTOBER 26, 1935 Vol. 136

Food Supplies and Health

THIS paradoxical situation, poverty in the midst of plenty, presents a problem the solution of which has proved beyond the power of individual national policies. A more equitable distribution of foodstuffs and renewed prosperity in the farming industry can only be secured by far-sighted co-operative planning on a world scale.

At the League of Nations Assembly in September, Mr. Bruce, speaking for the Australian Delegation, suggested combining the studies of national health and agricultural economics, in the belief that a practical treatment of the one question may help to solve the other. Delegates from twelve countries asked that an international inquiry into the relation of health to nutrition and their bearing on agricultural problems might be discussed by the present Assembly. On behalf of the Government of the United Kingdom, Lord De La Warr welcomed these proposals and looked forward to fashioning practical schemes which will turn increased powers of production into a blessing instead of a disaster and make possible a healthier and fuller life. The adjustment needed is the extension of consumption and not the restriction of output.

Every country has tried to stave off the ruin of its farmers, and some of the emergency measures adopted in self-defence have cut two ways. Restricted imports at first forced up the prices of home produce, but by reducing consumption in the long run reacted adversely on the farmer. Everyone prefers home produce if able to afford it. The extent to which lowered prices increase consumption has recently been demonstrated by two interesting experiments. By issuing vouchers to the unemployed, who formed one third of the population in a Durham town, the Potato Marketing Board effected a price reduction equivalent to 3*d*. a stone, and the total consumption of potatoes in the district increased by ninety-six per cent. Through another Government-aided scheme, the price of milk to school children was halved and within nine months the consumption was trebled. The price of meat might be lowered if it became customary in Great Britain, as on the Continent and in the United States, to market veal and 'baby beef' in place of old and costly fat-stock.

By judicious controlling of prices, the current of popular demand can be diverted towards the purchase of the right kinds of foods more surely and quickly than by any educational process. The artificial stimulation of the consumption of such foods as potatoes, milk and milk products, fish, eggs, fresh fruit and vegetables, will repay in health the money expended and may eventually pay in cash. It is good to read in a memorandum just issued by the Ministry of Agriculture and Fisheries that the wisdom of having spent millions on subsidising production is now questioned, and the financing of price cuts advocated as an alternative likely to pay a dividend in improved national health with less drain on the taxpayer.

From the point of view of nutrition, subsidies for sugar and wheat are unnecessary. Both these foodstuffs were already consumed in sufficient amounts and cannot be produced economically in Great Britain. For health reasons also, the growing consumption of sugar is to be deprecated. A subsidy might more profitably be devoted to the distribution of basic manures for those soured fields which produce nothing but fine crops of sorrel and daisies.

We look forward to the realisation of Mr. Bruce's ideal, the marriage of health and agriculture. At present there is no unity of action. Municipal sanitarians project ever larger and more expensive schemes for swilling wastefully into the sea the

precious mineral salts and organic matter, which, by the appropriate treatment of sewage, could be conserved and used to restore fertility to exhausted soil.

Foodstuffs are the material of which mankind is built, and cannot be viewed dispassionately as purely commercial commodities. An international committee might consider the bill-of-fare which each country can produce and advise how its deficiencies can best be supplemented in the promotion of health by suitable imports. The effect upon land-locked countries of a reduced import of sea-fish and fish-liver oils is now visible in the prevalence of goitre and rickets in Central Europe. Curtailed importations of citrous fruits, tomatoes, etc., may also prove harmful to health in winter-time.

The extent to which malnutrition exists cannot be assessed in the absence of a proper standard. The figures returned present obvious absurdities; a relatively prosperous borough like Twickenham claiming a malnutrition rate about six times as high as that of Wigan; and Bootle a rate twelve times as high as Liverpool, of which it is an extension. The immediate task is to create a higher standard of life in terms of health and proper food.

The Warburg Institute

Kulturwissenschaftliche Bibliographie zum Nachleben der Antike
Band 1: Die Erscheinungen des Jahres 1931. In Gemeinschaft mit fachgenossen Bearbeitet von Hans Meier, Richard Newald, Edgar Wind. Herausgegeben von der Bibliothek Warburg. (A Bibliography on the Survival of the Classics. First Volume: The Publications of 1931. The Text of the German edition with an English Introduction. Edited by the Warburg Institute.) Pp. xxiii+333. (London, Toronto, Melbourne and Sydney: Cassell and Co., Ltd., 1934.) 21*s*. net.

FOUNDED at Hamburg by a wealthy Jewish family who had made a fortune in America, and inspired by Prof. Warburg of that stock, the Warburg Institute has within the last two years been transferred to the banks of the Thames, and now takes rank with the numerous benefactions which our more tolerant nation owes to foreign persecutions. It consists of a rich and specialist library, well arranged in part of Thames House on the Embankment, near the new Lambeth bridge. The volume under review is the first issued from the Institute's new headquarters, and is for the first time introduced by a full and interesting English chapter, giving the general object of the Institute and the general scope of this issue. Both the volume and the Institute deserve the notice and the encouragement of readers of NATURE, because, though starting with a literary tradition, they offer promise of providing in England a more adequate library for the study of the history of civilisation (including, and based on, science) than can be found elsewhere. There is in fact no such collection of books anywhere available to the public, though a few private collectors, such as Dr. Merz at Newcastle-on-Tyne, have been inspired by the idea.

This *catalog raisonné* of more than 300 pages purports to be an account of only the books published in the year 1931, though, as the dates are not given after the separate entries, it is impossible to satisfy one's self on that score, and no doubt many are included which had appeared by then, though not exactly in that year. The editors explain in their introduction that their general ideal is that of promoting the study of the history of *Cultur*, and quote Burckhardt as the fountain-head. The notion has, however, been enlarged in one direction and narrowed in another, since Burckhardt's time, in the programme of the Institute, and this the editors attribute to Prof. Warburg himself. The 'culture' studied is not civilisation as a whole, but 'culture' as represented in the West by the tradition of Greece and Rome. But, while thus limited in extent, it became deeper in content by the inclusion of all forms of tradition in western Europe. Thus folk-lore and magic are included, as well as the æsthetic ideals which appealed to Burckhardt and the earlier students of the art of the Renaissance. Warburg refused to separate literary from artistic or religious documents, on the ground that the student who seeks to understand how the Olympian gods were revived in the Renaissance as æsthetic ideals must also study how they survived in the Middle Ages as astrological and magical demons.

The bulk of the volume is in German, and one can only indicate here in the briefest way the riches of its content. The survival of the classical tradition is discussed, first, in a general way—what does survival in this sense mean, and then, under

its separate sections, of religion, mythology, philosophy and the various sciences. A large section is devoted to the artistic tradition, both in the theatre and in the plastic arts. A similar division covers speech and music. Rather more than a third of the whole treats of the classical tradition, as it was displayed in particular epochs and regions. Thus both the Hellenistic West and Hellenistic Judaism are fully dealt with, and one passes through the transformations of Byzantium and the Middle Ages, down to the more fragmentary and slighter treatment accorded to the humanism of the present. On this last section the amount of the material available to the editors and their staff of critics was clearly not sufficient to allow the picture presented to be in any way adequate to the facts. But for all the earlier portions, and for the literary and artistic criticism of classical works of all kinds, published quite recently, the catalogue is a gold-mine. One finds here an account of books often not otherwise known at all in England, and the short summary and criticism appended are always expert, sufficient and enlightening. One short and interesting example (of the hundreds which the book contains) may be given:

"Nogara Bartolomeo. The Laocoon group in the Vatican.

"A summary history of the group since its discovery. Different attempts at restoration are described. . . . Interesting proof arises from Titian's travesty in his 'Apes-Laocoon', that the chief figure had his arm bent towards his head."

In recommending the whole undertaking, one would only repeat the hope that in the development of the work of the Warburg Institute in London, larger and larger attention may be given to the history of science. On art it is already ample and admirable. F. S. MARVIN.

Mechanisation in Industry

Mechanisation in Industry

By Harry Jerome. (Publications of the National Bureau of Economic Research, Inc., No. 27.) Pp. xxxi+484. (New York: National Bureau of Economic Research, Inc., 1935.) 15*s*. net.

THE habit of producing goods whether they are needed or not, of applying power whether it is effective or not, of utilising inventions whether they are useful or not, pervades almost every department of our present civilisation. The untoward consequences of this materialistic habit, as seen for example in employment, have led to increasing attention being given to the social consequences of mechanisation in recent years. We are at last coming to realise that social inefficiency may be too high a price to pay for mechanical efficiency and that, from the point of view of the community as a whole, industrial efficiency must take account of the effects on the worker and the community as well as of the purely mechanical or chemical efficiency of its processes.

Although the social and cultural aspects of mechanisation have received a certain amount of attention, there has as yet been no detailed account of the process of mechanisation in a broad economic setting, interpreting the details in regard to mechanisation as a whole and to related processes of economic life. Some such account Dr. Jerome attempts to give us in the present study, particularly in relation to the nature and significance of current changes in the degree of mechanisation. He emphasises the wide range of consequences which must be traced if we are to measure accurately the effects of a mechanical change, and his careful technique of treatment should supply a further corrective to hasty or ill-founded assumptions regarding the effects of mechanisation.

In the first instance, Dr. Jerome distinguishes between changes which increase the units of output per hour of labour and those which reduce the number of workers required. He also directs attention to the effects which may be produced not merely on labour operating a process but also on auxiliary labour such as that required in maintenance, or on embodied labour such as that required in the production of the machine or the power or other services required for its operation, as well as on indirectly required labour like that engaged in transport, selling or advertising. It is only as the effects in all these directions are visualised that we can compute the true effect of a technical change on the community, and attain such an understanding of current changes that the manner and rapidity with which they occur can be in some degree controlled.

Dr. Jerome suggests that the most important single question about current changes in mechanisation is the rate at which they occur. The evidence presented, drawn from a wide range of manufacturing industries as well as from agriculture, mining, building, transport and handling of

materials, etc., leads him to conclude that a continuing increase in mechanisation at a moderate pace may be expected. Though there are still many possibilities for the extension of mechanisation, there are sufficient obstacles to mechanisation to render uncontrollably rapid mechanisation unlikely. On the contrary, stabilising factors which limit the rate of mechanisation also suggest that the rate of change in mechanisation is relatively stable. Even within the limited range of fluctuations in the rate of mechanisation, the experience of the last ten or fifteen years indicates ill effects which deserve consideration and, moreover, are not beyond reasonable possibility of prediction and control. For example, rapid mechanisation brings a substantial amount of displacement of skill and technological unemployment which, even when the change represents a net gain to society as a whole, may bring serious losses to individual workers, particularly to the older and more highly skilled. Moreover, there is reason to believe that, while advancing mechanisation probably tends to lessen seasonal fluctuations in industry, it may aggravate cyclical fluctuations.

The evidence upon which these conclusions are based is admirably presented, and is supported by statistical data which give the book real value as a work of reference upon the rate of mechanisation of industry. The book is eminently readable, and, while limiting himself closely to the special aspects of mechanisation indicated above, Dr. Jerome indicates a number of directions in which further investigation is required. The challenge to research thus thrown down by problems of obsolescence and plant occupation, the effects of mechanisation upon labour turnover, etc., is not the least of the claims of this book upon the attention of the scientific worker. R. BRIGHTMAN.

Witchcraft and Psychopathology

The Medical Man and the Witch during the Renaissance

By Dr. Gregory Zilboorg. (The Hideyo Noguchi Lectures.) (Publications of the Institute of the History of Medicine, the Johns Hopkins University, Third Series, Vol. 2.) Pp. x+215+5 plates. (Baltimore, Md.: The Johns Hopkins Press; London: Oxford University Press, 1935.) 11*s.* 6*d.* net.

WITCHCRAFT and the witchcraft persecutions were a manifestation of the hysteria endemic among the European populations of the Middle Ages; and after the Renaissance, even when the flame of seventeenth century fanaticism, which made a belief in witchcraft a test of orthodoxy, had died down, sporadic outbursts of popular excitement still showed that the evil had not been completely allayed.

In these three lectures Dr. Zilboorg, skilled psychiatrist and trained sociologist, examines the records of the fifteenth and sixteenth centuries with the purpose of demonstrating why, while other branches of medical sciences at the time of the Renaissance entered upon a period of rapid growth with the introduction of the scientific spirit and scientific method, the true nature of the phenomena of witchcraft and demonic possession was only tardily recognised as due to an abnormal psychic state—and that merely by the few. The study of psychopathology and psychiatry made no advance between the middle of the sixteenth century and the end of the nineteenth century.

In the "Malleus Maleficarum", the guide to theory and practice of the medieval inquisitor and witch-finder, there is, Dr. Zilboorg shows, a complete clinical record of psychic abnormalities known to modern science. He also shows by an analysis of records of the examination of cases of demonic possession and of the writings of such authorities as Paré, Paracelsus and Cornelius Agrippa, that medical men 'shied away' from a province expressly, and often explicitly, debarred from the healing art and consigned to the Church and the Law, either as heretical and criminal—the witch; or as spiritual—the demonically possessed.

Glimmerings of the truth are to be observed among the more advanced masters of medicine, as, for example, in the writings of Paracelsus and Agrippa; but as Dr. Zilboorg shows by copious quotation, the introduction of a scientific attitude of mind and of accurate clinical observation of cases in this field is due to Johann Weyer (1515 or 1516–88), native of Brabant and physician to Wilhelm, Grand Duke of Trier. Weyer was the founder of psychiatry. Unfortunately, Weyer's work became inextricably entangled in the conflicts between heresy and orthodoxy and the Roman and the reformed Churches. Hence, notwithstanding the decay of the active belief in witchcraft, the field of psychopathology continued to be dominated by the theological attitude towards possession for just on three hundred years.

Study of X-Rays

X-Rays in Theory and Experiment

By Prof. Arthur H. Compton and Prof. Samuel K. Allison. Second edition of "X-Rays and Electrons" by Arthur H. Compton. Pp. xiv + 828. (New York: D. Van Nostrand Co., Inc.; London: Macmillan and Co., Ltd., 1935.) 31*s*. 6*d*. net.

"X-RAYS in Theory and Experiment" was originally conceived as a second edition of Compton's deservedly celebrated "X-Rays and Electrons". That book was published just at the time when the great revolution in physical theory, characterised by the new quantum mechanics, was making itself felt, and the changes which this new outlook produced—changes due not in small part to the work of the authors—have caused instead a second book to be written, twice as large, and containing far more than twice the amount of data and interpretation.

It is, of course, a different kind of book from "X-Rays and Electrons". The first was the product of pioneering and provocative research. The Compton effect was one of those final discoveries that made reconciliation between the wave and quantum aspects of radiation seem altogether impossible, and the impossibility of this reconciliation was underlined and emphasised all through the book. The theoretical physicists could no longer evade the contradiction; they must resolve it; and thus, through the works of de Broglie, Schrödinger, Heisenberg and Dirac we have learnt that both the wave and the quantum form are valid not only for radiation, but also for matter, and in a way that obliges us to consider both as we had never thought of them before. The contradictions earlier raised by Compton now found their solution in wave mechanics in the uncertainty principle, and so the new book takes on a far more finished character than the old. Problems and difficulties still remain, but they are no longer the predominating note. Instead, we have presented in field after field a satisfactory quantum mechanical explanation of the phenomena.

The subject covered by the book is one of those divisions of physics which, growing up naturally, takes its part in the classification of physics based essentially on the size of the energy changes with which it deals. Normal optics is concerned with changes from a fraction of a volt to 100 electron volts, X-rays in the widest sense from 100 to 100,000 volts, but mostly in the tens of thousands, and beyond it, there are nuclear physics and the ultra-physics of cosmic rays, ranging into millions and thousands of millions of volts. From another point of view, the study of X-rays is an extension of the familiar theories of physical optics in an unfamiliar world, where the apparatus is no longer mirrors and lenses, but crystals and electron clouds, and the refractive index is both imaginary and less than one. We have a theory of spectra, of fluorescence, of absorption and dispersion, just as in the optical field, as well as a theory of scattering and diffraction. On the experimental side, things are, of course, very different; all beams are divergent beams limited by slits. The one link is the photographic plate, but apart from that the ionisation chamber and the Wilson chamber take the part of the human eye, while the single and the double crystal spectrograph replace the spectrometer and the interferometer in the analysis of wave-lengths.

One of the particular advantages of the book is the logicality of its arrangement. After the history of X-rays, the theory of their production is discussed, and then of their scattering—by electrons, by atoms, by liquids and by crystals. In the light of this knowledge, particularly of crystal refraction, the fluorescence, the absorption and the spectroscopy of X-rays are treated. One of the most interesting chapters is Chapter iii, dealing with the theory of scattering and incorporating a great deal of Prof. Compton's new work. It is in itself an admirable introduction to the new quantum theory. In the first section, the experimental evidence for light consisting of discrete quanta is derived both from the change of wave-length on scattering and its dependence on angle, and from the velocity and angular distribution of the recoil electrons.

The next section gives the resolution of this dilemma by means of wave mechanics, where we are dealing with the interference of two trains of waves, photonic and electronic. It is possible to go further, and obtain, from the fine structure of the Compton scattered line, the analysis of the distribution of electronic velocity in an atom, complementary to the distribution of electronic density which is derived from the unmodified scattering. The next chapters of the book give a comprehensive account from the physicist's point of view of the scattering of electrons by gases, liquids and crystals.

It should be emphasised that the book is primarily a physical treatise concerned with the principles of the relation of X-rays, electrons and matter, and not with the chemical or crystallo-

graphic question of the structure of the different forms of matter. The accounts of the methods of X-ray crystal analysis would not, and cannot be expected to, be of the nature of a manual of practical crystal analysis, but it will be a great help for chemists and physical chemists if physicists acquire in this way a knowledge of the principal developments in this field. It would be possible, for example, to criticise as inadequate the information offered as to detailed electronic configuration of certain atoms, where values are quoted coming from work which has been superseded. In the same way, in the question of the structure of liquids, not enough account has been taken of the work of Prins, while other results, which are strictly applicable only to a certain class of polar liquids, have been given a too general application.

Particularly useful are the chapters on dispersion and absorption of X-rays—questions which have rarely received such comprehensive treatment in English works. The value of the section on X-ray spectroscopy lies particularly in the space given to the detailed analysis of spectral lines by means of the double crystal spectrometer which has been the particular work of Prof. Allison, and until now has been far too little known. A critical discussion of the value of the electronic charge, whether based on oil-drop or absolute wave-length measurement—which give a difference between 4·77 and $4{\cdot}80 \times 10^{-10}$ E.S.U.—is not brought to any definite conclusion: in fact, as yet, this crucial metrical problem has not been solved.

The presentation of the book is excellent. In the figures a new method of rather violent perspective and shading is used to give three-dimensional impression in an effective, though somewhat startling, way. Both in the book and the appendixes there are contained the tables of the latest values of most of the fundamental atomic constants, structure factors, wave-lengths, absorption coefficients, etc. "X-Rays in Theory and Experiment" cannot fail to become a standard work of reference, both for physicists and crystallographers.

J. D. BERNAL.

Experimental Bacteriology

Experimental Bacteriology in its Applications to the Diagnosis, Epidemiology and Immunology of Infectious Diseases

By Prof. Dr. W. Kolle and Prof. Dr. H. Hetsch. Translated from the seventh, completely revised German edition by Dagny Erikson. The English version, incorporating further revision, edited by Prof. John Eyre. Vol. 1. Pp. 592+49 plates. Vol. 2. Pp. 613+62 plates. (London: George Allen and Unwin, Ltd., 1934.) 30*s*. net each.

THE classical German textbook, which enjoyed much popularity under the title "Experimentelle Bakteriologie", has been translated into several languages and now appears for the first time in English. The whole work comprises two large volumes each of more than five hundred pages, and has been edited by Prof. Eyre. It may be stated at once that this has been well done, and that all those interested in bacteriology in its relation to disease, whether from the point of view of student, teacher or investigator, will be grateful to have this German work more easily accessible by reason of its English version.

The first volume follows the conventional course by opening with chapters on general morphology and the biological aspects of pathogenic organisms and on immunity. Serological diagnostic methods appear in due course, and the ground is prepared for the ensuing descriptions of purely bacterial infections such as diphtheria, anthrax, typhoid fever, the streptococcal infections, the anærobes, etc. With the exception of tuberculosis and leprosy, infections of bacterial origin are included in this volume.

The second volume deals with infections with the acid-fast bacteria, spirochætal infections, tropical diseases, the filterable viruses affecting man, and to some extent animals, and the filamentous fungi and yeasts.

Though this subject is vast, there is no suggestion that there has been undue compression of material. Each chapter deals with its subject matter in a quite convincing and, for the most part, thorough way. Each disease is treated from the aspects of causative agent, diagnosis, epidemiology and immunology and, where possible, information gathered from post-mortem material is included. It would, indeed, be difficult to better many of the descriptions, which are liberally reinforced by excellent illustrations, many of them colour plates, which are a very valuable addition to the work. These volumes will make an appeal because the difficult liaison between clinical and laboratory knowledge has been brought about in a natural and convincing way without undue stress on either branch. It is at the same time a work for the student of medicine, for those whose interest lies primarily in tropical medicine and a useful book of reference for the investigator.

The work as a whole is not, however, free from faults, some of which are glaring and could easily have been avoided. It is not surprising to find confusion in such terms as "typhus" and "typhoid" and it would be, perhaps, wiser in an English edition to avoid the use of the term "spotted fever". The word "virus" also connotes nowadays a recognised group of infective agents rather than a general term, and should not be used in connexion with such diseases as syphilis. These faults are not really important. Much more serious, however, is the inescapable conviction that reference to foreign published work, particularly English and American, is to a very great extent absent. It may be that the authors had not ready access to these publications, although it is difficult to believe that the absence of the Kahn test from the discussion on the serological diagnosis of syphilis can be put down to this. It should, beyond question, have found a place alongside the Meinicke and Sachs-Georgi methods. There is also a tendency to refer to the work of investigators throughout the text while omitting it from the list of references. The value of these volumes as a work of reference has to some extent suffered by such omissions.

As a general rule, whilst the authors are progressing along the older and better beaten paths of bacteriology, there is a surety of treatment and a careful discrimination in the selection of available material. The case of the filterable viruses, however, is not so happy. There it is essential to move with the times, and this has not been done. Certain filterable viruses, such as louping ill and Rift Valley fever, have been missed completely. Admittedly, to be quite up to date in a large published work is difficult, so rapid is the progress in this highly important field. In dealing with the question of psittacosis, reference to work so recent as 1934 is found, and a quite useful account of the disease is given. It is a mistake to dismiss the problem of prophylactic measures in the control of yellow fever without mention of the promising results of vaccination. The cultivation of filterable viruses is now an accomplished fact, and several investigators have made convincing claims for its practical importance in smallpox vaccination.

A true indication of the nature of the filterable viruses has not been given in these volumes by reason of omission of more recent work along this line. On this point, reference is made to the experiments of Frosch and Dahmen with foot-and-mouth disease, whereas no mention is made of the very important work of the Maitlands and of Hecke. Nor is it a good reflection of generally accepted opinion to find on page 523 of vol. 2 the statement that the Borrel bodies in fowl-pox are "specific products of reaction of the tissues". These are but a few instances, and no doubt in future editions the treatment of the filterable viruses will follow more closely recent developments and so reach the same high standard which for the most part characterises the rest of the work.

The translation, which must have been an arduous task, has been admirably done.

Les plantes alimentaires chez tous les peuples et à travers les âges :
Histoire, utilisation, culture. Par Prof. D. Bois. Vol. 3 : Plantes à épices, à aromates, à condiments. (Encyclopédie biologique, Vol. 7.) Pp. iii+289. (Paris : Paul Lechevalier, 1934.) 50 francs.

THIS part of the "Encyclopédie biologique" deals primarily with spices but contains, in addition, useful information on a number of economic plants yielding edible products that may not be generally regarded as spices.

The first half of the volume deals with the true spices, and the early pages are devoted to an interesting historical account of the spice trade, the early days of which were so filled with romance. The more important spices such as pepper, nutmeg, cloves, cinnamon, ginger, chillies and vanilla are dealt with in detail, while those of more limited consumption such as turmeric, Guinea grains and star-anise receive more summary treatment. In addition to a description of the spice and the plant yielding it, information is given regarding areas of production, cultural requirements and practice, yields, uses and common names in various languages.

In the section devoted to condiments there are good accounts of mustard, horse-radish and the various representatives of the families Umbelliferæ, Compositæ and Labiatæ that fall under this category. Brief accounts of edible oil- and sugar-yielding plants are given at the end of the volume. Their inclusion in a volume devoted to spices and condiments is perhaps somewhat surprising.

Structure et propriétés des noyaux atomiques :
Rapports et discussions du Septième Conseil de Physique tenu à Bruxelles du 22 au 29 Octobre 1933 sous les auspices de l'Institut International de Physique Solvay. Pp. xxv+365. (Paris : Gauthier-Villars, 1934.) 75 francs.

THE report on the seventh Solvay Conference (1933) at Brussels contains papers by Cockcroft, Chadwick, the Joliots, Dirac, Gamow, Heisenberg, with discussions by a galaxy of notable physicists on the structure of atomic nuclei, neutron, positron, neutrino and the 'materialisation' of gamma rays. The report adopts and recommends the notation $^{1}_{2}He$, $^{226}_{86}Ra$, and so forth, rather than $^{4}He_{2}$, $^{226}Ra_{86}$ . . . , a change which the chemist would approve. In these days of rapid development of atomic physics, it would be a great boon to receive these reports within a few weeks of each conference, and to find them with their edges cut.

Quelques éclaircissements épars sur mes Monumenta Cartographica Africae et Aegypti

Par Prince Youssouf Kamal. Pp. vi+216. (Leiden: E. J. Brill, S.-A., 1935.)

STUDENTS of the history of cartography in general, and of African cartography in particular, are deeply indebted to Prince Youssouf Kamal for the inception and production of his lavishly designed volumes—"Monumenta Cartographica Africae et Aegypti"—which he is presenting to all the important libraries of the world. When completed, this work will prove a valuable storehouse of cartographical material for students, to whom much of it would otherwise be inaccessible. Interpreting his title widely, he includes not only reproductions of original maps, but also reconstructions of the historical geography of various periods, and extracts from contemporary writers containing topographical references. The present volume is largely an explanation of the scheme upon which the "Monumenta" have been designed, and a commentary upon the material already published.

It is not a comprehensive history of cartography; the author is content rather to discuss, without being didactic, and sometimes discursively, some of the major problems, and to indicate lines of profitable research. Such points are the symbolical character of early maps, the origin of the maps illustrating Ptolemy's Geography—he omits consideration of the probability that the tables of data were largely derived from maps of some kind—the content of medieval *TO* maps, and the work of the Oriental or Arab cartographers. His analysis of the latter reinforces the evidence for their dependence upon classical sources. In discussing his plan for the final volume dealing with the European discoverers of the early modern age, he presents a useful summary of the cartographic evidence for maritime activity along the coasts of north-west Africa prior to the movement associated with the name of Prince Henry. It yet remains to be demonstrated by whom this work was performed, and the relative contributions of Portuguese, Spanish and Italian pioneers. It is evident that this formidable undertaking is the work of a true enthusiast, and a patron of research.

G. R. C.

Fundamentals in Teaching Home Economics

By Ivol Spafford. Pp. xiii+424. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1935.) 13*s*. 6*d*. net.

FEW students of social problems to-day will question the general statement that the strength and sanctity of home life is still one of the most vital elements in the national fabric; and that the efforts now being made by far-sighted educationists to place the study of home economics on a firm basis, occupying a high and secure position in school curricula, merit every encouragement. This need was well recognised by the inclusion in the recent Congress for Scientific Management of a section for domestic economy; and in the present excellent and comprehensive work that need is still more clearly and fundamentally emphasised and provided for. The book deals of course with the teaching of home economics in the United States, but its breadth of view and depth of thought are such as to make it international in scope and application.

Home economics is here seen to be a matter of deep interest to everybody, to all indeed who have or hope to have any sort of home life and wish to make the best of it in all its varied intellectual, practical and emotional aspects. It is something vastly greater than a cookery or sewing class for adolescent girls. It makes a stirring appeal to boys and to adults of both sexes. It reaches down to the fundamentals of education in its analysis of the desire to learn, to know the truth, of thinking and self-directed education, of measuring progress in learning, and of the philosophy of education in general. But besides these deeper general aspects of the subject, the book contains a wealth of practical and helpful instruction to the teacher in a very difficult field, based on the author's own wide experience and profound study which, judging from the copious list of references appended to each chapter, must have been of an unusually complete and indefatigable nature.

Sumatra

Its History and People, by Edwin M. Loeb; The Archaeology and Art of Sumatra, by Robert Heine-Geldern. (Vol. 3 of Wiener Beiträge zur Kulturgeschichte und Linguistik des Institutes für Völkerkunde der Universität Wien.) Pp. ix+350+40 plates. (Wien: Verlag des Institutes für Völkerkunde der Universität, 1935.) 23 Österr. schillings; 4.40 dollars.

ALTHOUGH both the authors of this volume have a first-hand knowledge of the indigenous peoples of the Dutch East Indies, they do not claim to have attempted more than compilation. The result of their labour is, nevertheless, welcome to English readers, among whom a knowledge of the Dutch language, in which the copious literature dealing with the antiquities, culture and peoples of these islands for the most part has appeared, is either non-existent or far from profound. A reference to the extensive bibliography of the works upon which they have drawn for their material will show how very extensive this literature has come to be. To a great extent, the bar of language has been responsible for the fact that the position of the Javanese in the ethnology of Indonesia and as a link extending from New Guinea to the Malay Peninsula has received less consideration than its importance warrants.

In the section dealing with art and archæology, the author distinguishes no less than ten cultural strata extending in date from palæolithic (here a cultural rather than a chronological term in the strict sense) to the Chinese influence of the end of the fourteenth century A.D. It is to be noted that in the palæolithic he discriminates between a flake culture, which he holds to be probably Veddoid, and a hand-axe culture, which he would assign to the Papuo-Melanesian.

The book is illustrated by excellent photographs.

Diesel Engines and Coastal Shipping

DURING the meeting of the British Association at Norwich, an evening discourse was delivered on September 6 by Dr. S. J. Davies on Diesel engines and coastal shipping.

After referring to the remarks of Sir Frederick Bramwell in 1881 and the comments made by Sir Alfred Ewing in 1931 on Bramwell's suggestion that by 1931 steam engines would be superseded by internal combustion engines, Dr. Davies said that, for transport by road and in the air, the internal combustion engine holds a practical monopoly, but in large power stations the steam installation successfully meets competition. But the contest goes on, improvements in competing types appearing almost daily, while apparently unimportant developments in physics or metallurgy may have far-reaching consequences. The production of a better heat-resisting metal, for example, might change the whole position of the contest. The competition in the marine-engine field has proved one of the most interesting. On passenger liners the contest between the two divisions of steam engines, reciprocating and turbine, had first to be settled. To-day, while the steam turbine shows outstanding advantages for the largest passenger liners, Diesel engines have met with some success on the smaller liners, although the question is still very open. It is in the remaining classes of ocean-going vessels of the mercantile marine that Diesel engines have their greatest application, while in the last few years their importance in coastal work has steadily increased.

The term 'coastal shipping' includes a variety of craft, but for his purpose Dr. Davies confined himself to the three divisions : tugs, fishing vessels and coasters. In comparison with ocean-going vessels, these are limited in size and in the lengths of their voyages. These limitations involved factors quite different from those governing the design of ocean-going ships and their machinery. Ocean-going vessels spend by far the greater proportion of their time under way in travelling steadily at normal engine speeds, the proportion of time at reduced speeds and while manœuvring in harbour being small. In other words, the loads on the engines are for the most part uniform, and the demands made in respect of repairs and overhauls consequently less exacting than in coastal vessels. An ocean-going ship might go for days without the engineers receiving any orders from the bridge, and all running conditions—such as cooling water temperature, injection, adjustments, etc.—can be set and left unchanged.

The coasting vessel, on the other hand, is steaming to bell most of the time ; entering ports and rivers, docking, turning and then steaming on to its next destination through relatively crowded waterways. It is thus essential that the engines of the coaster should continue to work without detail supervision, and that they should withstand without difficulty both the mechanical stresses imposed by rapid changes of load and speed, and also the changes of engine temperature involved. In coasting vessels, the opportunities for carrying out repairs and adjustments are more limited. Then, too, limitation of size involves other conditions. Whereas the ten-thousand ton vessel has a little spray blown over the engine-room hatchway in bad weather, a moderate breeze will cause a small coaster to be drenched with spray, and so the engine must be made waterproof. The coaster too, lying alongside quays, is exposed to dust and grit, and the machinery should be totally enclosed to avoid the wear of working parts from the abrasive action of the grit. It is therefore clear that the machinery works under most exacting conditions, and it is necessary that everything possible should be done to lighten the duties of the engineer and to facilitate the repair or renewal of engine parts.

The Diesel engine for coasters is still in the experimental stage. Many firms are entering the field, and the Diesel engine is justifying itself handsomely in certain applications. Nevertheless, the full benefits of the Diesel engine cannot be realised until a limited number of designs can be standardised. As a result of such standardisation, the first costs of the engines should be lower than at present, spare parts should be readily and cheaply supplied, and the proportion of time the vessel is laid up for overhauls should be reduced. One direction in which the duties of the engineer could be lightened is by removing the navigational control of the machinery from the engine-room to the bridge. The handle of what is normally the engine-room telegraph should be the control handle on the bridge, and the change of speed and reversing the propeller should be fully automatic in response to the movement of this handle.

Investigations into the wear of Diesel engine cylinder liners have demonstrated the bad effect of changes of temperature of the circulating water and in particular of running an engine with cold circulating water. Coastal vessels, with their rapid changes of load and speed, and relatively frequent stops, are especially subject to

these unfavourable conditions, and it would be sound economy on all but the smallest vessels to take steps to reduce their effects. To ensure efficient cooling of the cylinders, cooling, in all but the smallest vessels, should be by fresh water passing round a closed circuit consisting of a small tank well above the engine, feeding into the line near the pump suction, and a tubular cooler placed well down in the ship. Clean lubricating oil is always an economy. This is provided by employing the 'dry sump system' in which the oil from the crank chamber is forced into a storage tank through filters which extract the solid particles. The filtered oil is drawn from the storage tank, and delivered under pressure to the engines.

While matters of design, control and upkeep are common to all classes of vessels, each kind of service brings its own special problems, and the examples quoted should show how these have been solved. Diesel engines for tugs have become of considerable importance in the last seven years. On the Thames, goods are carried in flat-bottomed barges which are towed downwards and upwards with the tide, the current at full ebb and flow being about 3 knots. There are approximately 350 tugs engaged in lighterage on the river, of which already 150 are motor tugs. The Thames Steam Tug and Lighterage Co. has been one of the pioneers in the use of Diesel engines, and one of their vessels has been in use for more than five years. In the *Irande*, the propelling machinery consists of a six-cylinder directly-reversible four-stroke Carels-Ingersoll-Rand engine developing 340 b.h.p. Another vessel of the same company, the *Framfield*, has two six-cylinder four-stroke engines, each driving a dynamo delivering current at 350 volts to a 400 s.h.p. propulsion motor. Control is from the bridge, there being two control handles, one on the port side and the other on the starboard side, so that the steersman can use the one most convenient to him. Mr. F. T. Mayor, the superintending engineer of the company, kindly supplied figures which made a comparison of the working costs of a steam tug and motor tug possible. These figures are very favourable to the motor tug.

As regard fishing vessels, the application of Diesel engines has been very uneven at the various ports. The Cornish fishermen, for example, have applied small engines to practically all their sailing vessels. The Scottish fishermen have gone further and have applied Diesel engines to many vessels of the sizes formerly steam-driven. The larger classes of trawlers, having displacements up to 2,300 tons, have engines of 1,000 h.p. and more. Several such vessels have been built in Great Britain, but mainly for French owners, and are employed in cod-fishing. There is a difference of opinion as to the question of drive in certain classes of fishing vessels. For the largest vessels, directly-reversing engines with direct drive to the propeller are usual; for small vessels, combined speed-reduction and reversing gears give the best service. In view of the large mass of experience already gained at home and abroad with Diesel-engined vessels, reliability in service may now be taken for granted. Other factors must, of course, be taken into account in making a comparison between steam engines and Diesel engines, and since the first costs of the latter are higher than those of the former, Diesel engines must show other advantages to counterbalance their higher capital charges. These compensating advantages follow mainly from two important facts: first, for the same power and output Diesel engines occupy considerably less space than the corresponding steam engines and boilers; secondly, the Diesel engine has a much higher thermal efficiency than the steam engine.

Turning to the third division of coastal vessels, the coasters, Dr. Davies said the primary duty of these is to convey goods, although small numbers of passengers are carried in some of the larger vessels. Among the companies who have recently adopted Diesel engines for coastal work is Messrs. Coast Lines, Ltd. The first of their four motor-ships was launched just two years ago and the fourth in July last. Their M.V. *Pacific Coast* has a dead-weight capacity of 1,755 tons. She is a twin-screw vessel, having two five-cylinder Polar-Diesel two-stroke engines, each developing 628 b.h.p. at 250 r.p.m. The auxiliaries are all electrically driven, current being generated by three oil-driven dynamos.

Such large vessels, however, are exceptional and, in view of the smaller difference between their work and that of ocean-going vessels, the superiority of Diesel engines in their case could be almost taken for granted. In tugs and fishing vessels, too, the matter seems also to be clearly proved. It may be summarised broadly by saying that where the vessel is for the greater part of its time under way, the advantages of the Diesel engine more than balance its higher first cost.

Whether as a result of the application of the Diesel engine or not, there is an undoubted revival of interest in coastal shipping. That this question is being approached more scientifically than hitherto is to be seen in the recent report of the work of the Froude Tank at the National Physical Laboratory. It is interesting to note, too, that the researches carried out have led to results definitely favourable to engines driving propellers at higher speeds of revolution, which is usually the case when Diesel engines are employed. Dr. Davies' lecture throughout was illustrated with slides of the various types of craft and their machinery.

Absolute Units and Electrical Measurements

By Sir Richard Glazebrook, K.C.B., F.R.S.

THE absolute system of electromagnetic units was developed by the British Association Committee on "Practical Standards for Electrical Measurements". Of this Committee Sir Wm. Thomson (Lord Kelvin) and Clerk Maxwell were the leading members and the development of the system is mainly due to them. It may be of interest to have here a brief account of what is meant by an 'absolute system'.

The meaning given to the term 'Absolute Measurement' was clearly explained by the B.A. Committee in the report to the Newcastle meeting in 1863. The Committee states :—

"The word 'absolute' in the present sense is used as opposed to the word 'relative' and by no means implies that the measurement is accurately made or that the unit employed is of perfect construction, but only that the measurement, instead of being a simple comparison with an arbitrary quantity of the same kind as that measured, is made by reference to certain fundamental units of another kind treated as postulates."

"For true absolute measurement the unit of force is defined as the force capable of producing the unit of velocity in the unit of mass when it has acted on it for the unit of time. Hence this force acting through the unit of space performs the absolute unit of work. In these two definitions, time, mass, and space are alone involved and the units in which these are measured, i.e., the second, gramme and metre* will alone in what follows be considered as fundamental units."

The Report then goes on to consider the mechanical, chemical and thermal effects due to electrical action, and since the chemical and thermal effects are measured by reference to a mechanical unit of work, concludes that it is only necessary in developing an absolute system of measurement to attend to the connexion between electrical magnitudes and the mechanical units. We are thus led to the following explanation of an absolute system of measurement.

Electric or magnetic systems exert force and are sources of energy. Force and energy are measured in terms of length, mass and time.

The forces between two quantities of electricity or two magnetic poles, measured in any units whatever, can be shown to be proportional to the product of the charges or of the poles and inversely to the squares of the distance between them. The constants of this proportion form the links required to connect quantities of electricity or of magnetism with the fundamental units. A third constant is required to determine the relation between a quantity of magnetism and an electric current. These three constants, usually denoted by K_0, μ_0 and A, are reduced to two because it can be shown that

$$A^2/\mu_0 K_0 = C^2,$$

where C is the velocity of wave propagation.

In order to form an absolute system of electrical measurement, it is absolutely necessary to know *two* of these constants, which thus form the links connecting electrical and magnetic quantities with the fundamental units of length, mass and time. Such is the basis of the system of measurement conceived by Maxwell and the B.A. Committee in the year 1863.

The committee selected as fundamental units the centimetre, the gram and the second, thus establishing the C.G.S. system. That, of course, was not necessary; the metre, the kilogram and the second might have been taken, but the choice was deliberate and only arrived at after much inquiry*.

To complete the electromagnetic system the Committee had to select the values of the two constants μ_0 and A. It was at liberty to select any values it pleased for these; the selection would determine the units in terms of which quantities of magnetism and currents of electricity were to be measured. Further investigation showed that μ_0/A represents permeability—the ratio of the magnetic induction at a point in space to the magnetising force at that point—and it was a very natural step to assume that this ratio was unity, that is, to select the permeability of space as the unit of permeability, and thus to make $\mu_0/A = 1$ on the C.G.S. system of absolute units.

A further assumption was required as to A, and for this the Committee selected the value unity. It thus formed the C.G.S. absolute system of electrical measurement with the centimetre, gram and second as basis, together with unity as the value of each of the necessary constants μ_0 and A.

* The metre was changed later to the centimetre.

* See B.A. Reports on Electrical Measurements: A Record of the History of "Absolute Units" and of Lord Kelvin's work in connection with these. Reprinted by the Association, 1912 (Cambridge University Press). See also "Dictionary of Applied Physics", vol. 2, page 941, article on units of electrical measurement.

The last assumption, that A is unity, implies that $\mu_0 K_0 C^2$ is unity, and hence that $K_0 = 1/\mu_0 C^2$.

For mechanical purposes the M.K.S. system is excellent and has many advantages, the main one perhaps being that the Joule, 10^7 C.G.S. units of energy, is on that system unity. But in my view the M.K.S. (Resistance) system is not an absolute system of electrical measurement. A material substance—a tube of mercury or a coil of wire—will not of itself serve to connect electrical quantities with length, mass and time. There is a sense perhaps in which the M.K.S.Ω system (Ω the ohm) may be looked on as a kind of hybrid absolute system because the ohm, 10^9 absolute C.G.S. units of resistance as defined by the B.A. Committee, is by that system linked to the units of length, mass and time. Personally I should greatly regret to see the word 'absolute' divorced from its original meaning.

The M.K.S. system can, of course, become 'absolute' for electrical measurements just as the C.G.S. system has done. Three constants will be required: we may call them K_1, μ_1 and A_1. They will be connected by the equation

$$A_1^2/\mu_1 K_1 = C_1^2,$$

where C_1 is measured in metres per second.

On the C.G.S. system, A is an undimensional constant arbitrarily assumed equal to unity; we may agree to make the similar assumption on the M.K.S. system and thus put A_1 = unity. We are also free to assume any value we like for μ_1 which leads to the result that $K_1 = (\mu_1 C_1^2)^{-1}$, and we have then a second quite satisfactory system of 'absolute measurement'. This will usually differ from the C.G.S. system. If, however, we choose for μ_1 the value 10^{-7}, the M.K.S. system leads to practical results identical with those of the C.G.S. system, and the accompanying table gives the relations between the various quantities involved—it might, of course, be extended to include others.

This, then, briefly gives my reason for the desire that 10^{-7}, the value of space permeability* on the M.K.S. system, may be selected as a fourth fundamental quantity required by the M.K.S. system. It must, of course, be remembered that a fifth such quantity is needed and completeness is attained by assuming for the value of A_1 unity, as the B.A. Committee did for A.

At a conference at which I was present recently the question was asked: "What is the need for a 'fourth unit'?" The reply was to the effect that the 'fourth unit' is needed to complete the dimensional equations. Thus it is not put forward to simplify electromagnetic theory or place it on a firmer basis, but to fill a supposed gap in the dimensional equations.

Dimensions, as the term is used by Maxwell, have reference to the three fundamental quantities of length, mass and time, and he set out with the object of expressing all electrical quantities in terms of these three. This proved to be impossible. Using more modern terms and symbols, the quantities denoted now by A, μ_0 and K_0 are involved and these are connected as explained above by the equation $A^2/\mu_0 K_0 = C^2$.

The dimensions of $\mu_0 K_0/A^2$ are those of the reciprocal of the square of a velocity, but without some further assumptions we can proceed no further. Maxwell tacitly assumed A to be unity and undimensional, leading to the result that $\mu_0 K_0 = 1/C^2$.

Maxwell points out that two assumptions are possible: on the one, the electromagnetic, μ_0 is treated as an undimensional constant of value unity and we have the electromagnetic system, on which, for example, the dimensions of a resistance are those of a velocity, those of a coefficient of induction are a length, etc. For the electrostatic system, K_0 is treated as an undimensional constant of value unity.

There is, however, another solution to the equation $\mu_0 K_0 = 1/C^2$. We may assume μ_0 and K_0 each to have unknown dimensions in length, mass and time, but to be so connected that the dimensions of their product are those of $1/C^2$. The dimensions of a coefficient of induction are then those of $\mu_0 \times L$; those of a resistance are those of

TABLE SHOWING THE RELATION BETWEEN QUANTITIES ON THE C.G.S. ELECTROMAGNETIC SYSTEM AND ON THE PROPOSED M.K.S. SYSTEM

	Length	Mass	Time	Space Permeability μ_0/A	Electromagnetic Coefficient A	Coulomb	Ampere	Volt	Ohm
C.G.S.	1 cm.	1 gramme	1 second	1	1	10^{-1}	10^{-1}	10^8	10^9
M.K.S.	1 metre	1 kilogramme	1 second	10^{-7}	1	1	1	1	1

On Maxwell's theory of the electrical field the permeability of space is assumed to be a quantity having dimensions. The value, therefore, will depend on the system of units employed. The symbol μ_0 is used to denote this quantity. On the C.G.S. system the permeability of space has been selected as the unit of permeability. Hence on this system the value of μ_0 is unity. On the M.K.S. system its value is 10^{-7}, and on the 'rationalized' M.K.S. system the value of μ_0 is $4\pi \times 10^{-7}$.

At the same time the S.U.N. Commission desires to take this opportunity of placing on record its recognition of the fact that there are important electrical theories supported by a number of physicists in accordance with which $\mu_0 K$ is a pure number.

* In cases in which it is desired to use the "rationalized system of units", this will become $4\pi \times 10^{-7}$, while the value of A will be unity.

$\mu_0 L/T$, and both are unknown. But nothing is really gained by taking either of these quantities as a 'fourth unit' and treating it either as a fourth dimension additional to those of length, mass and time, or as a quantity of unknown dimensions in length, mass and time.

The first alternative is an additional complication to electromagnetic theory—it does no doubt simplify certain dimensional equations; the second is secured by the acceptance by the I.E.C. of the statement that 'μ_0 possesses physical dimensions'.

What is necessary to place the M.K.S. system on a secure basis is the realisation of the facts that the two quantities A and μ_0 are essential, and that if the units of the system are to be the practical units of the C.G.S. system, their values (unrationalised) must be 1 and 10^{-7} and (rationalised) 1 and $4\pi \times 10^{-7}$.

It must, of course, be recognised that another solution to the equation $A^2/\mu_0 K_0 = C^2$ is open to us. We may, with Gauss, put $A = C$ and then $\mu_0 K_0$ becomes a numeric.

Adolf von Baeyer, 1835-1917

By Prof. J. R. Partington, M.B.E.

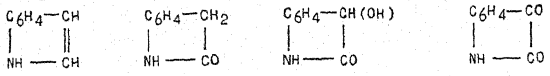
TWO of the outstanding organic chemists of the later nineteenth and early twentieth centuries were Adolf von Baeyer and his pupil Emil Fischer. As the late Prof. W. H. Perkin said, "their influence has been profound, mainly no doubt because of the immense amount of work of fundamental importance which they have left behind, but to a scarcely less degree by reason of their influence as teachers". The discoveries of Baeyer have also had a most important bearing on chemical industry, although he himself was little interested in their commercial exploitation. The side of theoretical organic chemistry which interested him most was the structural aspect, and in this his views, even in his early publications, were remarkably accurate. He modified in many ways the picture as left by Kekulé, and in some parts modern developments have merely filled in the details.

Adolf von Baeyer was born in Berlin on October 31, 1835. His chemical training began, like that of so many others eminent in this science, with Bunsen at Heidelberg. There he worked on cacodyl compounds, already made important in the early history of organic chemistry by the investigations of Bunsen. The latter had little interest in the development of organic chemistry at that time, and Baeyer, who wished to take up this branch of the science, spent two years in a private laboratory of Kekulé at Heidelberg. In 1858 he followed Kekulé to Ghent and began work on derivatives of uric acid. His interest in this was aroused in a curious way. During his journey from Heidelberg he became acquainted with a former pupil of Liebig, who gave him a box of specimens of uric acid derivatives. The further investigation of this class of bodies, carried out by Baeyer and his pupil Emil Fischer, may therefore be said to go back directly to the early work of Liebig at Giessen.

In 1860 Baeyer returned to Berlin as a teacher of organic chemistry in a small technical school. In this poorly paid and modest position he remained for twelve years, during which period he had in his laboratory such men as Graebe, Liebermann and Victor Meyer. The work on uric acid derivatives was continued, and in this period Baeyer also put forward the suggestion (in 1870) that the formation of sugar in plants is due to the reduction of carbonic acid, HO.CO.OH, in the green leaves and under the influence of light, to formaldehyde, H.COH, which then undergoes polymerisation to grape sugar, $C_6H_{12}O_6$. The study of a very important class of reactions called condensations began in 1866 with an investigation of the action of acids on acetone, and was developed in various directions, including the condensation of hydrocarbons with phenols and aldehydes. One outcome of this work was the use of phthalic anhydride, which led to the discovery of the phthaleins, many of which are dyestuffs, such as fluorescein, eosin and the rhodamines.

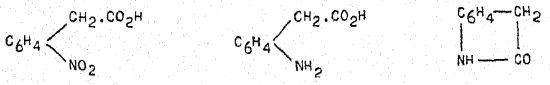
After a period from 1870 until 1875 at Strassburg, where Emil Fischer was his pupil, Baeyer succeeded Liebig at Munich. For more than twenty years, Liebig's activities at Munich had been confined to lecturing and studying the applications of chemistry to agriculture and medicine. There was no laboratory, and Baeyer's first task was to plan large new laboratories which were completed in 1877. In these he continued the investigation of indigo which he had begun in 1865, preparing several derivatives. He found that isatin (IV), a red substance discovered by Laurent in 1840 and produced by oxidising indigo with nitric acid, on reduction yields first dioxindole (III) and then

oxindole (II), which on distillation with zinc dust is reduced to the parent substance, indole (I):

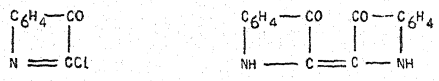


I II III IV

In 1870 Baeyer and Emmerling had found that isatin chloride when heated with phosphorus and hydriodic acid yields indigo, and thus when isatin was synthesised from *o*-nitrophenylacetic acid in 1870, this was also a synthesis of indigo:



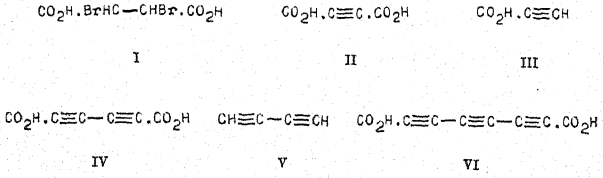
o-nitrophenylacetic acid — *o*-aminophenylacetic acid — oxindole



isatin chloride — indigo

Several other methods of synthesising indigo were worked out in the period until 1885, and naturally the German dyestuff firms became interested in the matter. They spent great sums of money on research, but all the processes tried at first proved too expensive, and since Baeyer declined to take an active part in helping to solve the commercial difficulties, some ill-feeling developed on the side of the firms, which led Baeyer to terminate his researches on indigo altogether in 1885.

Baeyer then turned to the investigation of a series of interesting but dangerous compounds, the polyacetylenes. From dibromosuccinic acid (I) he obtained acetylene carboxylic acid (II), from which by removal of carbon dioxide he prepared propargylic acid (III). From this the compounds diacetylene carboxylic acid (IV), diacetylene (V) and finally tetracetylene dicarboxylic acid (VI) were obtained. The latter was very explosive.

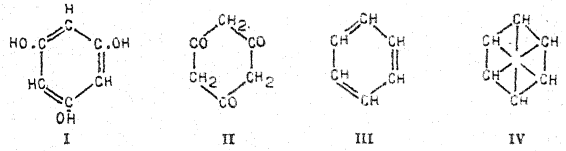


I II III

IV V VI

The properties of these compounds led Baeyer to consider the nature of the triple bond and the stability of rings of carbon atoms, the result being announced in the 'strain theory', in which stability is related to the strain to which the valencies of carbon atoms, normally directed from the centre of the tetrahedron model towards the corners, must be subjected in the formation of closed rings. Although this theory has been to some extent modified by later work, the idea of a resistance to bending exhibited by carbon valencies has been fully substantiated.

In the period between 1884 and 1893 Baeyer published a mass of important work of very varied kind, including the proof that phloroglucinol can function either as trihydroxybenzene (I) or triketohexamethylene (II), a case of what was called tautomeric change, many examples of which Baeyer brought to light.



I II III IV

He also worked on partially reduced benzene rings, and made out the profound change in 'aromatic' properties which occurs when a ring is saturated with hydrogen atoms. This work led him to abandon the Kekulé formula for benzene (III) and to adopt the centric formula (IV), in which six valencies of the carbon atoms in the ring, instead of being linked in three double bonds, appear as six valencies directed towards the centre of the hexagon. This formula had been proposed by H. E. Armstrong.

Baeyer's work on the terpenes from 1893 until 1899 was important, although the theory was fully clarified only by Wagner and later workers. An oxidising agent used in this work was Caro's acid, which Baeyer and Villiger in 1900 showed was permonosulphuric acid, $HO.O.SO_2.OH$. This led to the study of organic peroxides, such as the benzoyl compound, $C_6H_5.CO.O.OH$, and the two ethyl compounds $C_2H_5.O.OH$ (unstable) and $C_2H_5.O.O.C_2H_5$ (stable), the second of which, on reduction, yielded two molecules of alcohol, hence pointing to the formula HO.OH for hydrogen peroxide.

At the age of sixty-six years, in collaboration with Villiger, Baeyer published a long and important series of researches on oxonium compounds, having become convinced of the truth of Collie and Tickle's interpretation of the salts of dimethylpyrone as containing basic oxygen, a view which he at first opposed. His last research, published in 1915, two years before his death, was on the pyrones and contains the first description of the oxonium colouring matters, which have such an important relation to natural pigments.

Baeyer's work covers a wide range, and it is practically all of fundamental importance.

Obituary

Dr. H. W. Dudley, O.B.E., F.R.S.

ON October 3, nearly three weeks after a serious operation, Harold Ward Dudley died in a London nursing home. His death was a peculiarly tragic one, for until a month before it occurred his friends had no reason but to expect that there lay ahead many fruitful and happy years for him. That this was not to be is a most serious loss to biochemistry, creates a deplorable gap in the ranks of a wide circle of acquaintances, and is a cause of unfathomable grief to his family and to his intimate friends.

The eldest son of Florence and the late Rev. Joshua Dudley, he was born at Derby on October 30, 1887, and educated at Truro College, King Edward VI Grammar School, Morpeth, and the University of Leeds, where he specialised in chemistry. That his career was so uniformly successful was due to a combination of rare gifts with happy associations.

It was Dudley's good fortune while at Leeds to come under the influence of that inspiring trainer of biochemists, the late Prof. Julius B. Cohen, and further, after taking the degree of M.Sc. by a thesis on optical activity in menthyl esters, to obtain an 1851 Exhibition research scholarship. In the choice of Emil Fischer's laboratory as the place in which to work during the tenure of this scholarship he was again well advised, and there, under the immediate guidance of Prof. Wilhelm Traube, he carried out an investigation on the then topical subject of the purines, for which he received the Berlin Ph.D. in 1912.

There followed what was perhaps the most important step in Dudley's career when, on his return from Berlin, he became an assistant in the Herter Laboratory, New York; there he not only carried out important work under the guidance of another former Leeds student, H. D. Dakin, but what was more, formed a friendship which he treasured throughout the remainder of his life. It is needless to enumerate their publications, for their work is well known to biochemists and others whom it concerns, but one might mention 'glyoxalase', which they discovered, and 'protein racemisation' which they investigated, both of which are known to every student of biochemistry, as an indication of the fundamental nature of their researches.

Returning to Leeds in 1914, Dudley was for about a year lecturer in biochemistry, but soon the insistent voice of war called for the application of his high gifts in the service of his country, and he did not hesitate to respond. On the formation of an anti-gas research department under the leadership of Lieut.-Colonel E. H. Starling, at the Royal Army Medical College at Millbank, Dudley began work with the rank of Lieut. R.E. early in 1916, and was soon assisting in the evolution of the small box respirator, and in many other ways giving his fertile mind to problems of chemical warfare. Having by 1918 acquired a large experience of the subject, he was sent, with the rank of Major, in charge of a responsible anti-gas mission to the United States. He fulfilled these duties with characteristic care and thoroughness, and made many and varied new friends. He was awarded the O.B.E. for these war services.

After the War he returned, not without relief, to biochemistry, as head of the Department of Biochemistry of the Medical Research Committee (since Council), and worked at the Lister Institute until, in 1919, the Council obtained possession of its premises at Mount Vernon. There he worked until September 5 last, and formed a happy and fruitful association with the director, Sir Henry Dale, and with many other of his colleagues.

It was during these years that Dudley's best and most mature work was done. His work on the active principles of the posterior lobe of the pituitary body, although it fell short of his own expectations and high standards of achievement, was none the less a masterpiece of technique and a monument of patience. Then, after the discovery of insulin, by Banting and Best, he and Sir Henry Dale went to Toronto and established important contacts there on behalf of the Medical Research Council. Afterwards his fine flair for chemical methods was illustrated by the introduction by him of the picrate method for the extraction of insulin, and for its ready purification. After other important work on the subject of the preparation of insulin, he was entrusted with the preparation of the first international standard of that substance. The work, carried out in collaboration with others, on spermine, histamine and acetyl choline as tissue constituents also represented fundamental contributions to biochemistry, and are illustrations of his wide knowledge and abundant resource in investigation. He was elected a fellow of the Royal Society in 1930.

Dudley's last research probably represented his most valuable contribution to knowledge, since it culminated in the discovery of the active alkaloid of ergot, called ergometrine. The last paper on this subject from his pen appeared in the *Proceedings of the Royal Society* on the day of his death. Although search had often been made for the constituent of ergot to which the contractions of the puerperal uterus which its administration occasions were due, it was shown by Moir that none of the hitherto known constituents of ergot was clinically responsible for this action. Dudley succeeded, in collaboration with Moir, who carried out the clinical tests, in isolating this new alkaloid, which, thanks to him, is now "by far the most readily accessible alkaloid of ergot", and is already on the market.

The list of Dudley's great services to biochemistry would be incomplete without reference to his work for the Biochemical Society: he acted as secretary

in 1922–24, and then became, jointly with Prof. Arthur Harden, an editor of the *Biochemical Journal*. In the performance of this arduous duty, which he continued for six years, it is true, as Boswell said of Johnson, that "That part of his labour which consisted in emendation and improvement of the productions of other contributors, like those employed in levelling ground, can be perceived only by those who had an opportunity of comparing the original with the altered copy". Certain it is that over this duty, and other editorial work as assistant editor of "British Chemical Abstracts", which he performed with equal care and thoroughness, he often worked far into the night, and over many of his week-ends. In 1921 he married Mary Nettleship, who, after prolonged illness, which was a source of the deepest sorrow to him, died as recently as last April. She was a great help to him in his editorial work, and those who heard her sing will long remember her beautiful voice.

Dudley was a keen fly fisher and of musical and artistic tastes. Though of a retiring disposition, he was always ready to place his wide knowledge at the service of others. He had a wide circle of friends and was a member of the Savage Club. Had he wished, he could have had many intimate friends, for his was a personality of rare charm. Those who were honoured with his close friendship will always treasure in their hearts the memory of his unselfish character, affectionate sympathy and characteristic placid wit, his patience in adversity and his intuitive penetration of all humbug. Our sympathy goes out especially to his mother, who had such good reason to be proud of him. C. A. L. E.

Prof. Rhoda Erdmann

THE death of Prof. Rhoda Erdmann, of Berlin, has deprived the scientific world of a distinguished research worker and a most notable personality.

Dr. Erdmann began her scientific career as a protozoologist. Shortly before the War, she went to the United States, where she collaborated with Woodruff in protozoological studies which are now classical. When the United States entered the War, Dr. Erdmann, as a German subject, became the victim of war-time hysteria. She happened to be investigating an organism pathogenic to mice only, when a serious epidemic broke out in a neighbouring military camp. She was accused of having secretly infected the troops with the organism she was studying, and was arrested and imprisoned in New York. Her scientific and medical friends in the United States rallied to her aid and eventually she was acquitted of the fantastic charge.

After the War, Dr. Erdmann returned to Germany and began to work with tissue culture, mainly on problems connected with tumour growth. She was appointed a professor of the University of Berlin and placed in charge of the new Institut für Experimentelle Zellforschung at the Charité. She developed the institute until it became one of the principal centres for tissue culture research in Europe. At the same time she set herself to organise experimental cytology throughout the world. The *Archiv für Experimentelle Zellforschung* was founded in 1925 at her instigation, and was edited by her until her death. She also conceived the idea of an international society of experimental cytology which should hold a triennial congress and of which the *Archiv* should be the official organ. This scheme she successfully accomplished, and thanks to her tireless efforts as general secretary three congresses have now been held, the third being at Cambridge in 1933.

The change of government in Germany involved Dr. Erdmann in much hardship and difficulty, and in 1933 the institute to which she had devoted so much labour and care was closed, and she was pensioned. This was a great grief to her as she lived for her scientific work. She was accordingly delighted when in December 1934 the German Government decided to open another institute for experimental cytology under her directorship. Her health, which had troubled her for many years, was failing rapidly, but with undaunted courage and enterprise she began the task of creating her institute anew in a set of empty rooms in a private house. This task she was not destined to complete, and on August 23 she died at the age of sixty-four years.

Perhaps the quality which most endeared Dr. Erdmann to her friends was her gallant spirit. Oppressed by burdens of mind and body which many would have found overwhelming, she never lost heart but continued to work and plan for the future with the energy which characterised all she did. To those of us who knew her well, her death is a personal loss. H. B. F.

DR. HYNEK VYSOKÝ, professor of classical archæology in the Charles University, Prague, died at Rychnov, his birthplace in north-east Bohemia, on August 27, at the age of seventy-four years. He was educated at Prague and Berlin, and afterwards studied in Italy, Greece and Turkey. He wrote a number of Czech and German works on Greek archæology and mythology, and compiled most of the material dealing with archæology in Otto's (Czech) "Encyclopædia".

WE regret to announce the following deaths:

Prof. Carl Barus, emeritus professor of physics in Brown University, Providence, R.I., known for his work on interferometry and acoustic pressures, on September 20, aged seventy-nine years.

Mr. F. Escombe, who collaborated with Mr. H. T. Brown in noteworthy investigations on photosynthesis, on October 12, aged sixty-three years.

Major-General A. W. Greely, known for his geographical work in the Arctic, aged ninety-one years.

Dr. Walter Hough, head curator of the Department of Anthropology in the U.S. National Museum, on September 20, aged seventy-six years.

Mr. Joseph A. Johnson, president of the American Institute of Electrical Engineers in 1934, on October 5, aged fifty-three years.

News and Views

The E.R.A. Laboratory at Perivale

ON October 22, the Duke of Kent opened the new laboratory of the British Electrical and Allied Research Association which has been built at Perivale, Middlesex. Referring to the importance of research, he said that, in a mechanical era such as ours, it is one of the most important features of productive industry. The Association is supported by the Department of Scientific and Industrial Research, the Institution of Electrical Engineers, the British Broadcasting Corporation and many other bodies, including electric supply undertakings in the dominions and colonies. Electrical manufacturing firms are now well-equipped with laboratories for conducting research into problems bringing immediate profit to themselves, and they spend in this way hundreds of thousands of pounds a year. The Research Association conducts researches of general interest, which are of benefit to the user of electricity (the public), the user of electrical plant and apparatus (the electricity supply undertakings and the public) and to the manufacturer who uses electrical materials. The research work is carried out under the guidance of its council and seventy-five technical committees consisting of 450 leading experts in all branches of the industry who give their services voluntarily. The research work as a whole is supervised by the director, who is assisted by a staff of forty-seven technical experts and thirty-two clerical workers. Most of the work is done in existing establishments, the National Physical Laboratory, universities, manufacturers' laboratories, etc., but where special facilities are required it is carried out by the technical staff.

THE Association's new laboratory has a total floor space of about 14,000 square feet; but there is room for increasing the staff without further extension of the premises, and the site is capable of further development. The power frequency and heavy current laboratory contains a trench specially constructed for tests on cables laid horizontally. The standardising laboratory, physics laboratory, and generator room are also on this floor. In the east wing are situated laboratories which are specially equipped for researches on heavy current circuit breakers. The west side contains the radio and telephone laboratories, high-voltage laboratory, chemical laboratory, workshop and main store. The plant comprises a 230 volt–450 ampere hour battery which is charged automatically during the night by a mercury arc rectifier, and its output voltage is controlled by an automatic voltage regulator. Over each investigator's bench there is a small switchboard from which any of the numerous A.C. or D.C. circuits can be obtained. The high-tension laboratory is equipped for tests up to 80,000 volts. The heating plant is operated automatically, and burns a cheap grade of coal. The laboratory has been designed with a view to economy and efficiency. The night and week-end temperature is automatically maintained at a somewhat lower value than the thermostatically controlled temperature of the working period.

Bridging the Gap: Metropolitan-Vickers Laboratories

BETWEEN the abstract idea of an invention, or new scientific knowledge, to demonstrated utility, there is generally a wide gap, and to bridge this gap much work has to be done in special research laboratories. At the end of the War, Metropolitan-Vickers was one of the first large industrial organisations to realise the great part which scientific research would play in the development of industry. The building of the research laboratories, which now have a floor area of more than 40,000 square feet, was commenced in 1920. A rule has been made that all materials and products which enter the company's works as 'raw materials' must be subjected to test by the Research Department. As this Department is in close touch with the works and factories which develop the raw materials, these tests have been a great help to suppliers in improving their products.

THE Research Department is organised into a series of sections which form one co-operative whole, and this enables each problem to be investigated rapidly in the most efficient way. The four main buildings may be roughly described as the chemical, mechanical, high-tension and physical laboratories. Photographs of some of the apparatus used in making tests is shown in the pamphlet. Many of the machines used are unique; some of them incorporate the latest methods devised by scientific workers, and there are few machines in Great Britain which rival them in size. We were much impressed by the photograph of the M.V. 500 kw. wireless valve, installed at Rugby and continuously evacuated by M.V. oil condensation pumps and a single rotary pump. In the library section, current scientific, technical and economic literature is scrutinised and translations are constantly being made from many languages.

The Mitten Crab in English Rivers

IN the review of Peters and Panning's "Monograph of the Mitten Crab" published in NATURE of June 9, 1934, an account was given of the invasion of European rivers by this Chinese species, and the probability of its spreading to English rivers was pointed out. This seems now to have come to pass. About a fortnight ago, a living specimen was found on one of the screens guarding the pipes through which water is pumped from the Thames into the condensers at Lots Road Power Station in Chelsea. It is a full-grown male, the carapace measuring 63 mm. in length, by 68 mm. in breadth. The exact way in which the species has reached Great Britain is

a matter for conjecture, but the possibilities of transport from the estuaries of Holland or North Germany are obvious. Some highly coloured forecasts have appeared in the daily Press regarding the damage likely to be caused if the crab becomes established in English rivers and estuaries. It can safely be said, however, that there is little ground for apprehension. On the Continent, the banks of rivers have been undermined in places by the burrows of the crabs, but the most serious damage has been caused to fresh-water fishes. In Great Britain, where fresh-water fish have for the most part only a sporting value, the new addition to the fauna may justify some anxiety on the part of anglers in the eastern counties. There is fortunately no reason for anticipating that the crab will introduce into Europe the lung disease, paragonimiasis, of which it is one of the vectors in the Far East.

Association of British Chemical Manufacturers

THE nineteenth annual report of the Association of British Chemical Manufacturers, submitted to the annual meeting on October 10, records an increase in membership from 109 to 118, while the number of affiliated associations is now 13. Reference is made to the participation of the Association in the Brussels International and Universal Exhibition, the British Chemical Exhibit at which has been organised by the Association at the request of the Department of Overseas Trade. The safety activities of the Association have been continued, and the Association has submitted a list of solvents in general use as a basis for the investigation, which has now been commenced by a special committee under the Medical Research Council, on their physiological effects in relation to industrial risks. The investigation on tests for the detection of low concentrations of toxic gases that are likely to be encountered in industry, to which the Association has contributed half the cost, is nearing completion. Methods of detection and estimation, usually with test papers, have been worked out and standardised for a number of gases by the Chemical Defence Research Department, and a printing method has been discovered which will give consistent results and yield permanent stains. The Association is also supporting financially work on the testing of respirators for industrial use to ensure that they give adequate protection, which is being carried out by the Chemical Research Department. The Association has taken over from the Chemical and Allied Employers' Federation the regular collection and investigation of accident statistics as part of its normal safety activities. Other matters on which action has been taken during the year relate to the Provisional Poisons List and Poisons Rules and the report of the Poisons Board, trade marks, Government patents and the transport of chemicals by road.

IN moving the adoption of the report at the annual meeting, Mr. T. Wallace, who deputised as chairman in the absence of Dr. F. H. Carr, through illness, referred particularly to the manner in which the Government left the chemical section of the Polish Treaty to be worked out between the Association and the Polish Union of Chemical Industries. The importance of industrial reorganisation was stressed, particularly the necessity for further co-operation in regard to research, production and marketing. Commenting on the position of the fine chemical industry, Mr. Wallace said that since the report was written a supplementary memorandum has been submitted to the Key Industries Committee of the Board of Trade, detailing reasons why the manufacturers considered the progressive development of the industry would be better assured by a continuance of the key industry duties than by a transfer to the Import Duties Act.

Roman Yorkshire

As progress is made in the excavation of the Roman villa at Rudston, six miles west of Bridlington in Yorkshire, it affords a more extended view of settled life under what has been termed the 'signal-station' system, which archæological discovery in this area has revealed as a characteristic feature in the organisation of this section of Roman Britain. The site has now been under investigation for three seasons by a local committee in conjunction with the Roman Antiquities Committee of the Yorkshire Archæological Society, the excavation being in charge of Messrs. A. M. Woodward and K. A. Steer. Both coins and types of pottery point to an occupation of considerable duration, the former ranging from Domitian to Valens, and the latter including late first century, Samian, third century types from the Yorkshire pottery at Throlam and 'signal-station' types of the end of the fourth century. A system of pre-Roman ditches below the foundations may go back so far as the Bronze Age. An interesting building to the west of the residential block, discovered in 1934, which measures not less than 50 ft. by 22 ft., is now seen, according to a report of the latest results of excavation (*The Times*, Oct. 22), to have been used for a variety of purposes connected with the needs of the villa. *Tesserae* of sandstone not of local origin, and many chippings of chalk and tile, confirm the view suggested by earlier discoveries of chalk *tesserae* and red and blue tiles that it was a workshop for making and repairing mosaic flooring. Further, remains of no less than six ovens point to other uses not yet completely apparent. An early suggestion that they were part of the equipment for the manufacture of wool or for tanning has now been abandoned in favour of the view that they were for drying or roasting grain preparatory to grinding.

The College of Science, Benares Hindu University

FEW countries are, in proportion to their literate population, so well equipped with modern laboratories as India. The reproach can no longer be levelled at Indian university education that it is purely literary. We need only cite as examples the fine laboratories to be found at the University College of Science, Calcutta, the Presidency College, Madras, and the Royal Institute of Science, Bombay. From the time of its foundation in 1911, the Hindu University at

Benares has paid particular attention to the teaching of science, both pure and applied. The science departments with a staff of seventy provide accommodation for about one thousand students, and these departments have now been constituted a separate College of Science within the University. This College, of which Prof. K. K. Mathur has been appointed the first Principal, was formally opened on September 12 by the veteran Vice-Chancellor and founder of the University, Pandit M. M. Malaviya. In his opening address, the Vice-Chancellor emphasised the need in the present economic position of India for increased facilities for the study of science in all its branches. The Hindu University has already played a prominent part in the industrial development of the United Provinces, and we are sure that the foresight of the Vice-Chancellor and executive body of the University in establishing this new college will lead to an expansion of its activities.

New German renderings of 'Foreign' Words

IN NATURE of September 28, p. 495, we published a short notice of the second edition of "Theoretische Physik" by Dr. Georg Joos. Our reviewer commented very favourably upon the book, but animadverted upon the addition of a glossary of "foreign" words (*Erlaüterung einiger Fremdwörter*), "in which *Absorption* (*Verschluckung*), *Elastizität* (*Dehnbarkeit*), *Kapillarität* (*Haarröhrchenkraft*) and such-like non-Prussian words are translated into the new German, although these 'foreign' words appear in the articles in Gehler's 'Physikalisches Wörterbuch' of more than a hundred years ago". We have now received an indignant letter from Dr. Joos, containing the following explanation of this glossary. "Many English readers, who according to the reporter are to be impressed comically through these things, will know that the graduates of the 'Oberrealschule' have studied neither Latin nor Greek and that for them an explanation of these words is very desirable", adding, "According to the wording of the report the reader must think that it is my intention to seriously substitute 'Verschluckung' for 'Absorption' or 'Segelstange' for 'Antenne' ". As regards the last sentence our reviewer suggested nothing about Dr. Joos' intentions, but stated the bare fact that the glossary had been added to the book, leaving his English readers free (if we may use the word without offence) to draw any conclusions they wished. Many will, no doubt, share his and our surprise that words which have been in regular use in the German language for four generations and more, a period sufficient, we should have thought, to guarantee their incorporation, should be regarded and named as foreign.

OUR reviewer adds: "We note that graduates of the Oberrealschule have studied neither Latin nor Greek, but then they did not do so at the time of the first edition, which did not contain the glossary; in fact, they never did. Most students in England and other countries are equally unfamiliar with Latin and Greek, but have no difficulty over 'elasticity' and 'capillarity', while Germans unfamiliar with French have, we believe, no difficulty over '*General*' and '*Soldat*'. Dr. Joos does not seem to realise that, if there is any force in his contention, most German students will not know what his book is about, since both '*Theoretische*' and '*Physik*' are Greek words not explained in the *Erläuterung*. For that matter, *Electricität* (may we suggest *Bernsteinreibungskraft ?*) is not in the glossary, although *Kapazität* (*Fassungsvermögen*) is: *Alkali* (a Semitic word which occurs in the book combined with a Latin word as *Alkalispektren*—shall we suggest *Pflanzenaschenerdelichterscheinung ?*) is missing, although *Kondensator* (*Verdichter*) is included. We hope in the next edition to see the glossary either omitted or properly completed. We in England find so much in the present-day activities in German universities to move us to tears that Dr. Joos really must allow us a faint smile when we come across something harmlessly amusing from that quarter, and permit us to be our own judges of what is 'comical' ".

International Exhibition of Nature Photography

THERE was a large assembly of naturalists and Nature photographers at the opening on October 16 of the *Country Life* International Exhibition of Nature Photography at the British Museum (Natural History), Cromwell Road, South Kensington. The Earl of Onslow, president of the Society for the Protection of the Fauna of the Empire, referred to the great value of Nature photography and cinematography as "a very powerful incentive towards the preservation of wild life in all its forms", and to the fact that the Exhibition contains a large number of subjects that have never been seen before. He went on to remark that "there is a very grave danger at present hanging over us and that is that unless wild animals, big-game and birds of all kinds are carefully preserved a great number of species will become extinct and they will be a downright loss to the world in general. We could do without poison snakes but most other animals are a very valuable asset not only from the natural history point of view, but from the scientific point of view and from the point of view that they tend to preserve the balance of Nature." The audience, which included, among many others well known for their interest in wild life, the Duke of Sutherland and Lord Desborough, afterwards inspected the Exhibition. More than thirteen hundred photographs are displayed on screens in the Whale Hall, one wall being devoted entirely to the work of pioneer photographers, which includes the late J. H. Symonds' picture "Goldfinches fighting on Teazle", "Marsh Harrier" by the late Col. H. Moore, and no fewer than seventeen fine studies by Mr. C. J. King. The Exhibition will be open—admission free—until November 30. A souvenir volume (5*s*.), containing reproductions of 120 pictures from the Exhibition, has been published.

Edwin Klebs

IN a centennial note published in the *New England Journal of Medicine* of July 11, Dr. Leona Baumgartner, of Cornell University Medical College, New York, claims that Edwin Klebs, who was born

on February 6, 1834, and died in 1913, was not only one of the pioneers of bacteriology, but also made important contributions to other fields of medicine. In addition to being the first to describe the causal organism of diphtheria in 1875, he described acromegaly in 1884, two years before Pierre Marie; inoculated primates with syphilis fifteen years before Metchnikoff; isolated colonies of bacteria on solid media in the form of Sturgen's glue nine years before Koch; was the first to produce tuberculosis experimentally in animals by the injection of milk from infected cows, thereby establishing the bovine origin of the disease; and described the typhoid bacillus before Eberth. Klebs pursued his medical education in his native town of Königsberg under Rathke, Helmholtz, Burdach and Werther, and later in Würzburg under Virchow, Kölliker, Leydig and Scanzoni. He led a wandering life, being successively professor at Berne, Würzburg, Prague, Zurich and the Rush Medical College, Chicago. His contributions to pathological anatomy and physiology included the first experimental production of valvular disease of the heart and the recognition of bacterial infection in the production of the subsequent endocarditis, the description of hæmorrhagic pancreatitis as a rapidly fatal disease, the introduction of the paraffin embedding method and his textbooks on pathological anatomy (1869–76) and general pathology (1887–89). Klebs also took an active part in the foundation of three important medical journals, namely, the *Correspondenz-Blatt für Schweizer Aerzte* (1871), which some years ago was renamed *Schweizer medizinische Wochenschrift*, the *Archiv für experimentelle Pathologie und Pharmakologie* (1873) and the *Prager Medizinische Wochenschrift* (1876).

Work of the Government Chemist

THE report of the Government Chemist on the work of the Government Laboratory for the year ending March 31, 1935 (London: H.M. Stationery Office, 9*d*. net), outlines the work carried out in the Government Laboratories for the Admiralty, Ministry of Agriculture and Fisheries, the Air Ministry, Crown Agents for the Colonies, Board of Customs and Excise, Ministry of Health, Home Office, Post Office and other Government departments. The total number of samples examined during the year was 522,788, as compared with 503,592 in the previous year. There was an increase of 26,594 in the number of samples examined in the laboratory at Clement's Inn Passage, and decreases at the Custom House laboratory and at the chemical stations of 232 and 7,166 respectively, the latter being due to the closing of the Manchester chemical station and the transfer of the examination of samples of tea to tea inspectors of Customs and Excise. The principal increases occurred in the number of samples of hydrocarbon oils, beers, wine, spirits, cocoa and chocolate, samples for duty under the Import Duties Act, 1932, Safeguarding of Industries Act, 1921, tobacco and silk exportations, samples of sugar composite goods and British sugar, and in samples taken under the national marking schemes.

THE hydrocarbon oils duty has involved the examination of nearly 17,000 samples for assessment of duty on importation or drawback of duty on exportation, the increase being due to the duty of 1*d*. per gallon charged on oils other than light oils. Many of the samples had to be examined for other dutiable substances, such as alcohols, esters and chemicals listed by the Board of Trade under Part I of the Safeguarding of Industries Act. The growing use of duty-free spirits and industrial methylated spirits in industry involves an increase in the consultative work of the Laboratory, apart from the examination of samples to ascertain whether the conditions of use laid down by the Commissioners of Customs and Excise have been fulfilled. The number of samples of cocoa, chocolate and wine submitted for examination increased by 1,400; samples of beer increased by 1,609, of silk and rayon by 1,866, while the Laboratory was also called upon to deal with the testing of animal and vegetable fibres and hairs of all kinds under the Import Duties Act. The number of samples of tobacco and snuff examined has also increased, and improved methods for the analysis of tobacco have been studied. Much work has been carried out on the revision of existing methods and the investigation of new methods of detection and determination of substances.

Petroleum and Tar Oils as Insecticides

AN important paper by Dr. Hubert Martin on the standardisation of petroleum and tar oils and preparations as insecticides appears in the *Annals of Applied Biology* (**22**, 334). In recent years, a great deal of attention has been devoted by research workers and by the appropriate Government departments to the standardisation and specification of the sprays and dusts employed for the control of insect pests and diseases infesting agricultural and horticultural crops. An important body of knowledge on the chemical constitution and physical properties of these materials is scattered through the literature of the subject, and is so extensive as to be available only to relatively few. Of the many insecticides now in use, the petroleum and tar distillate oils occupy a very important position, and their use, already widespread, is expanding. Dr. Martin gives an extended and critical review of the published information of the chemical and physical factors defining these products, and in addition incorporates much original work of his own.

DR. MARTIN sets out in a concise and ordered way how the chemical and physical criteria can be correlated with insecticidal and phytocidal properties, and finally builds up from his own analyses specifications which he considers are available for judging the suitability of these oils, and preparations made from them, for their various uses as insecticides. In addition, the analytical methods available are considered, and the most suitable set out with supporting evidence in considerable detail. This paper is an important step towards the realisation of the hope, that a reasonable standard of efficiency and safety in use

and of uniformity of quality may be attained for these important products. It is published with the object of ascertaining how the various specifications will work out in practice, and thus it is advisable that interested manufacturers, horticultural advisers, and large users will give it the attention it deserves. The Council of the Association of Applied Biologists has consented to the paper being reprinted for sale, the price being 2*s*. post free; it is obtainable from the author (Research Station, Long Ashton, Bristol).

International Congress of Mining, Metallurgy and Applied Geology

THE seventh International Congress of Mining, Metallurgy and Applied Geology was opened at the Sorbonne, Paris, on October 20, and will continue until October 26. The President of the Republic, M. Lebrun, was present at the inaugural session. Sir Robert Hadfield, the delegate of the Iron and Steel Institute, presented to M. Lebrun a copy of the picture in the Bodleian Library, Oxford, depicting Roger Bacon presenting a book to the Chancellor of the University of Paris. Sir Robert also presented a miniature knife of steel made by Michael Faraday during the years 1819–24 while he was residing at the Royal Institution. The steel contains 0·74 per cent platinum. The weight of the blade is one-hundredth of an ounce, and that of the complete knife, one-twentieth of an ounce. Sir Robert suggested that the knife should be handed either to Dr. Leon Guillet, head of the Ecole Centrale des Arts et Manufactures, or to the Ecole des Mines.

Pasteur Institute of India, Kasauli

IN the thirty-third annual report for 1933 of the Kasauli Pasteur Institute, the Director, Lieut.-Col. Shortt, gives an account of the work of the Institute for 1933. The total number of patients attending the Institute and its various centres was 19,524, an increase of 4,406 as compared with the previous year. Such a large number of patients indicates the widespread threat of rabies in India. The vaccine used was carbolised 5 per cent Paris sheep vaccine, and three out of every four cases with face bites received antirabic serum in addition, as this appears to improve the results obtained. Deducting some 2,000 cases that did not complete the treatment, and 1,446 cases whom it was considered did not require treatment, there were 1,356 Europeans and 14,582 natives treated. There were no deaths among the Europeans, and 83 deaths among the natives, a combined percentage death-rate of only 0·52.

Australian Statistics

THE Official Year Book of the Commonwealth of Australia for 1934 (Commonwealth Bureau of Census and Statistics. 5*s*.) gives as usual an exhaustive summary of all aspects of Australian life and activity. The call of economy still hampers the editor in carrying out all his projects, but he has achieved great success in presenting information in forms that are useful to economists and others. Many details of the census of 1933 are incorporated. An appendix gives a summary of the chief events in connexion with the financial crisis that began in Australia in 1929.

Craftsmanship in Scientific Instruments

THE Physical Society announces that the seventh annual craftsmanship and draughtsmanship competition will be held as usual in conjunction with its annual exhibition of scientific instruments and apparatus in January next. Competitors must be in the regular employ of a firm or institution which will be exhibiting or has exhibited at least once during the previous three years, and has been invited by the organising committee to enter its employees for the competition.

Chinese Medical Association

THE third general meeting of the Chinese Medical Association, the official medical association of China, will be held on November 1–8. This association is the successor to the China Medical Missionary Association organised in 1886. The 1935 meeting will be held at the Canton Hospital, Canton, China, because it was here that Dr. Peter Parker introduced Western medicine into China one hundred years ago. He was also the world's first regularly appointed medical missionary. A centennial "History of the Hospital" is now in the press (Kelly and Walsh, Shanghai). Besides the regular scientific sessions of the conference, November 2 will be devoted to the centenary celebrations. The new Canton Hospital will be formally opened, and the foundation stone will be laid for the new medical school building. The money for the latter has been obtained by a special grant from the Central Executive of the National Government of China.

New Secretary of the Institution of Naval Architects

MR. G. V. BOYS has been appointed secretary of the Institution of Naval Architects, in succession to Mr. R. W. Dana, who will retire at the close of this year, after thirty-four years of service as secretary. Mr. Boys, who is a son of Sir Charles Vernon Boys, is a graduate of Trinity College, Cambridge (Mathematical Tripos, Pt. 1, and Mechanical Science Tripos). He is an associate-member of the Institutions of Mechanical and Electrical Engineers, and was for some years a demonstrator in mathematics and mechanics at the Imperial College of Science and Technology; previous to this he was one of the founders of the University of Cambridge Engineering Society. For the past fourteen years he has been on the staff of Messrs. Kennedy and Donkin (consulting engineers).

Royal College of Physicians

THE annual Harveian Oration was delivered on October 18 at the Royal College of Physicians by Sir Henry Dale, director of the National Institute for Medical Research, whose subject was "Some Epochs in Medical Research". The substance of the lecture is printed on p. 690 of this issue. The president of the Royal College of Physicians, Lord

Dawson of Penn, afterwards presented the Baly Gold Medal to Dr. F. H. A. Marshall and the Bisset-Hawkins Gold Medal to Sir George Newman, lately Chief Medical Officer of the Ministry of Health. The Baly Medal is awarded annually for distinction achieved in the science of physiology. The Bisset-Hawkins Medal is awarded triennially for "such work in advancing sanitary science or in promoting public health as in the opinion of the College deserves special recognition".

Care of Cripples and Invalids

A JOINT conference of the Invalid Children's Aid Association and the Central Council for the Care of Cripples will be held on November 7–8 at the Drapers' Hall, Throgmorton Street, London, E.C. The opening address will be given by the Minister of Health, Sir Kingsley Wood. The subjects for discussion will be: (1) infectious diseases and their after-effects; immunisation and other preventive measures; (2) the problem of physical handicap in modern life; (3) the after-effects of accidents; rehabilitation. Visits will also be paid to various homes and hospitals. The Conference fee, including the report of the proceedings, is 7*s*. 6*d*., and should be sent to Miss Wynne (Invalid Children's Aid Association) or Miss Nangle (Central Council for the Care of Cripples), Carnegie House, 117 Piccadilly, W.1, from whom further information may be obtained.

Announcements

SIR ALBERT HOWARD, formerly director of the Institute of Plant Industry, Indore, will deliver a lecture entitled "The Manufacture of Humus by the Indore Process", before the Royal Society of Arts on November 13 at 8 p.m.

PROF. HERMANN LEVY will deliver the Sidney Ball lecture in the University of Oxford on October 29 at 5 p.m. He will take as his subject "The New Aspects of Industrial Combination" and the lecture will be given in the Examination Schools, Oxford.

THE Masters Memorial Lectures of the Royal Horticultural Society will be delivered in the lecture room of the Society's new hall in Greycoat Street, Westminster, on November 5 and November 26, at 3.30 p.m., by Sir William Wright Smith, on "Problems connected with the Classification of Plants". Sir Arthur Hill and Sir Daniel Hall have consented to take the chair on these occasions.

PROF. GREGORIO MARAÑÓN, president of the Spanish Academy of Medicine, has recently been elected president of the Hispano-Belgian scientific *entente* committee.

DR. FRITZ LENZ, professor of racial hygiene, University of Berlin, has been awarded the Josef Schneider medal by the medical faculty of the University of Würzburg.

A COMMITTEE has been formed for the erection of a monument at La Ciotat, by the sculptor Paul Gondard of Marseilles, to the brothers Louis and Auguste Lumière, who were the first to exhibit cinematograph films in September 1895.

ON the occasion of the fiftieth anniversary of the first inoculation for rabies on July 20, a bust of Pasteur was unveiled at Havana in a square to which his name had been given, on the initiative of the academy of Sciences of Havana, in conjunction with the Franco-American Committee of Paris.

PROF. WILHELM HABERLING, of the Düsseldorf Academy of Medicine and joint editor of *Mitteilungen zur Geschichte der Medizin, der Naturwissenschaften und der Technik*, has recently been awarded the Sudhoff medal by the German Society of the History of Medicine for his eminent services to the study of the history of medicine.

VICTOR COUSIN in 1848 described at length a MS. of the Abbey of Corbie now in the Municipal Library of Amiens, which contained a number of treatises by Roger Bacon, written while he was teaching in the University of Paris. Under the title "Opera Hactenus Inedita Rogeri Baconi", the Oxford University Press is publishing shortly the last—the thirteenth—of a series of fasciculi, completing the publication of these treatises, which represent the teaching of the Faculty of Arts in the first half of the thirteenth century. The editors are Mr. Robert Steele and the Rev. Père F. M. Delorme.

THE Royal Commission for the Exhibition of 1851 has re-issued its list of whole-time awards for scientific research, other than professorships, offered by public and private bodies in Great Britain and Northern Ireland. The list does not include awards of value less than £150 a year, neither does it include awards offered by universities and scientific societies exclusively for the benefit of their own members. The list, which brings together in convenient form a good deal of useful information, can be obtained from the Secretary of the Commission, 1 Lowther Gardens, Exhibition Road, London, S.W.7, price 6*d*.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A senior assistant to the principal (also to teach mechanical engineering) in the Barrow-in-Furness Technical College—The Director of Education, Town Hall, Barrow-in-Furness (Nov. 4).

An assistant (III) at the Fuel Research Station, East Greenwich and a junior scientific officer at the Chemical Research Laboratory, Teddington—The Establishment Officer, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (Nov. 5).

A senior lecturer in mathematics, and lecturers in mechanical and civil engineering in the Lester School and Institute, Shanghai—The Lester Trust, c/o Messrs. Viney, Price and Goodyear, Empire House, St. Martin's-le-Grand, London, E.C.1 (Nov. 30).

A lecturer in mechanical and civil engineering in the Rotherham College of Technology and Art—The Director of Education, Education Offices, Rotherham.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 686.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

A New Type of Skeletal Movement

FIGS. 1 and 2 reproduce photographs of a model demonstrating a type of skeletal movement which depends upon automatic adjustments of hydrostatic pressure acting upon an elastic body wall. Neither muscular nor nervous mechanism is demanded. These skeletal movements, according to investigations I have made recently, appear to have characterised some of the Cambrian Cystoidea—the earliest and most primitive of all the Echinodermata. The automatic adjustments of body wall and skeleton, it is suggested, were brought about by varying ciliary activity during the rise and fall of the tide.

The model consists of a football bladder, representing the elastic body wall of the animal. Upon this are fixed a double row of oblong thin blocks of rubber representing a portion of the food grooves. Fig. 1 shows the body collapsed and the grooves closed. Air blown into the bladder (Fig. 2) increases the tension on the elastic wall. This causes a pull on fibres attached to the blocks and to the body wall. The blocks, working on the hinge of attachment to the wall, are pulled over and the groove opens.

The place of air as a means of inflation was taken, in the lifetime of the Cystid, by water introduced into the body through the stone canal (here the neck of the bladder). Cilia in the stone canal drove a water current through it and so increased the hydrostatic

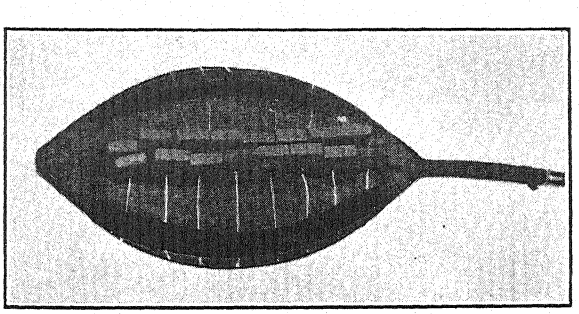


FIG. 1.

pressure. A change of conditions (suggested below) caused the ciliary movement to cease. The elastic tension of the body wall would reverse the current, force water out through the stone canal, with consequent collapse of the form and closure of the groove again.

The suggested mechanism fits in with what is known of the state of preservation of the fossils and the conditions under which the beds containing them were deposited. *Stromatocystis* found in the Lower and Middle Cambrian affords a good example. The Lower Cambrian beds of Newfoundland, in which

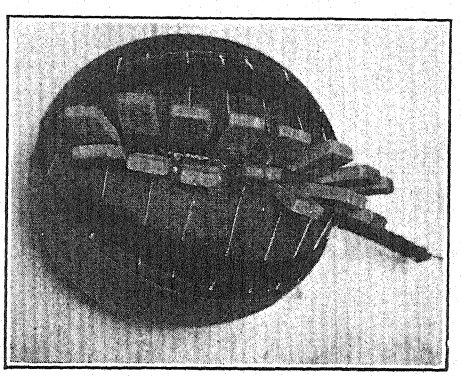

FIG. 2.

forms were discovered by Schuchert, have, as that author has shown, rain pits and all the other evidences of shallow water deposition. All the specimens of *Stromatocystis* both from Newfoundland and Bohemia (Middle Cambrian) which I have examined show the body collapsed and the groove closed. Related forms from deeper waters show an open groove and a firmer skeleton. Comparison of these various forms suggests that the collapsible skeleton and groove of *Stromatocystis* was adapted to intertidal conditions. When the tide came in, freshly aerated water would be brought in, which would stimulate the cilia of the stone canal. The animal would swell, rise above the surface of the sand, the groove would open and the animal begin to feed. After the tide had retreated, the water immediately around the animal's body would become saturated with carbon dioxide, the cilia would cease motion and the animal would collapse into the wet sand which would preserve it from desiccation.

Gray[1] has described a somewhat similar phase in the feeding periods of *Mytilus*, and it is because of this work that I am venturing these views, which do much to clear up many difficult points in Cystid structure.

W. K. SPENCER.

Ipswich.
Sept. 25.

[1] "Ciliary Mechanisms".

Infra-Red Spectrum of Hexadeuterobenzene and the Structure of Benzene

In our letter in NATURE of June 22 (p. 1033), we referred *inter alia* to our measurements of the Raman and infra-red spectra of C_6D_6, but did not give the infra-red results, as a collective publication of this and other spectra was projected. In the August number of the *Journal of Chemical Physics* (p. 446), Barnes and Brattain have now reported some infra-red measurements[1], and we therefore cite our own data for comparison. The principal frequencies (cm.$^{-1}$) are in Table 1, but we omit the record here of the numerous very weak bands, obviously combination tones, which form an almost continuous background to the spectrum. Intensities are roughly indicated by asterisks. Our complete map of the spectrum shows much less background than appears in Barnes and Brattain's graph, but except for this and the deviations in the extreme frequencies, the agreement is good so far as the ranges overlap.

Table 1.

Assignment	C_6H_6	C_6D_6		Assignment
	Literature	B. and B.	This note	
$A2u$	669 **	—	671 *	
	1030 ***	797	817 ****	
$E\bar{u}$	1483 ***	1147	1150 *	$E\bar{u}$
	1620 *	1321	1334 **	
	1780 **	1439	1448 **	
	1950 **	1608	1610 *	
	3073 **	2294	2246 ***	
	4070 *	—	2985 *	

[The unassigned frequencies are assumed to be combination tones.]

In our previous note we showed that an analysis of the Raman frequencies of C_6H_6 and C_6D_6 with the aid of Teller's product theorem[1] permitted an unequivocal assignment of frequencies to the proper vibrations of the plane hexagonally symmetrical model of benzene. We shall now show that a similar statement is true for the infra-red spectrum. The model requires four infra-red fundamentals divisible into two symmetry classes as shown in Fig. 1. Class $A2u$ consists of one hydrogen vibration perpendicular to the ring; class $E\bar{u}$ contains three degenerate vibrations in the plane of the ring. The product theorem gives, for the (H/D)-quotient of the products of frequencies of like symmetry, $\tau(A2u) = 1{\cdot}36$, $\tau(E\bar{u}) = 1{\cdot}93$, and these figures, together with consideration of the intensities of the bands, lead to the assignment indicated in Table 1. The work is incomplete as it is unsatisfactory to have to identify the $A2u$ benzene frequency by exclusion: search for the corresponding C_6D_6 frequency (at ν 491) requires a modification of apparatus, to effect which will take some time.

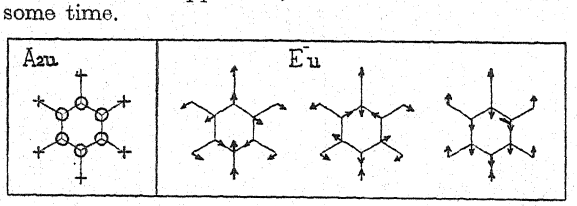

FIG. 1.

The reason which led many physicists to reject the plane hexagonally symmetrical benzene model was the appearance of coincident frequencies in the Raman and infra-red spectra: it was assumed that these were coincidences of principle and not of accident, and the conclusion then followed inescapably by Placzek's theory that no centre of symmetry was present. An immediate result of our work is *that certainly all but one, and very probably all the coincidences, are accidental.* They are shown (with the very generous allowance of 40 wave-numbers) in Table 2. Of the four in C_6H_6, three disappear in C_6D_6. One new one appears, but it was not present in C_6H_6. Only one (marked *) remains common, and apart from the poor agreement of frequencies, it occurs in a region where (as Dr. Placzek pointed out to us) accidental coincidences would be expected owing to the relatively weak coupling of individual C–H stretching vibrations. Thus no good reason remains for rejecting the benzene model which chemists prefer.

Table 2.

C_6H_6		C_6D_6

[1] This will be discussed in a forthcoming publication by G. Placzek and E. Teller.

Diurnal Variation of Cosmic Ray Intensity and Nova Herculis

LAST year several articles were published describing measurements made with the intention of deciding whether the outburst of the Nova Herculis had an influence upon the intensity of cosmic radiation. The results obtained with the coincidence method are not in perfect agreement with each other: Kolhörster[1] has found, and we[2] have not found, a Nova effect. To clear up the question we made, from July 24 until August 5, 1935, measurements with two Geiger-Müller counters of 100 cm. effective length, and 4 cm. diameter, placed 7 cm. apart with their axes parallel to the north-south direction, one above the other. We used the Barnóthy coincidence method which makes it possible to neglect the number of chance coincidences, as they are less than 0·4 per cent of the true ones. The apparatus is provided with an automatic impulse size regulator which kept the sensibility of the counters during the whole time of measurements at a constant value, so that they were not influenced by any changes occurring in the inside temperature or in the supplying voltage. In 349 hours we registered 1·53 million coincidences; their distribution during the three periods of the day is shown in the accompanying table.

We infer from the foregoing that the intensity between 8^h and 16^h is with $1{\cdot}37 \pm 0{\cdot}17$ per cent more than during the other two periods. It may be of

interest to compare our results with those of Kolhörster[1] as the 'field' of our apparatus was similar to his. Kolhörster found for the same hours an intensity surplus of $1{\cdot}76 \pm 0{\cdot}28$ per cent, and interpreted it, with reservation, as an effect of the Nova Herculis. The two results, between the limit of error, can be said to be equal, notwithstanding the fact that

Interval (*M.E.T.*)	Intensity in coincidences per minute	Increase
8^h —16^h	$73{\cdot}78 \pm 0{\cdot}10$	$1{\cdot}37 \pm 0{\cdot}17$ per cent
16^h —24^h	$72{\cdot}78 \pm 0{\cdot}07$	
0^h — 8^h		

in our case, contrary to Kolhörster's, the Nova was not at that time in the 'field' of the apparatus. When the Nova, with an average magnitude of 7 in August, was in the 'field' of the apparatus, we found the intensity $1{\cdot}84 \pm 0{\cdot}13$ per cent less than the average during other hours of the day (Fig. 1).

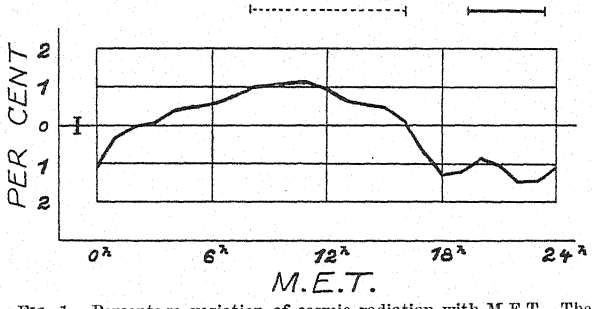

FIG. 1. Percentage variation of cosmic radiation with M.E.T. The points do not represent the original hourly values, but to smooth the curve the fourth means are plotted. Above the graph the time is marked when the Nova passed through the 'field' of our apparatus (July 1935, full line) and through Kolhörster's (Dec. 1934, dotted line).

It seems to be evident that the supposition expressed in an earlier paper[3] is justified, and that the intensity surplus observed by Kolhörster is really nothing else but the daily intensity variation of the cosmic radiation. The real cause of this daily variation, and the reason why it is larger with counter-tube methods than with ionisation chamber methods, cannot yet be satisfactorily explained. We believe, however, that it is not caused by the influence of the sun, but it may be the consequence of the daily variation of the earth's magnetic field intensity, perhaps diminished by the daily variation of the outer temperature. To support this opinion we may say that we have found a correlation coefficient of $-0{\cdot}73$ between hourly means of the cosmic ray intensity and horizontal intensity of the earth's magnetic field[4], and again a coefficient of $-0{\cdot}67$ between daily averages of cosmic ray intensity and outer temperature.

The experimental part of this work was kindly aided by the Hungarian Council for Natural Sciences.

Positive and Negative Ions in the Primary Cosmic Radiation

THE observed east–west asymmetry of the cosmic radiation, and its increase with increasing altitude, has been interpreted in terms of an unbalanced primary radiation which is positively charged. It has been suggested by Compton and Bethe that the radiation probably consists of protons, the rest of the primary radiation consisting of equal numbers of positrons and electrons.

The existence of such an unbalanced positively charged radiation would mean that there would be a preponderance of ions of one sign in interstellar space, and, as has been pointed out by Swann[1], this would give rise to enormous differences of potentials between points separated by distances which are relatively small according to astronomical standards. That such differences of potential do not exist is guaranteed by the observed state of rest of the interstellar ionised calcium clouds as shown by Ross Gunn[2]. These considerations suggest strongly that equal numbers of positive and negative charges exist in the cosmic ray beam.

Swann[1] has shown further that any attempt to consider the emission of a greater number of ions of one sign than the other from stars or other heavenly bodies results in a condition in which the particles become bound to their respective stars as a sort of space charge.

Similarly, it would appear that if the earth had been bombarded, since its formation, by a primary cosmic radiation in which positively charged particles predominated, it would have gradually acquired a high positive potential. Finally it would, therefore, tend to repel those ions which were positively charged, while attracting those whose charges were negative. This would result in a gradual reduction of the earth's potential until equal numbers of positive and negative charges would be incident on the earth. It is apparent, therefore, that equal numbers of positive and negative ions must be falling on the earth at any instant, and it must be concluded that the azimuthal asymmetry must be explained in some different way other than in terms of an unbalanced positive component.

Ross Gunn has suggested that the positive and negative ions travel through space with equal velocities, and that the asymmetry is due to the differences between the penetrating power of the positive and negative ions, and to the different spirals, which, on account of their different rest masses, these particles describe in the earth's magnetic field.

Slow Neutrons

FOR some months past we have been investigating the influence of the temperature of hydrogen containing material on the activity of silver irradiated by slow neutrons. In our experiments we have cooled down paraffin wax to the temperature of liquid air. Under these conditions, no increase of activity of silver has been observed. Moon and

Tillman[1] and also Fermi[2] have shown that the activity of silver increases to about 10–30 per cent when paraffin wax is cooled through the same range of temperatures as in our experiments. The only difference in the experimental conditions consisted in the fact that Tillman and Moon used a layer of cooled paraffin wax 1·7 cm. thick while in our experiments the thickness of this layer was about 10 cm. The discrepancy of the results may be explained by the assumption that the process of slowing down neutrons is accompanied by the absorption. In fact, if cooled paraffin wax absorbs slow neutrons more strongly than the paraffin at room temperature, then the decrease of the number of neutrons reaching the target in the case of a thick layer of cooled paraffin wax may counterbalance the increase of activity of neutrons.

We repeated our experiments under the former conditions and also measured the temperature effect using different thicknesses of paraffin cylinders containing the silver target. Neutrons before reaching these cylinders were strongly retarded. Experiments were made with three cylinders, 0·8 cm., 1 cm. and 1·7 cm. thick respectively. In all three cases, in cooled paraffin wax an increase of activity of silver was observed which diminished with the increase of thickness of paraffin. The increases amounted to 45, 24 and 13 per cent respectively. There was no increase of activity when the thickness of the paraffin layer was about 10 cm. The range of thicknesses investigated was greater than the mean free path of slow neutrons (0·5 cm.). At smaller thicknesses, a decrease of the influence of temperature should be again observed.

Our experiments prove the existence of the temperature effect and demonstrate the absorption of slow neutrons by paraffin. The absorption becomes stronger as the paraffin is cooled, that is, increases with the decrease of velocities of thermal neutrons.

The effective cross-section of neutrons calculated from our data, assuming the absorption by protons in paraffin wax, is about 10^{-24} cm. sq. The existence of the absorption of slow neutrons explains very well the fall of activity with great retarding thicknesses of water in the well-known experiments of Westcott and Bjerge[3]. The results of Lea's[4] experiments also may be explained in the same way, if under the conditions of his experiments the slow neutrons were present in sufficient number.

Suggested Improvements of Morse's Rule

MORSE'S empirical relation[1] between r_e and ω_e for di-atoms has recently formed the subject of considerable discussion. It has been amended by three authors, (*A*) Allen and Longair[2], who introduce the 'reduced mass' μ, (*B*) Badger[3], who utilises the bond-constant k_0 derived from a pendulum-type formula, and (*C*) one of us (C. H. D. C.)[4], who uses the group number n. It is noteworthy that each of these modifications introduces period constants, varying discontinuously between different molecular periods. The amendments assume interest in view of the preliminary theoretical attack on the problem from the point of view of wave-mechanics by Newing[5], whose general conclusion is: "We shall expect a law of the type that has been suggested by Badger and by Clark". Further analysis is promised.

The modifications may be tested in their capacity to reproduce experimental values of r_e (in A.) from known ω_e (in cm.$^{-1}$). The following average ($\pm$ per cent) errors are found for 31 electronic levels of di-atoms of the *KK* period: (*A*) 2·7, (*B*) 1·7, (*C*) 1·2, as against the unmodified formula: 5·3. The *C* formula ($\omega_e r_e^3 \sqrt{n} = 9{\cdot}70 \times 10^{-21}$ cm.^{2}) is therefore the best for this period.

Allen and Longair[2] have stated that the *C* formula will be inapplicable to isotopic molecules, where the r_e's may be closely alike whilst the ω_e's are different. The only case cited in the *KK* period is of $B^{10}O$ and $B^{11}O$, where in the ground states the *C* formula gives errors of $-1{\cdot}1$ and $-0{\cdot}2$ per cent, respectively. Since both these numbers are within the average error ($\pm 1{\cdot}2$ per cent), it would appear that in practice the objection of Allen and Longair has no very serious weight.

Further details of the above and kindred calculations will be published elsewhere.

Viscosity of Air and the Electronic Charge

THE greatest uncertainty in determining the electronic charge e by the oil drop method of Millikan is introduced by the uncertainty in the assumed value of the coefficient of viscosity of air, η. The value adopted by Millikan in 1917

$$\eta_{23^\circ} = (1822{\cdot}6 \pm 1{\cdot}2) \times 10^{-7}$$

is probably too low, and its accuracy overestimated, as is pointed out by Shiba[1].

Considering the fundamental importance of the constant e, I have undertaken a new determination of η, using the rotating cylinder method also employed by Millikan and his co-workers[2,3]: An inner cylinder of electron metal, suspended vertically by a fine phosphor-bronze wire between two guard cylinders of equal diameter is deviated from its equilibrium position through an angle φ by a concentric outer cylinder, rotating with constant velocity, η being calculated from the equation

$$\eta = \frac{I\,(b^2 - a^2).\varphi\, t}{2\, a^2 b^2\, l\, T^2}\,, \quad \text{where}$$

a = the radius of the inner cylinder = 2·81767 cm. at 20°;
b = the radius of the outer cylinder = 3·26628 cm. at 20° or = 3·18328 cm. at 20° (two different cylinders);
l = the length of the inner cylinder = 9·9981 cm. at 20°;
t = the time of revolution of the outer cylinder (20–150 sec.);
T = the period of oscillation of the suspended system (53–128 sec., using different suspensions);

I = the moment of inertia of the suspended system about the line of suspension = 423·22 gm.cm².

The mean value of 51 determinations of η for dry air at temperatures between 18·9° and 20·9° is

$\eta_{20°} = (1820·0 \pm 3·0) \times 10^{-7}$ corresponding to
$\eta_{23°} = (1834·8 \pm 3·0) \times 10^{-7}$.

From this we get

$$e = \left(\frac{1834·8}{1822·6}\right)^{3/2} \times 4·770 \times 10^{-10} = (4·818 \pm 0·012) \times 10^{-10} \text{ E.S.U.},$$

the uncertainty stated being due only to the viscosity, other sources of error not being considered here.

I am, therefore, of the opinion that the discrepancy between the 'oil drop value' of e and the 'X-ray value' can be explained by the error in η.

A more detailed report will be published elsewhere.

Nature of Atmospherics

A SYSTEMATIC study of atmospherics was recently commenced in this laboratory (lat. 11° 25′ N., long. 79° 44′ E.), in view of the importance of the problem in connexion with broadcasting in the tropics. A tuned receiver and a galvanometer of period 1 second were used to record photographically the atmospherics. The results obtained during the months of October and November 1934 (a period during which the atmospheric activity was extremely severe) are of much interest, in connexion with the discrepancies observed between the results for the average duration of atmospherics as recorded by several investigators.

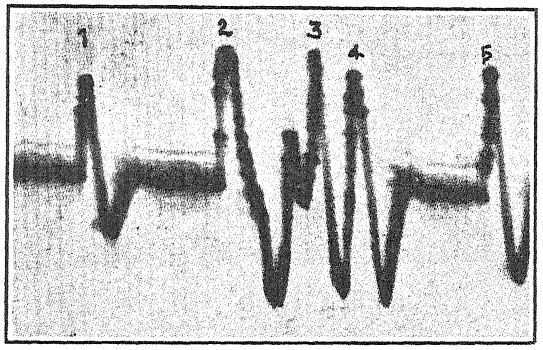

FIG. 1.

In the accompanying illustration (Fig. 1), which is an enlargement of a section of one of the records, certain thickenings are observed along the trace of the galvanometer motion. The number of thickenings or dots, which indicate the number of separate impulses received by the galvanometer in any given interval, can be arranged into groups taking into consideration the rate at which they succeed each other. The curves show that the number of components in groups 1–5 are 4, 12, 8, 10 and 6 respectively. The total duration of each 'atmospheric' is about ½ second. The number of components as indicated by the dots range from 4 to 12. These separate impulses may be due to the separate strokes ranging in number from 1 to 12, constituting a lightning discharge, observed by Schonland and Collens[1].

These individual strokes themselves may be composite, but their nature cannot be recorded or indicated by instruments of periods 0·1–1 sec. The peaks in the records of Munro and Webster[2] may be taken to correspond to the thickenings or the dots in the curves reproduced here.

The dots indicate what may be called the *gross structure* of the atmospheric. In addition to this, there is also evidence of a *fine structure* as revealed by the cathode ray oscillograph records of Watt and Appleton[3]. The durations as observed by them are of the order of milli-seconds, and in many cases the main structure of the atmospheric was supplemented by ripples superposed on the growth and decay slopes. The variations observed during these small intervals may be referred to as the *fine structure* of the components of an atmospheric and are probably due to lightning discharges succeeding each other at intervals of the order of milli-seconds.

The records reproduced here throw light on the discrepancies between the observations of lightning flashes reported by Schonland and Collens, Boys[4] and Halliday[5] on one hand, and Munro and Webster[2] on the other. The former authors record about 10–12 component flashes, whereas the latter have observed up to fifty. Although this difference may be explained according to Munro and Webster[2] on the supposition that a multitude of small flashes occur within the cloud and hence could not be recorded by the camera, there is another explanation which is in agreement with all the observations.

Taking into account the results outlined above, the close agreement between the number of components of an atmospheric as recorded by instruments of relatively long periods (0·1–1 sec.) and the number of lightning flashes recorded by moving lens cameras, and also the complex nature of these components revealed by the work of Watt and Appleton[3], it appears reasonable to suppose that the fifty flashes observed by Munro and Webster are not in the same temporal relation with one another. These can be divided into 10 or 12 groups, each group being separated from the previous one by periods of the order of 0·1 second. Each group may consist of 4 or 5 flashes (occurring either inside the cloud or outside visibly) succeeding each other at intervals of the order of milli-seconds and giving rise to what has been described as the fine structure.

This view is supported by the recent work of Appleton and Chapman[6] on lightning flashes, and is in agreement with the facts revealed by the cathode ray oscillograph and by instruments of much larger periods and with all the observations on lightning flashes recorded so far, as well as with the audible effects produced in a wireless receiver.

Influence of Substituents on Organic Reactions: a Quantitative Relationship

FLÜRSCHEIM[1] made the classical observation that substituent atoms or groups influence the dissociation of carboxylic acids and amines in a manner related to their effect on further substitution in benzene derivatives containing them. This has led, directly or indirectly, to much further work which has established that this type of qualitative relationship applies to the velocities of a wide variety of reactions and to a number of dissociations. The results have been extensively discussed either in terms of Flürscheim's Theory of Valency or in terms of the electronic theory which has incorporated the essential elements of the earlier conception. But these discussions have been concerned with sequences of groups or other qualitative considerations.

In more limited fields such relationships have been found to be quantitative. For example, H. B. Watson and his collaborators[2] have found quantitative relationships between the dipole moments of substituents and their influence from the *m*-position on the velocities of side-chain reactions and also on dissociations. Hammett and Pfluger[3] found a linear relationship between the logarithms of the velocity constants for the reaction of a series of methyl esters with trimethylamine ($R.CO.OMe + NMe_3 \rightarrow R.COO' + NMe_4^+$) on one hand and the logarithms of the dissociation constants of the corresponding carboxylic acids on the other*.

It now appears that this last quantitative relationship is more general. Plotting the logarithms of the dissociation constants of a number of *m*- or *p*-substituted benzoic acids as a reference series and, against them, the logarithms of the velocity constants of a number of side-chain reactions involving substances containing the same *m*- or *p*-substituents, one obtains a series of linear relationships. For example, a straight line is obtained for the alkaline hydrolysis of the various substituted ethyl benzoates, another for the substituted benzamides and others for the solvent hydrolysis of the benzyl chlorides, the acid catalysed hydrolysis of the potassium arylsulphates, the alkaline hydrolysis of the ethyl cinnamates and so on. The logarithms of dissociation constants other than those of the substituted benzoic acids (for example, those of the phenylacetic acids) can be similarly related to the same reference series. The choice of this is quite arbitrary and the relationships of course hold between the different phenomena as well as between them and the reference series. The significance of individual deviations from the straight lines constitutes a separate problem but the deviations do not vitiate the generalisation. This has been applied here to *m*- and *p*-substituted derivatives only, but this does not represent the limit of its applicability although the curves for other types of compound will not generally be co-linear with those for the *m*-*p*-series. Reactions which have required special consideration in terms of electronic theory will, in general, show more complex relationships to those of the linear group.

The applicability and significance of these relationships are discussed in a more detailed communication which is being submitted for publication, but a few general points may be noted here.

The slopes of the curves measure the relative sensitivities of the different phenomena to variations of structure of the type considered, but in interpreting this in detail the slight variation of slope with temperature must be allowed for.

According to the transition state method as used by Evans and Polanyi[4], the velocity constant of a reaction is determined by the equilibrium between the initial and transition states. Log k (velocity) is directly related to the free energy change in this process as log K (equilibrium) is to the total free energy change in dissociation, and the linear relationships described above may be stated as follows in terms of the transition state conception:

The influence of substituents on the free energy change associated with the equilibrium between the initial and transition states, in a reaction considered in respect of velocity, is directly proportional to their influence on the free energy change between the initial and final states in a corresponding acid dissociation.

The interpretation of this in terms of the Arrhenius Equation seems to require a parallelism between the variations in the α and in the E terms.

Spectrum Analysis

IN response to Mr. Twyman's appeal[1], may I express the hope that the term "spectrum analysis" will continue to be used "to denote the analysis of substances by means of their spectra"? The term is a technical one with an established meaning which a student has to learn, and it would introduce a very bad principle to change such terms whenever opportunities arise for them to be misunderstood by those who have not taken the trouble to find out what they mean. We might, for example, be asked to abandon the term 'solar time', because a post-relativity physicist takes it to be the time kept by an observer on the sun; or to give up speaking of 'stellar magnitudes' now that we have learnt to measure stellar volumes.

There are strong historical reasons for confining 'spectrum analysis' to its original meaning. It formerly included every spectroscopic operation, and when other than analytical applications of the instrument became predominant, the more general term 'spectroscopy' was introduced (I think by Schuster), 'spectrum analysis' remaining as a particular and decreasingly important part of the wider subject. In recent years—thanks partly to the better understanding of spectra and their variations which has come from physical theory—there has been, as Mr. Twyman well knows, a remarkable revival of spectrum analysis, while the term-analysis of spectra, on the other hand, has proceeded so far as to be well on the decline. It would therefore not only be inappropriate to rob a rejuvenated subject of its name in favour of a declining one, but it would tend also to hinder reference by modern workers to such ancient classics on spectrum analysis as those of Lockyer, Roscoe, Schellen and others, which record practical experience now largely forgotten and well worth attention by practitioners of a revived art.

I am loth even in appearance to temper these remarks by discussing Mr. Twyman's suggested alternatives, but since he intends temporarily to adopt one of them, I am tempted to do so. Spectroscopic (or spectrographic, which, as Prof. Curtis would probably agree, better describes modern practice) analysis seems preferable to spectrochemical analysis for the following reason. There are three experimental 'hall-marks' of an atom—atomic weight(s), spectrum, chemical properties—and, correspondingly, three methods of analysis, which might be called 'mass-analysis' (by Dr. Aston's instrument, for example), 'spectrographic analysis' and 'chemical analysis'. 'Spectro-chemical analysis' would then indicate an analysis jointly by spectrographic and chemical methods—a not uncommon process, I believe, as in cases where the qualitative analysis is spectrographic, and the quantitative, chemical. It would be a pity to give the name 'spectro-chemical analysis' to a process in which chemical methods are not used.

I repeat my opinion, however, that the proper course to take would be to call spectrum analysis by its own name, and let the penalties of misunderstanding fall on those who are ignorant of physical nomenclature rather than on those who conscientiously learn it.

Antagonistic Effect of Potassium Iodide in Baldness due to Thallium Acetate

THALLIUM salts administered per os or subcutaneously in the body disturb the equilibrium of mineral metabolism[1], bring about lesions in the central and peripheral nervous system[2], cause disturbances in the endocrine system[3], have a deleterious effect upon the heart[4], bring about disturbances in the digestive tract[5] and kidneys[6] and have unfavourable effects upon development and growth of animals[7]. Further, the daily administration of thallium for a longer period of time brings about in animals, especially in young ones, under-development of skin[8], atrophy of hair follicles, hyperplasy and hypertrophy of sebaceous glands[9], degenerative changes of hair[10], and alopecy[11].

In our experiments we used six groups of rats. The first three groups received daily, per os, 3, 4 and 6 mgm. of thallium acetate per 1,000 gm. weight, respectively. The other three groups received the same quantity of thallium acetate per os, and in addition, each animal received daily, subcutaneously, 0·75 c.c. of a two per cent solution of potassium iodide. After 12–16 days, the rats which received only thallium acetate started losing their hair and at the end of the experiment (35 days) all the surviving animals had lost most of their hair, and some of them, especially those which were getting higher doses, became entirely bald. On the other hand, the rats which received thallium acetate per os and potassium iodide subcutaneously retained completely their hair coating. Also, the mortality in the groups with potassium iodide was smaller, which indicates that potassium iodide reduces the toxicity of thallium acetate.

The object of further experiments being carried out by us is to determine whether other salts of iodine, such as sodium iodide, lithium iodide, calcium iodide and magnesium iodide, prevent partly or entirely the loss of hair caused by thallium and reduce the deleterious action of thallium upon organisms.

A 'Dope' for Embedding Wax

ATTENTION has been directed by Higgs[1] to the effect of small quantities of petroleum ceresins in causing paraffin wax to cool in a microcrystalline state. It seemed possible that this effect might be valuable in the technique of cutting paraffin sections. During this summer we have been using, for the routine sectioning of early amphibian embryos, a paraffin wax mixture, without addition of beeswax but containing 0·5 per cent of petroleum ceresin which was supplied by Messrs. Shell-Mex and B. P., Ltd. The results have been all that could be desired, the wax cooling with a very fine texture even when the embedding dish was allowed to cool in the air without being immersed in water. It is necessary to use a mixture having a melting point, before the addition of ceresin, slightly lower than is normally appropriate. The electrostatic properties of the wax appear to be unaltered. The 'dope' may be particularly useful in embedding large objects, in which ordinary wax tends to cool too slowly in the centre of the block.

Corophium curvispinum, G. O. Sars, var. *devium*, Wundsch, in England

WHILE passing through Tewkesbury on June 30, 1935 I found thirteen specimens of *Corophium curvispinum* var. *devium*, inhabiting tubes made upon submerged plants in shallow water near the left bank of the River Avon about two hundred yards below King John's Bridge. From the associated flora and fauna I believe this water to be permanently fresh, though I took no measurements of salinity. Prof. Wundsch has kindly confirmed my identification.

The species *C. curvispinum* was described and figured by Sars[1] from the Caspian Sea in 1895. In 1912, Wundsch[2] described *C. devium* as a new species from fresh water in the Müggelsee, near Berlin. Later

Behning[3], having seen specimens from other localities, reduced *C. devium* to a freshwater variety of *C. curvispinum*, an alteration to which Wundsch[4] agreed. In both these papers Wundsch gives figures adequate for identification.

Wundsch[5] gave a map of the known distribution of the variety in 1919, and Wolski[6] in 1930 gave a list of localities without adding much to the range known in 1919. It inhabits the lower and middle courses of rivers running into the Caspian Sea (Volga and its tributaries), the Black Sea (Danube, Dnieper and Don) and North Sea and Baltic (Niemen to Elbe): also two lakes in the Caucasus near the Caspian Sea. It has not yet been found west of the Elbe.

Wundsch[4] stated that in 1915 this variety was spreading rapidly in Germany, moving through canals and rivers from east to west and usually downstream.

It is unlikely to have been introduced from its European localities with living fish, since no example of such importation of stock to the Severn or Avon is known to the secretaries of the Bristol Naturalists, the Fishmongers Company or the Severn Fishery Board. But ships from the Baltic and the Black Sea reach Bristol Docks, and might carry specimens in the fouling on the hull. Nothing is known of the resistance of this variety to sea-water travel.

It would be of interest to ascertain the present distribution of this variety in England, and in Europe west of the Elbe. It might thus be made clear how it reached Tewkesbury, and how rapidly it is able to spread in our rivers.

Its usual localities are the lowland fresh-water reaches of sluggish rivers. It lives in tubes made of mud upon weed or piles. Specimens of *Corophium* found burrowing in mud are almost certain to be the common species *C. volutator*.

I shall be pleased to identify any specimens of *Corophium* sent me. The general aspect of species of this genus is clearly shown in the drawings of Sars[7].

Points from Foregoing Letters

A MODEL consisting of a football bladder and rubber blocks, to illustrate how early forms of sea-urchins (of Cambrian age) may have behaved under tidal conditions, has been constructed by Dr. W. K. Spencer. The model opens and closes automatically under the influence of changes in hydrostatic pressure, acting upon the elastic body-wall.

To elucidate the 'shape' of the benzene molecule, the principal lines of the infra-red spectrum of benzene containing heavy hydrogen, C_6D_6, are compared with those of ordinary benzene, C_6H_6, by a group of investigators from University College, London. The authors conclude that, as in the case of the Raman spectra, the apparently coincident frequencies are accidental, and consequently there is no longer any reason for physicists to reject the regular hexagon model accepted by chemists for the benzene molecule.

An increase in the intensity of cosmic rays was observed by Kolhörster during the outburst of Nova Herculis, between 8 h. and 16 h., when that star was in the 'field' of his apparatus, and he therefore suggested that cosmic rays originate in novæ. Drs. J. Barnóthy and M. Forró now find an increase in the intensity of cosmic rays between 8 h. and 16 h. as a normal diurnal variation, which they tentatively ascribe to changes in the earth's magnetic field and in the outer temperature.

It has been suggested that there are more positive than negative particles in cosmic 'rays'. H. J. Walke enumerates several objections to this view. He prefers Ross Gunn's explanation of the east-west asymmetry of the cosmic rays, namely, that it is due to differences in the penetrating power of positive and negative particles and in the spiral paths which they describe under the influence of the earth's magnetic field.

Moon and Tillman have found that the radio-activity induced in silver by neutrons slowed down by passage through a thin layer of paraffin wax is increased when the wax is cooled by liquid air. Prof. P. Lukirsky and T. Zarewa, using a thicker layer of paraffin, failed to observe this temperature effect; but now, using thinner layers, they confirm it. With thicker layers, the increase in the activity of the neutrons, caused by lowering the temperature, is apparently counterbalanced by loss due to absorption.

C. H. Douglas Clark and J. L. Stoves claim that the modification to Morse's relation between the equilibrium internuclear distance r_e and the vibration frequency ω_e of 'di-atoms', suggested by one of them (C. H. D. C.), gives better approximations to the actual experimental values than either Allen and Longair or Badger's suggestions.

The charge of an electron calculated from X-ray wave-lengths determinations comes to $4{\cdot}80 \times 10^{-10}$ E.S.U., whilst the usually accepted value obtained from the rate of fall of electrified droplets is $4{\cdot}77 \times 10^{-10}$ E.S.U. Dr. Gunnar Kellström has re-determined the viscosity of dry air and finds a value different from that used by Millikan when he calculated the electronic charge by the falling droplets method. The recalculated electronic charge agrees with that deduced from X-ray wave-length determinations.

Records of atmospherics obtained with a galvanometer (of period 1 second) by N. S. Subba Rao indicate that lightning flashes have, in addition to the 'fine' structure revealed by the cathode ray oscillograph, also a 'gross' structure, due to the fact that the flashes occur in groups of 4–12. The duration of such a group is about $\frac{1}{2}$ sec. Each member of the group may be due to 1–12 separate strokes as observed by Schonland and Collens, and these strokes may themselves be composite. This complex nature of the electric discharge may account for the divergence in the observations of lightning flashes reported by various investigators.

Experiments upon rats, carried out by O. V. Hykeš and F. A. Diakov, indicate that potassium iodide reduces the toxicity of thallium acetate, and in particular prevents the loss of hair caused by thallium poisoning.

Research Items

Flint-mining at Grime's Graves, Norfolk

SINCE 1921 Mr. A. Leslie Armstrong has been engaged in exploring Grime's Graves, the famous East Anglian prehistoric flint mining site. A report on the results of the excavations, which are still in progress, was presented by Mr. Armstrong to Section H (Anthropology) at the Norwich meeting of the British Association on September 6. A gradual evolution in mining methods, in the tools used, and in the form of the mine shafts has now been demonstrated. Three well-defined phases are recognisable: (1) The primitive phase, in which the shafts are devoid of galleries, and picks made from the long bones of animals are used exclusively; (2) the intermediate phase, in which the shafts are in the form of open workings, but are devoid of galleries, and deer antler picks appear for the first time, increasing until they exceed the earlier bone form in number; (3) the late phase, of deep shafts with mined galleries, in which celts with pointed butts appear and the picks are of deer antler. Trenching and trial excavation have defined the area in which mining was carried on and have also revealed the circumstances which caused the mining to be confined within these limits. There is evidence of occupation in bronze-iron age times, but all mining had ceased before this date.

Wild Cat in Scotland

A SUMMARY of the position of the Scottish wild cat at the present time has recently been given by G. Dent (*J. Soc. Pres. Fauna of the Empire*, N.S., Pt. 26, **48**, Sept. 1935). In the years just before the War, the species was confined to a limited area in the counties of Ross and Sutherland. The author thinks it unlikely that any survived to the south of Loch Ness. The advent of the War gave the wild cat a chance of multiplying and spreading. By 1919 it had crossed Loch Ness and become well-established in Inverness-shire and parts of Perthshire; individuals were trapped on estates where none had been seen for fifty years or more. They have penetrated into parts of Stirlingshire; and have reached so far south as Callander, Gleneagles and Loch Lomond-side; westwards they have appeared in eastern Argyllshire. The author is of opinion that the wild cat will maintain its hold in many parts of the newly-won territory.

South African Fishes

AMONG many interesting papers published in the *Records of the Albany Museum* (**4**, Part 2, 1935), Mr. J. L. B. Smith describes some new and little-known fishes from South Africa. A large number of specimens of *Myliobatis cervus* n.sp., 'Pyl-Stert' (Krysna) were obtained. This species is very like *M. aquila*, and the females can only be distinguished by the shape of the snout. The female of *M. cervus* appears to seek the shallow banks of the river, where the young are born. One large specimen after capture gave birth to seven young. These 'rays' are evidently preyed upon by various species of 'sharks'. On one occasion a large *aquila* was observed to take refuge in a few inches of water on the edge of a bank in the river, violently beating the water with its pectorals in order to scare off a large 'shark' which lay close in, with part of its body out of the water. The *aquila* was secured, an adult female, and three young were born after capture. On another occasion, a large female *aquila* was caught on a line and, being too large for the boat, was tied to the bows. Several young were born, and drifted down with the tide, one being swallowed by a large 'shark'. In the summer months at Krysna a cold current, of temperature 50° F., frequently sets inshore, numbing innumerable fish. It is shown that an *Iso natalensis* (Atherinidæ) does not seem to be inconvenienced by this cold water, and the presence of *Chaetodon marleyi*, a species of a genus usually found farther north, in the river, is a sure sign that the onset is imminent; when the cold water actually enters the river dead specimens are usually thrown ashore.

Digestive Tract of *Emyda vittata*

A. NARAYANA RAO (*J. Mysore Univ.*, **7**, 1933–34) describes the digestive tract of the mud-turtle, *Emyda vittata*, which lives near the water-margins of the tanks and burrows in soft earth. The œsophagus is differentiated into two regions, an anterior lined with stratified epithelium and with few mucous cells, and a posterior with numerous mucous cells. In the stomach are two kinds of glands—tubular glands lined by cubical cells and mucous glands, but there are no oxyntic cells. There is no pyloric sphincter between the stomach and intestine. The pre-rectal region of the intestine possesses a longitudinal typhlosole which reduces the cavity of the intestine to a semilunar slit. The author states that the turtle feeds on animal dung and other matter poor in nutriment, and the typhlosole presents a larger surface for absorption and also retards the rate of passage of the food. He directs attention to the appearance of the typhlosole in this turtle as an archaic character. Spaces lined by cells, and with a rich supply of blood-capillaries, occur between the circular and longitudinal layers of muscle in the wall of the rectum. "The animals when kept under water are seen to take in large quantities of water and the presence of blood vessels in the vicinity of these spaces . . . points to the existence of intestinal respiration."

Maturity of Fruit

THE term 'maturity' as applied to fruit denotes, for practical purposes, a condition where maximum value as an article of human food has been attained. Physical and chemical changes which accompany the process of maturation have been studied by Dr. J. C. Hinton, of Long Ashton Research Station, Bristol, who publishes a series of three papers on this subject in the Station's annual report for 1934 (pp. 29–108). The first paper, which is really the fourth of an extensive series, traces the changes in catalase and oxidase content. It shows that the former increases for a time, whilst the latter decreases steadily during storage. An ingenious hardness tester has been used to obtain the results reported in the second paper. Apples soften steadily during storage; but the rate depends upon the time of picking. The rate of loss in weight during storage is

also correlated with time of picking, and it is further suggested that apples growing in grass-covered orchards, or on trees which have been bark-ringed, or where fruit thinning has been prosecuted, ripen slower than in orchards with clean cultivation. Changes in nitrogen, acid-hydrolysable material, total sugars, and sucrose in relation to reducing sugars, are discussed in the third paper.

A Disease of Young Walnut Trees

DR. JOYCE B. HAMOND, of the East Malling Research Station, Kent, has published the results of her work on "The Morphology, Physiology and Mode of Parasitism of a species of *Chalaropsis* infecting Nursery Walnut Trees" (*J. Pom. and Hort. Sci.*, **18**, 81, June 1935). Walnuts are propagated at East Malling by grafting scions upon seedlings of *Juglans nigra*. The method is usually successful, but in the spring of 1930, a large number of grafts failed, as a result of attack by a fungus. This parasite is now known to be *Chalaropsis thielavioides*. It produces macrospores and endospores, appears under four strains on different hosts, attacks lupins and causes a rot upon carrots. Infected grafts show discoloration of the scion, with a mass of black, sooty spores along the plane of union. Weak solutions of formalin are used to paint the cut made upon the stock during grafting, and to spray the walls and shelves of the propagating house. These precautions control the disease effectively in practice.

Origin of Potash-Rich Rocks

RUTH DOGGETT TERZAGHI has recently discussed the origin of 'orthoclase-rich rocks', which term she applies to those of which the composition lies in the orthoclase field of the felspar equilibrium diagram (*Amer. J. Sci.*, April 1935). Reference is made to Vogt's suggestion that when water is present in relatively large quantities in the liquid phase, potash and plagioclase felspar may be in equilibrium with a liquid having a higher ratio of *Or* to (*Ab*+*An*) than if the melt is 'dry'. It is also shown that high pressure may be expected to displace equilibrium in the same sense. More important, however, is the recognition that some of the potash-rich rocks which appear to be of igneous origin may have been produced by metasomatic processes, such as the felspathisation of quartzite. It is also pointed out that, during hydrothermal alteration and weathering of igneous rocks, the potash/soda ratio may undergo a considerable increase which is not always accompanied by easily diagnosed changes in the appearance of the rock. Attention has been more recently directed to relevant work by Fenner on the action of hot waters on the Yellowstone lavas (*Amer. J. Sci.*, Aug. 1935). In this investigation, Fenner conclusively proved that obsidian is greatly enriched in potash by a process of adularisation accompanied by devitrification of the ground-mass (*Trans. Amer. Geophys. Union*, Fifteenth Annual Meeting, 1934, pp. 241–243).

Light of the Night Sky

LORD RAYLEIGH and H. Spencer Jones have analysed measurements made on the light of the night sky at Terling in Essex, Canberra and the Cape over a period of more than eight years (*Proc. Roy. Soc.*, A, **151**, 22, August, 1935). The measurements were made in spectral regions in the blue, in the red, and around the green auroral line. Periodic yearly and half-yearly variations were detected at all the stations, the former apparently depending on latitude in a complicated way. The auroral component shows a long-period variation common to the three stations and clearly connected with the sunspot cycle, while the slow variation in the blue and red regions is much less clearly defined. There is rather feeble evidence of a connexion between the irregular variation of the auroral green light and magnetic disturbance. The absolute intensities of the light at the three stations are comparable, but seem to be higher at Terling and lowest at the Cape.

A New Discharge Tube Vapour Lamp

AT the opening meeting of the Illuminating Engineering Society, on October 8, a novel 'super high pressure' mercury vapour lamp was shown. It was developed in the physics laboratories attached to the Philips' factories, the aim in view being to increase the light-giving power of ordinary h.p. mercury vapour lamps. It consists of a quartz tube with thick walls having an internal diameter of $\frac{3}{64}$ in. and an external diameter of $\frac{1}{4}$ in. The electrode at each end of the tube consists of a simple tungsten wire sealed into the quartz; an interposed layer of a special grade of glass being necessary as the coefficients of thermal expansion for tungsten and quartz are so different that they prevent hermetical sealing. To facilitate the emission of electrons, the electrode tips are coated with a deposit of alkaline earth oxides and project from a small drop of mercury which condenses at each end. The lamp is placed inside a jacket containing running water. It needs no special stabilising apparatus as it is fed through an auto-transformer. The spectrum of the light produced is continuous, but the mercury lines stand out and are broadened. The luminous efficiency is about 50 lumens (4 candles) per watt. One of the most important advantages of the lamp is that the luminous part is less than $\frac{3}{64}$ in. and so the brightness is very high—about one quarter of the brightness of the sun. This makes it valuable when a concentrated beam is necessary as, for example, in cinema projectors, lighthouses and in all kinds of projectors. The source is almost a point and absorbs 1,500 watts per inch length of discharge. As a source of ultra-violet light, it seems likely to be of use in medical applications, and the absence of thermal inertia is of great value in cinematograph projection.

Chemistry of Antiquities

J. R. PARTINGTON (*Chemistry and Industry*, **54**, 884; 1935) has summarised the results of chemical interest arising from the recent excavations in the Bucheum, near Armant, carried out by direction of Sir Robert Mond and published as the forty-first memoir of the Egypt Exploration Society by Mond and Oliver H. Myers. The article deals with the process of mummification which was probably used for the sacred bulls, with a description of two curious instruments employed in the process. It also gives a table of analyses of metal objects found on the site, some of the bronzes containing large amounts of lead. Some additional information on textiles is also given. The remains probably date from about 357 B.C. to about A.D. 295, and the results are particularly interesting to the historian of chemistry, since it was in this period that the beginnings of chemistry are supposed to have had their origin in Egypt. The article directs attention to this aspect.

Man and the Universe*

THE WIDER PROBLEMS OF ASTRONOMY

WHEN the theory of relativity was enlarged so as to cover the facts of astronomy, it became necessary to discard the symmetry between space and time which had hitherto prevailed. Thus time regained a real objective existence, although only on the astronomical scale, and with reference to astronomical phenomena. De Sitter attacked the problem from the other end, and reached the same conclusion. He began by postulating symmetry between space and time, and found that for such symmetry to prevail, the universe must be totally devoid of matter. As the actual universe certainly contains matter, it is clear that de Sitter's postulate must be discarded. In other words, space and time must be intrinsically different in their natures—which is of course precisely what the plain man has believed throughout. This gives us every justification for reverting to our old intuitional belief that past, present and future have real objective meaning, and are not mere hallucinations of our individual minds—in brief, we are free to believe that time is real.

In 1926 de Broglie and Schrödinger introduced the new quantum mechanics. The universe was no longer regarded as a collection of particles, but as a collection of waves—particles no longer appeared in the picture at all. The new picture was not a mere amplification of the old—it ignored the old altogether and started anew on a clean canvas; and the new picture was strikingly successful. From this time on, there was not one single picture of Nature of which both waves and particles were constituents; there were two distinct pictures—one containing only waves, and the other containing only particles.

This and other occurrences have gradually made it clear that the material world consists of something which cannot adequately be described as either waves or particles. It is obviously something which cannot be grasped in its entirety by the human imagination, so that the best we can do is to represent it by pictures, each of which contains a partial, but only a partial, approximation to the whole truth. The mathematician has a specification of the constituent parts of the universe which he believes to be fairly complete. Looked at with care, and it will be seen that the universe consists of particles. Now let the mathematician go through the process which he will describe technically as "changing the variables", and look again. It is a specification of precisely the same universe, but it is present in an altered form, and we see now that it represents a series of waves—the particles have disappeared from the picture.

In general, it is true that we live in a mathematical universe, so that if we want the ultimate truth about this universe, or anything in it, we must go to the mathematician. When we regard the material world as made up of particles, we can obtain agreement with observation only by supposing that the motion of these particles is not fully determinate. The motion of any one single particle does not appear to obey any definite determinate laws, although the motion of a great number of particles is found to obey a quite definite statistical law. Indeed, it is from such statistical laws that the apparent uniformity of Nature proceeds. If, then, we confine ourselves to the particle-picture, we inevitably conclude that Nature in the last resort is not strictly determinate—somewhere there is an opening for new features to appear in the universe, although we do not know from whence they proceed or what causes them.

The wave picture, on the other hand, seems at first sight to tell us that Nature is strictly deterministic. The waves spread like ripples on the surface of water. Now such ripples follow a predetermined course, and from a knowledge of the ripples at any one instant, the mathematician can calculate what the motion of these ripples will be, and so what the configuration of the surface will be at any future instant. The determinism which we find in the waves is not one of motions or configurations of parts of the universe, but merely of our knowledge of these motions and configurations. If we acquire new knowledge of the universe, as for example by performing an experiment on any small part of the universe, this accession of new knowledge changes the total of our knowledge, and so changes the waves which represent this small part of the universe in the wave-picture.

The meaning of the determinism which is implied in the wave-picture now becomes clear. If we gain no new knowledge, our old knowledge remains our whole stock-in-trade for estimating the future course of events, whereas if we gain new knowledge we can estimate the future with greater precision. Thus the wave-picture does not proclaim that the course of Nature follows undeviating and unchangeable laws, but merely that our knowledge of Nature can only be altered by the acquisition of new knowledge. This is the only kind of determinism that we find in the wave-picture, and we see that it tells us nothing at all as to the actual course of Nature.

Both the particle- and the wave-pictures have been made to agree completely with Nature, but the particle-picture only by introducing a great number of restrictions and laws which appear to have only an artificial and even arbitrary basis. The wave-picture agrees with Nature almost automatically without any such artificialities; it is simple and complete in itself, and seems to fit the observed phenomena exactly. Thus we seem justified in regarding the wave-picture as our best representation of ultimate reality, while the particle-picture is only an artificial model, which is useful as a concession to the limitations of the human mind. Waves do not depict the electron, but what we know about the electron. They depict something inside our minds, not something outside. Thus the wave-mechanics give no countenance to the supposition that the electron has an objective existence independently of our knowledge of it—rather it suggests that our knowledge of the universe (or a bit of it) is fundamental, and that the electron is a clumsy creation of our own, resulting from our efforts to locate our universe in space and time. The apparent indeterminacy of the particle-picture becomes meaningless,

* Substance of the Sir Halley Stewart Trust Lecture delivered by Sir James Jeans, F.R.S., at the Memorial Hall, Farringdon Street, London, on October 22.

while the determinacy of the wave-picture has nothing to do with the course of objective Nature.

In brief, science is unable to give any decision—even to produce any evidence—in the long debated question of determinacy. We still may or may not be automata; science cannot prove that we are not, but it gives us no reason for thinking that we are.

Reviewing the history of science as a whole, we see scientific knowledge continually compelling man to lower his estimate of his own importance and position in the universe, until the beginning of the present century. It is perhaps still too early to form any judgment of more recent events, both because they are still so near at hand, and also because there is not yet complete agreement about them amongst scientific workers themselves. But it seems that the tide has begun to turn. In the light of recent knowledge gained from the theory of relativity and quanta, we seem entitled to take a more hopeful view of our position than Victorian science had been willing to concede. Man had formed a view of his position, influenced largely, no doubt, by his vanity and self-importance, but based on the whole of his practical everyday experience of life: he believed he was free to choose between the higher and the lower, between good and evil, between progress and decadence. Victorian science seemed to challenge all these beliefs: to it there seemed to be neither higher nor lower, neither progress nor decadence. The machine merely ran on automatically, and of its own inertia, as if it had been set to run on the first morning of the Creation and would continue so to run, following out its predestined course, to the end of time. We now begin to suspect that this challenge was a mistaken one. The universe is more like the untutored man's common-sense view of it than had seemed possible a generation ago, and we may not have been mistaken in thinking that humanity is free to choose between good and evil, to choose its direction of development and, within limits, to carve out its own future.

Epochs in Medical Research*

HARVEY'S "De Motu Cordis", though based on knowledge long available, as well as on new observation and experiment, found a world unready to accept its great discovery. Character and courage, in alliance with scientific genius, were needed to break through the mists of hallowed error, and to walk boldly into the light of a new epoch.

More important to medical progress than a discovery of such profound and lasting significance was the creation and display for all time of the method of discovery by experiment. In preaching this new principle of advancing knowledge, Harvey moved with the great spirits of his age. Though Harvey was a physician, most of his directly clinical observations seem to have been lost, with the political destruction of his papers during the Civil War. As an experimental biologist, he had contact with some who were to be among the original fellows of the Royal Society, founded five years after Harvey's death, with the aims which Harvey had so insistently advocated. After Harvey's discovery of the circulation, a solution of the next main problem of nascent physiology, the meaning of respiration, was dependent on progress in the new science of chemistry, and involved the discovery of oxygen. This, which was nearly attained by Boyle and his associates in the early years of the Royal Society, became obscured by the phlogistic theory for more than a century, until Lavoisier finally revealed the nature of combustion and respiration, and made possible the reunion of physiology with medicine.

To-day, as in the past, there are new domains opening to physiology which can only be explored by men trained in other disciplines than that of medicine. The result, as in the past, will be ultimately to infuse new life into medicine itself, provided that clinical medicine, in the hands of those whose first aim is to increase knowledge, remains and increasingly becomes an experimental science, as Harvey saw it.

Harvey's other and much longer book, "De Generatione Animalium", not only gives us further evidence of his genius as an observer, but also shows into what vague and fruitless speculations even he could wander, when he forsook his own precepts. In his suggestions, however, as to the meaning of supposed cases of spontaneous generation, he appears to have been far ahead of the prevailing ideas of his time.

It is fitting, in commemorating Harvey as the founder of experimental medicine, to consider certain recent phases of active development in that field.

We date the epoch of medical bacteriology from Pasteur and Koch. It left the causation of many important infections unsolved, and we witness to-day what may be the beginning of a new epoch as important for medicine, in the study of infective viruses beyond the range of detection by ordinary microscopy. Influenza is a recent addition to the list. In the dimensions of some of the most finely particulate viruses we seem to approach a borderland between organisation and colloidal dispersion, and perhaps to encounter a new order of vital phenomena.

The most general characteristic of the present epoch in medical research seems to be the growing dominance of chemical ideas and the success of chemical methods. Many hormones and vitamins, of which but a few years ago the very existence was merely a matter of indirect presumption, have been isolated, chemically identified, and even prepared by artificial synthesis. In immunology, embryology and in the physiology of muscular activity and nervous transmission, the methods and conceptions of exact chemistry are finding a rapidly growing application.

All aspects of medicine—diagnosis, treatment, prevention—are profoundly affected by this development. Are we at the beginning of a great new epoch, of a major advance? Or will physiology and biochemistry early find themselves halted and baffled by a complexity which their methods have revealed? We must be content to go forward in the faith of William Harvey, that "Nature herself is to be addressed; the paths she shows us are to be boldly trodden; for thus, and whilst we consult our proper senses, from lower advancing to higher levels, shall we penetrate at length into the heart of her mystery".

* Substance of the Harveian Oration delivered by Sir Henry Dale, C.B.E., F.R.S., before the Royal College of Physicians on October 18.

Nutrition and Catering

THE report of the Nutrition Committee of the British Medical Association, issued in November 1933, and reviewed in NATURE of January 13, 1934 (133, 53), was designed to determine the minimum weekly expenditure on foodstuffs which would maintain in health and working capacity families of various sizes. A supplementary pamphlet is now issued to be of practical help to the housewife*.

The translation of food schedules into appetising meals was first undertaken by teachers of domestic science who attended the summer school of the Board of Education in London in 1934. The B.M.A. specimen diet No. 16 for a man, wife and three children was the chosen model. Improvements were introduced to make more variety without increasing cost. Menus for the principal meals for three weeks have been planned, and the dishes for each day illustrated in colour. Shopping lists of food quantities and recipes are included, and a table of food values. Owing to local and seasonal variations in prices the total cost is not here estimated, but in the original report the average price was assessed at 5*s*. 5½*d*. per man weekly.

The American Medical Association has for many years concerned itself with teaching the public the principles of hygiene, including proper nutrition. We welcome this evidence that the B.M.A. is awakening to the fact that the fight against malnutrition is at the present time the most important problem in preventive medicine. The manner in which the information is presented in this pamphlet is simple and attractive, and beyond criticism, but the nature of the diet recommended is not so faultless. The principles of the newer knowledge of nutrition have not been applied; there is close adherence to the obsolete standards of the pre-vitamin era with the focus too exclusively on calories and an unnecessarily high total protein ratio. The supply of vitamins and minerals is sub-optimal. The proportion of fat, and therefore of fat-soluble vitamins, is admittedly low.

The sum allowed weekly for fresh fruits and vegetables has been cut down from the 2*s*. 6*d*. allowed in the first report to a scanty 1*s*. 11*d*. for a family of five; the amount of vitamin C is further reduced by pickling some vegetables. No advisory note is inserted that *wholemeal* flour and bread provide for the same money better value than white cereal products in respect to quality of protein, vitamins and mineral salts. If, as is probable, white bread, etc., are used, 60 per cent of the total calories are derived from over-refined foodstuffs lacking vitamins and deficient in mineral salts, and leading inevitably to malnutrition. Where money is short the best slogan is that advocated by Prof. Sherman, 'no calories without vitamins'.

The health value of this diet would be greatly improved by an increase of butter or milk and of green vegetables; by a decrease in sugar; by replacing white cereals, sago, etc., by whole cereals; by decreasing the total cereals and increasing the amount of potatoes. As a basis for planning healthy and inexpensive diets Dr. Mikkel Hindhede's book on health by correct and simple diet, reviewed in NATURE of June 22, 1935 (135, 1016), might with advantage be consulted.

* "Family Meals and Catering." Pp. 27 + 3 plates. (London: British Medical Association, 1935.) 6*d*.

Universities and Business Training

AT the discussion on "The Universities and Business" arranged by the Department of Industrial Co-operation, Section F (Economic Science and Statistics), at the British Association meeting at Norwich on September 5, Dr. J. A. Bowie discussed the need for more intimate co-operation and suggested that British university schools of business were supplying a negligible percentage of the men required for administrative positions in industry and commerce. Dr. Bowie estimated that over the whole of British industry there were about one million suitable appointments for the business graduate. If the British schools of business were supplying the administrative grade of employee at the same rate as the replenishment in the closed professions, they should be producing about 40,000 graduates annually instead of the actual 200–300.

It was not suggested that such graduates were entitled at once to a responsible managerial post, but the importance of finding them a progressive post leading to such positions was stressed. Dr. Bowie urged that the main reason for the low output of graduates from the university schools of business in Great Britain lay in lack of close working association between education and business. He considered that academic ideas had influenced too largely the commercial courses in Great Britain, which should be modelled on those of the medical school rather than the arts course.

University education for business should aim at giving the student a knowledge of the facts and principles relating to the nature and functions of business and our economic institutions; the capacity for disciplined thinking, for logical analysis and reasoning with respect to the problem of business and of modern society; facility in oral and written expression; an acquaintance with the operating tools of management such as general and cost accounting; and personal effectiveness including the capacity for job analysis and co-operation. At present Dr. Bowie considered that insufficient attention was paid to the development of facility in oral and written expression, the operating tools of management, and the development of personal effectiveness. The employer attached primary importance to the possession of desirable traits of personality and

character and to the capacity to co-operate effectively with others in the attainment of common ends, and the university should supplement its scholarship test by stimulating the development of such personal qualities, by inculcating right attitudes towards life and work and emphasising the need for disciplined habits of thought.

Dr. Bowie suggested further that the determination of the ideal curriculum for business training awaited the result of an inquiry which had yet to be made, and that industry in its turn should pay more attention to the training of its recruits and to definite schemes of promotion. The tendency for the universities to become too exclusively recruiting and training grounds for the professions was socially undesirable and economically disastrous.

Dr. Bowie's address provoked a lively discussion, particularly with reference to the curriculum of the university schools of business, and the place of economics in such training. Opinion was strongly expressed that it would be disastrous to confuse the academic study of economics and research in this field with preparation for a business career, and that the two were best kept distinct. Dr. Bowie himself suggested that economics was probably best studied at a final stage of a business training rather than as a basic subject for such training.

The whole value of such courses of training for business was challenged in the discussion and opinion was expressed that, provided the recruit entered business with a trained mind, it did not greatly matter whether that training had been given in a science or in an arts course. Business could always utilise the trained mind. Against this view it was pointed out that the transfer of knowledge and training was not high and such a policy might involve serious waste. A plea was made that something in the nature of refresher courses in business subjects on the lines of the post-graduate courses now arranged annually in a number of technical colleges and universities might be useful, and it is possible that the university schools of business may render some of their most important services to industry in the provision of such courses for those actually engaged in responsible administrative work. Somewhat surprisingly, despite Dr. Bowie's remarks, no reference was made to the tendency for administrative work itself to be regarded as a profession or at least to be influenced increasingly by professional ideals.

Educational Topics and Events

ABERDEEN.—Dr. William Hamilton Fyfe, principal and vice-chancellor, Queen's University, Kingston, Ontario since 1930, has been appointed principal of the University of Aberdeen, in succession to the Very Rev. Sir George Adam Smith, whose resignation will take effect on October 31. Dr. Hamilton Fyfe was, in 1919–30, headmaster of Christ's Hospital.

CAMBRIDGE.—D. H. Valentine, of St. John's College, has been appointed to the Frank Smart University studentship in botany.

At Girton College the Founders' Memorial Lecture will be given by Sir Frank Dyson on Saturday, October 26, at the College. The title of the lecture will be "The Discovery of the Solar System".

At Christ's College the following members of the College have been elected honorary fellows: Prof. Arthur Hutchinson, Master of Pembroke College and emeritus professor of mineralogy; Prof. J. Graham Kerr, M.P., emeritus professor of zoology, University of Glasgow, formerly fellow of the College; Prof. G. H. F. Nuttall, emeritus professor of biology and director of the Molteno Institute of Parasitology, formerly fellow of the College; Dr. A. W. Rogers, lately director of the Geological Survey, Union of South Africa, president of the Royal Society of South Africa.

With the withdrawal of the opposition, the offer of £10,000 to the University by Sir John Siddeley for the promotion of aeronautical research has been accepted by the Regent House. The *non-placet* was withdrawn in a fly-sheet in which the signatories explained that their attitude, when the offer was originally made in July, was that the money should be used only for work of a fundamental and non-military character. Prof. Melvill Jones, it is stated, gave in effect the assurance required, for he said that all work done in his department was published in the ordinary way and that Sir John's gift was unconditional. The supporters of the *non-placet* add that, since the promotion of human knowledge and welfare is the special responsibility of the University, "it should not even appear to be associated with work that has the destruction of civilization as its object". The suggestion is also made that the "University should define its position on the whole question of military, commercial and secret research, and that an early opportunity should be given for a discussion of this question".

OXFORD.—Dr. J. G. Priestley has been appointed deputy for the professor of physiology during the vacancy caused by Sir Charles Sherrington's retirement.

Dr. F. G. Hobson has been appointed Litchfield lecturer in medicine and Mr. H. A. B. Whitelocke Litchfield lecturer in surgery.

Dr. J. Marschak, All Souls' College, formerly of the Universities of Heidelberg and Kiel, has been appointed director of the new Institute of Statistics for five years from October 1.

Dr. L. H. D. Buxton has been appointed reader in physical anthropology for seven years from October 1.

FEDERAL aid for schools in the poorer regions of the United States is being urgently demanded on the ground that the existing system of school finance, based on the small school district, has, in many localities, completely broken down. "Our American school system is fighting for its very existence," said a member of Congress recently when introducing a Bill for establishing such a measure of federal participation in public instruction as would ensure a reasonable standard of education for every boy and girl in the Union. In support of his contention, he cited statistics showing that salaries of teachers amounting to more than 57 million dollars are in arrears, and that outstanding salary warrants non-cashable or subject to heavy discounts amount to nearly 50 millions. The resources available in the different States for the maintenance of schools differ very widely, and the years of industrial depression have strengthened the hands of the politicians who hold that the Federal Government should now take more responsibility for education.

Science News a Century Ago

Maury's Work on Navigation

MATTHEW FONTAINE MAURY (1806–73), the distinguished American meteorologist and hydrographer, wrote the first of his books, his work on "Navigation", while serving as master of the United States sloop *Falmouth*, to which he was appointed in 1831. It was during his voyage from New York to the Pacific that he conceived the idea of his celebrated wind and current charts.

Writing to his brother from Philadelphia about his book, Maury said, "Without wishing to excite your expectations, I will let you into the secret of my plans, which I wish you to preserve as a secret, in order that if I should not succeed in what I undertake, my friends and family may not feel the effects of disappointment. You must bear in mind that this is the first nautical work of science that has ever come from the pen of a naval officer; and upon its merits I intend to base a claim for promotion. Such a case has no precedent. Therefore you must look upon it as an experiment, in which I may or may not be successful. If I succeed, I shall be put over the heads of many who are now above me. . . . I wish to impress upon you that I am not sanguine of success, but am resolved to try every honourable means to accomplish the object, and to take the most favourable time for it. The book, I hope, will be out in about six weeks. . . ."

When Maury's book appeared, it was favourably noticed by the highest nautical authorities in Great Britain, and it became the textbook of the United States Navy.

Lindsay's Electric Lighting Experiments

ON October 30, 1835, a letter from James Bowman Lindsay on his electric light appeared in the *Dundee Advertiser*. "As a notice of my electric light," the letter ran, "has been extensively circulated, some persons may be anxious to know its present state, and my views respecting it. The apparatus that I have at present is merely a small model. It has already cost a great deal of labour, and will yet cost a good deal more before my room is sufficiently lighted. . . . I am writing this letter by means of it at 6 in. or 8 in. distant; and, at the present moment, can read a book at the distance of 1½ feet. From the same apparatus I can get two or three lights, each of which is fit for reading with. . . . Brilliant illumination will be obtained by a light incapable of combustion; and, on its introduction to spinning mills, conflagrations there will be unheard of. . . . Exposed to the open air, it will blaze with undiminished lustre amidst tempests of wind and rain; and, being capable of surpassing all lights in splendour, it will be used in lighthouses and for telegraphs. The present generation may yet have it burning in their houses and enlightening their streets. Nor are these predictions the offshoots of an exuberant fancy or disordered imagination. They are the anticipated results of laborious research and of countless experiments. Electricity, moreover, is destined for mightier feats than even universal illumination."

On January 15, 1836, Lindsay gave a lecture in the Thistle Hall, Dundee, on his experiments, and publicly exhibited his electric light.

Societies and Academies

PARIS

Academy of Sciences, September 16 (*C.R.*, 201, 510–512). JEAN LEGRAND: New data for the study of periodicity. Study of the periodic relations between rainfall, mean tide-level, and sunspots.

September 23 (*C.R.*, 201, 513–532). CHARLES RICHET: Notice on the work of the late Léon Fredericq. I. VINOGRADOV: The summations of H. Weyl. VLADIMIR KOSTITZIN: The intoxication of a medium by the catabolic products of a population. LÉOPOLD ESCANDE: Remarks on the perturbations maintained in resonance at the lower end of a water main. MAURICE ROBERT and JULES FOGLIA: The measurement of the flux in coils with iron core, and the realisation of a direct reading Henrymeter for any self-induction. GABRIEL VALENSI: The oxidisability of nickel. The results of experiments on the rate of oxidation of nickel foil are given graphically. The data can be expressed by the Arrhenius formula, $n = 11{\cdot}46^{-11210/T}\sqrt{t}$, in which n is the grams of oxygen fixed per cm.^{2}, T is the absolute temperature and t the time in hours. JEAN TIMMERMANS and GUSTAVE POPPE: The mutual solubility of heavy water and organic liquids. JACQUES DE LAPPARENT: The place of montmorillonite in the category of phyllitous silicates. RENÉ SOUÈGES: The embryogeny of the Verbenaceæ. The first terms of the development of the albumen in *Verbena officinalis*. JEAN MARIE LE GOFF: The differential biological reaction of cobalt compounds and of certain complex cobalt compounds (cobalt-ammines).

CAPE TOWN

Royal Society of South Africa, August 21. J. A. PRINGLE: Observations on certain wood-boring Coleoptera occurring in South Africa. C. VAN RIET LOWE: The Smithfield 'N' culture. Attention is directed to the wide range of artefacts employed by those who practised this variation of the main Smithfield culture. Sites and assemblages of artefacts are described, and it is suggested that this peculiar variation of the parent culture owes its characteristics to a changed environment—necessitating a change in employments and in consequence a new variety of tools—brought about by a migration and probably influenced by other cultures. A description is given of the diffusion of the culture, and the five marked, yet intimately related, variations of the common parent are linked up and explained.

SYDNEY

Royal Society of New South Wales, September 4. F. P. DWYER and J. W. HOGARTH: Oxidation of cobalt amalgam. Cobalt amalgam prepared by electrolysis is shown to have the composition, Co_2Hg_3. Although rapidly oxidised in the air to a mixture of Co and CoO, in the ratio of 3 : 1, it is perfectly stable in dry air, oxygen-free water, and inert gases. Cobalt suboxide, Co_4O, is suggested as an intermediate in the oxidation of the amalgam. The oxidation product readily reduces nitrites and nitrates in neutral solution to ammonia, and, on being freed from oxide by ammonium salts, gives a pyrophoric form of cobalt.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Saturday, October 26

BRITISH PSYCHOLOGICAL SOCIETY, at 3.—(in the Physiology Theatre, University College, Gower Street, W.C.1).—Dr. B. P. Wiesner: "Psychophysiological Studies of Animal Drives".

F. B. Kirkman: "Field Experiments with Birds".

Sunday, October 27

BRITISH MUSEUM (NATURAL HISTORY), at 3 and 4.30.—Miss M. H. Smith: "Parasites".*

Monday, October 28

BRITISH MUSEUM (NATURAL HISTORY), at 11.30.—E. Barclay: "North American Deer".*

UNIVERSITY OF LEEDS, at 5.15.—Prof. S. Sugden: "Artificial Radioactivities".*

UNIVERSITY COLLEGE, LONDON, at 6.30.—Dr. R. R. Marett: "Magic and Religion".*

Tuesday, October 29

ROYAL INSTITUTION, at 5.15.—Sir James Jeans: "Physical Astronomy" (succeeding lectures on November 5, 12 and 19).

WARBURG INSTITUTE, at 5.30.—Anatole de Monzie: "L'Idée Encyclopédique".*

HALLEY STEWART TRUST LECTURE, at 6.—(in the Memorial Hall, Farringdon Street, E.C.).—Prof. E. V. Appleton.*

Thursday, October 31

UNIVERSITY OF LONDON, at 5.—(at the Royal Society of Medicine, 1 Wimpole Street, W.1).—Sir St. Clair Thomson: "The Defences of the Air Passages" (Semon Lecture).*

HALLEY STEWART TRUST LECTURE, at 6.—(in the Memorial Hall, Farringdon Street, E.C.).—Prof. E. Mellanby.*

Friday, November 1

CHADWICK PUBLIC LECTURE, at 5.30.—(at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, W.1).—Dr. C. Killick Millard: "The Vaccination Question To-day".*

UNIVERSITY OF DURHAM PHILOSOPHICAL SOCIETY, at 6.30.—(at Armstrong College, Newcastle-upon-Tyne). Dr. E. L. Hirst: "The Chemical Nature of Vitamins".*

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS, at 7.—Eng.-Comr. C. J. Hawkes: "Heavy-Oil Engines for Ship Propulsion" (Andrew Laing Lecture).

ROYAL INSTITUTION, at 9.—Clifford C. Paterson: "The Liberation of the Electron: its Industrial Consequences".

Scientific Methods and the Advance of Social Conditions

Life and Leisure in London*

THE last volume of the great "New Survey of London Life and Labour" has now appeared. We noticed the first in NATURE of March 21, 1931, p. 430, and have now to add a word of hearty congratulation to Sir Hubert Llewellyn Smith and his staff on having brought their ship into port. It is a fine piece of work, and both the thoroughness of the execution and the general hopefulness of the conclusions will bring happiness to Mr. Charles Booth in the shades and to all his friends who remember the devotion and the insight with which he initiated and carried through the earlier survey forty years ago. That was a scientific expression of the humanitarian spirit, parallel to, and no doubt largely inspired by, the same ideas which had just founded Toynbee Hall, as the practical expression. Both movements have been followed by hundreds of successors in all parts of the world. It is one of the most interesting features of this new survey that its director, Sir Hubert Llewellyn Smith, had a hand in both the earlier experiments in the 'eighties and 'nineties of the last century.

The present survey was undertaken in 1928 by the London School of Economics, and has been supported by the funds of more research foundations and charities' trustees than we can find the space to enumerate. The money has been well spent, for the results, established with the utmost impartiality and marshalled with skill, are a permanent record of the contemporary state of the largest aggregation of human beings on the earth. It is formally limited to an area lying somewhere between the County of London and the Greater London which comes under the Metropolitan Police. It deals with a population of about five and a half million, though its results would be in the main applicable to a much larger area and are broadly typical of most great urban centres at the present time. Hence its high scientific importance as a sociological document.

This ninth, and last, volume of the work, dealing with life and leisure, will probably attract more general attention than any of the others, because of the multitudes involved in all the main activities which it describes. We all go at some time to the 'pictures'; the wireless is as popular a pastime with the well-to-do as with the poor. Indeed it might be said that this levelling up, or levelling down, of the whole population by the aid of mechanism, is the most outstanding feature of the whole report. When one sees the sort of personal activities by which the more vigorous individuals strive to win spiritually above the mass, it is clear how very similar are the tastes and efforts of all classes in the nation. They all take to a garden when they can. They all, in similar proportions, run their rowing, football and cricket clubs. They all, though in a still smaller proportion, endeavour to follow some form of serious study. Everyone therefore will feel that there is something to his own account in what purports to be an inquiry into the conditions of the 'working classes'.

One ought perhaps to make two partial exceptions to this wide conclusion, both mainly connected with difference of income. Drunkenness has markedly gone out, we are told; and gambling has very much increased. The former is certainly true equally of all classes. What the report relates, in this matter, of the working classes in

* The New Survey of London Life and Labour. Vol. 9: Life and Leisure. Pp. xiv+446. (London: P. S. King and Son, Ltd., 1935.) 17s. 6d. net.

the last forty years, is only the social extension downwards of what had been going on among the well-to-do for more than a century. It may encourage us to hope for a similar diffusion of better tastes and wider interests in other matters. Cycling is another example of the same sort. But the vast increase in gambling seems exceptionally to belong to the wage-earning class. The chapter on this subject gives interesting and intimate accounts of how the betting business is actually carried on, and the fun which often arises from it in the family circle. As throughout the volume, the tendency is to look rather on the harmless and cheerful side, and, on the whole, it is both morally right and scientifically sound to do so. Clearly the life of the multitudes in the great urban centres is not generally degraded or unhappy, and the standard has risen very greatly in the period under review, both in comfort and in the pleasurable and harmless use of the increased leisure and material means which have accrued. This is the main point, and the surveyors take care to stress it, perhaps with a slight tendency to over-satisfaction. Those reading what they say will often reflect on the other side of the picture and sigh for the what might be. This rage for gambling, and the huge crowds which frequent the football matches, are one of the chief points which suggest such thought. The State is obviously justified in taking what measures it wisely can, to restrain the passion, when, as in the case of greyhound racing, a large new industry arises, consuming millions of money, in which practically the sole motive is stimulating gambling, already appealed to on many other fields.

The other most noticeable difference in the use of leisure, due mainly to difference in education and income, is the overwhelming preference for the cinema over the living drama or music. There are roughly three times as many cinemas as theatres and music-halls together, in the County of London, and no doubt the proportionate attendance in the former as compared with the latter would be greater still. When we consider that this includes the principal theatre area in the whole country, and that a majority of the towns in England have no theatre at all, worthy of the name, one must ask whether the State is justified in staying its hand, as it does, and treating all forms of amusement as equal before the law.

While holding firmly to the main principle that it is far better for people to do things for themselves than have them done by a State, however benevolent, one must recognise at the same time the duty, sometimes the necessity, for the authorities, who, after all, represent the deliberately constituted will of all, to intervene on occasions, to prevent a gross evil, to assist a better cause, to give, in fact, guidance rather than command. We do it rather too much in the schools, where the effort to inculcate a love and knowledge of the national classics—Shakespeare and Scott and others—has often the opposite effect to that desired. But, after the school-age, we go to the other extreme and tend to remain nationally indifferent, leaving to private enterprise the foundation of a national theatre, the encouragement of music, the employment of leisure. The more enterprising and intelligent of the public librarians endeavour to educate the taste of their readers; but such a policy of selection, though it seems to be having some effect in the quality of the books read, is by no means popular, and is actually disputed in theory by some quite serious people. "We pay the rates", it is said. "Why should we not have what we prefer to read?"

But the better opinion will surely be that there is room and full justification for further action, carefully devised and experimental, but not to be set aside on the vague denunciation of State socialism. The British Broadcasting Corporation, though tending rather to popularity in its programmes, is on the whole a successful move in the right direction. Where its resources have been used to maintain good concerts, open in the ordinary way to the public, it has been proved that there is a large and still unsatisfied taste for good music. The field here, with free and open-air concerts, is almost limitless.

On another—still wider—point, one is inclined to go beyond the terms of reference of these surveyors of London. One cannot look with complacency on the vast extensions of urban residence in connexion with our great cities, and especially with London; however much we may rejoice that the conditions of life are as much improved as the surveyors demonstrate. While tens of thousands of fresh residents are poured out each week to the suburbs of London, especially to the south, it has taken fifteen years of persistent and difficult contrivance to build up a community of a little more than ten thousand at a garden city (Welwyn) which is really in the country and offers advantages of a healthy, pleasant and natural life far beyond those of the best ordered urban area. Is there no scope here for further

strong and deliberate State efforts to mitigate the urbanisation of England and have a larger proportion of the people in country surroundings? It is a commonplace that the country is the natural home for childhood, and yet every decade for more than a century we have allowed a smaller proportion of our children to enjoy it.

Scientifically then, this "Survey" is invaluable, as confirming, by minute inquiry into a large typical area, the general conclusion which M. René Sand submitted to us recently in his magnificent "Economie humaine par la médecine sociale". That is, that a marked and demonstrable improvement has taken place in social conditions generally throughout the world, as a result of applying scientific methods deliberately to social needs. Both René Sand and this "Survey" fully admit the black spots, and the "Survey" studies these (for example, sex-delinquency and crime, in this volume) with the utmost care and sympathetic insight. But both authorities agree as to the main conclusion, and also that we may reasonably expect a further advance by pursuing the same methods, if possible with greater vigour.

Morally and politically, the "Survey" suggests some other large questions at which we have hinted above. Mechanism and the increase of leisure have given us a far larger population of tolerably well-off and semi-educated people, living in great and growing masses in urban areas in all industrialised countries. The supreme problem now faces us of how so to act that the highest human ideal may be opened to all, according to their capacity. This involves doubtless much well-directed collective effort. Still more it points to the cultivation by all sensitive and capable persons of a divine discontent with a falling off from the best, either in themselves or in those who share the common civilisation which we have inherited from the past. To keep this alive, and make it operative in ever-widening circles, must appear the highest moral and intellectual obligation on all with means of action; and every man has a certain field of action in himself. F. S. M.

Flow as a Property of Matter

First Report on Viscosity and Plasticity

Prepared by the Committee for the Study of Viscosity of the Academy of Sciences at Amsterdam. (Verhandelingen der Koninklijke Akademie van Wetenschappen te Amsterdam, Afdeeling Natuurkunde, (Sectie 1), Deel 15, No. 3.) Pp. viii+256. (Amsterdam: N. V. Noord-Hollandsche Uitgevers-Maatschappij, 1935.) 10 guilders.

THE problem of flow has diverse aspects. We have the flow of gases, the mechanism of which is tolerably well understood, so that in the case of certain simple gases the viscosity, and its variations with temperature, can be calculated. We have liquids, of which the viscosity is precisely defined by a constant and can be accurately measured: the mechanism of the flow is imperfectly understood, but it is certainly quite different from that of gases, as the contrasting effect of temperature in the two cases abundantly demonstrates. When we come to the movement of solids under stress, where even the definition of constants which shall describe the experimental facts presents grave difficulty, we are confronted with a still more complex problem. In general, a finite stress is needed to produce permanent set, but this appears to be about the only common factor of the behaviour of such different classes of bodies as polycrystalline metals, metal single crystals, doughs, clays, glasses, gels, rubber and living protoplasm, and in certain cases matters are made still worse by the phenomenon known as thixotropy, a term applied to the marked decrease of viscosity caused by shaking or similarly disturbing certain colloidal substances. The evident complexity of the problems long kept investigators from this field, but, within the last twenty-five years or so, serious attempts have been made to systematise our knowledge. Imperfect as our general theories still are, the time is definitely ripe for a collected and critical account of the present state of the subject, and all workers in the wide field will welcome the enterprise and applaud the courage of our Amsterdam colleagues in issuing the "Report" under notice.

The report deals with the measurement and physical significance of the different types of slow flow observed for liquids and solids, and excludes vortex motion. It opens with a general review of the field; a brief summary of the properties of the simple liquid is followed by an elegant description of Maxwell's theory of a relaxation time, which covers both true liquids and substances which definitely creep on loading and unloading,

although it is doubtful if any such substance quantitatively obeys Maxwell's original law. We then have what is probably the most complete and systematic description yet given of the various models that can be constructed of springs and damping cylinders (elastic and viscous elements), with the object of imitating the behaviour of true solids, reference being made to the electrical analogy in which resistance and condensers are the elements. With such models a rough general demonstration of the experimental effects can be given, but, once more, quantitative description leaves something to be desired. The work of the present writer has been so generously handled in the "Report" that he hesitates to refer to his suggestion, not here considered, that a rotating element, giving a "saturation value", if it may be so called, of the part of the flow which it contributes, may be usefully invoked in this field, and probably has a physical meaning.

A very full description is then given of Prandtl's model for explaining elastic hysteresis. This model is certainly elegant, but seems very artificial, demanding, as it does, regular rows of molecules slipping in the direction of the row, independent of the direction of the forces. It may have a physical significance when applied to single crystals, but it is difficult to see how it can represent very closely the state of affairs in, say, Chatterton compound, with which Braunebek has carried out experiments to verify it. Nevertheless, in view of the fact that it has not hitherto received much attention, at any rate in Great Britain, nobody will grudge the space devoted to it. The chapter, written by J. M. Burgers, closes with a sympathetic account of the present writer's attempt to formulate a theory of liquid viscosity. The whole chapter is clearly and concisely written, and the part dealing with the elements of the subject is a model of exposition.

The second chapter, likewise by J. M. Burgers, discusses the flow of some actual solids, and gives provisional definitions applying to the different stages, this classification being extended later, when the behaviour of polycrystalline metals is discussed. It is not, of course, possible to characterise plasticity by a single constant, but here and elsewhere in the report, notably in the chapter by C. J. van Nieuwenburg on the technical aspect of the subject, the use of what are called D-τ diagrams is emphasised, D being the steady rate of flow under stress τ. Such diagrams are naturally only possible when a constant rate is attained, and by their nature tell us nothing of the early hardening during flow under constant stress. The technical part of the report provides the physicist with a very interesting view of the significant work that is being done on industrial products, and should be of help to the technologists, especially as regards notation and expression of results.

H. G. Bungenberg de Jong deals with the flow of colloids, and provides much practical information. He restricts himself, however, almost entirely to dilute lyophilic colloids, which do not show the troublesome peculiarities of the more concentrated preparations. He also attempts to apply Einstein's theory to lyophilic sols, naturally without any striking success, since the conditions contemplated by Einstein are certainly not fulfilled, even approximately, in this case*.

One of the most valuable parts of the report is that in which W. G. and J. M. Burgers collaborate on the plastic properties of metals. They discuss the behaviour of polycrystalline metals under various loads in a more systematic way than is usual in textbooks, considering briefly the experimental facts of hardening under stress and age-hardening, and pointing out the significance, limited enough, of the experiments on the damping of vibrations of metal wires. Incidentally, they state that polycrystalline lead shows permanent deformation under even the smallest load, which is contradicted by the recent experiments of Bruce Chalmers. They then pass on to the plastic deformation of single crystals, round which so much discussion took place at the International Conference on Physics last year. Here, as with ordinary metals, one of the main problems is that of hardening under stress. The views of Smekal, Becker, Taylor, Orowan and others are discussed, but the statement that "it is not always an easy matter to arrive at a precise picture of the mechanism that the various authors have in view" will arouse a sympathetic echo in many breasts. The ingenious but somewhat artificial assemblages of flaws or dislocations as well as faults of other kinds can often be made to explain particular observations, but it cannot be said that the assumptions are always well established, or that a simple and convincing scheme has yet been produced. Even the appearance and distribution of the slip bands themselves are still imperfectly understood. The authors put forward a picture which is a combination of the Becker–Orowan theory, constructed to explain the dependence of the rate of flow on stress and temperature, and the Taylor theory, constructed to explain hardening. This is attractively presented and seems promising.

In the last chapter, H. J. Jordan deals with a subject unfamiliar to most physicists and chemists, namely, the mechanical properties of muscles. He distinguishes between the mainly elastic type of muscle, of which striated muscle is the general

* Dr. Eirich, of Vienna, recently described to me some very striking work, shortly to be published, which constitutes a great advance in this direction.

example, and the mainly plastic type, exemplified by the smooth muscles of hollow organs, strips of the cutis of holothurians being, apparently, the most convenient example for experiment. Various models, made up of elastic and plastic elements, effectively in series or in parallel, are discussed. Needless to say, the phenomena are extremely complicated and their interpretation difficult.

Although the book is written in English by Dutchmen, there are very few foreign turns of phrase, and none such as to render the sense in doubt. The general style is particularly lucid. The work, especially the part of it due to J. M. Burgers, alone and in collaboration with W. G. Burgers, is informed by a clear and critical spirit, and can without exaggeration be said to be indispensable to all workers in the subject. In the preface the prospect is held out of a second report, dealing in particular with problems of flow in colloidal structures. We trust that the reception of the report now before us will encourage the Committee to set about this task forthwith, and then to provide an index which will include the present volume. E. N. DA C. A.

Botanical Nomenclature

International Rules of Botanical Nomenclature, adopted by the International Botanical Congresses of Vienna, 1905, and Brussels, 1910, revised by the International Botanical Congress of Cambridge, 1930. Compiled by the Editorial Committee for Nomenclature from the Report of the Subsection of Nomenclature prepared by John Briquet. (Règles internationales de la Nomenclature botanique) (Internationale Regeln der botanischen Nomenclatur.) Dritte Ausgabe. Pp. xi+152. (Jena : Gustav Fischer, 1935.) 7 gold marks.

BOTANISTS who are interested in precision in nomenclature have awaited with some impatience the publication of the new edition of the "International Rules of Botanical Nomenclature" which would embody the results of the deliberations of the International Botanical Congress at Cambridge in 1930.

Precise botanical nomenclature originated in the "Lois de la Nomenclature botanique" drawn up by Alphonse de Candolle and adopted after discussion by the Paris Congress of 1867. Though the 'laws' were widely accepted, differences of interpretation and usage rendered increasingly imperative in the course of years a revision and amendment. Such revision was the chief work of the Vienna Congress in 1905, completed at Brussels in 1910. In the meantime, however, an influential section of American botanists had promulgated a "Code of Rules" which, while based on the de Candollean laws, differed in some essential points from the Vienna rules, and this Code had been adopted by a proportion of American workers. The aim of the Cambridge Congress was if possible to unify procedure, and to clarify and, where necessary, amend the rules in the light of experience gained in the intervening twenty-five years. The discussions were marked by a general desire to come to agreement on the various points at issue.

The burden of the work of preparation for the discussions at the Congresses and the editing of the results, since 1900, had fallen on Dr. John Briquet of Geneva, nominated *rapporteur général*, but his regrettable death in 1931 occurred before he had drafted the new edition of the rules. It devolved, therefore, on the remaining members of the editorial committee (Prof. H. Harms, Prof. Al. Mangin, and Dr. A. B. Rendle) to prepare the revised edition from Dr. Briquet's report of the discussions published in the general report of the Congress (1931) and from notes taken at the Congress by the recorders. As certain 'proposals' presented to the Congress by a group of British botanists were the basis of many of the alterations introduced into the rules, the first draft was prepared by the English member of the Committee in consultation with some of the British botanists. This formed the basis of discussion by the Committee, and is followed in the volume by the French and German translations by Prof. Hochreutiner (*vice* Prof. Mangin) and Prof. Harms respectively. Prof. Harms, as *vice-rapporteur*, acted as general editor.

Generally speaking, the alterations in the new edition are framed to render the rules more precise and easier of application. One result has been a sub-division of some of the rules, which now number twenty-four as compared with fifty-eight in the earlier edition. Greater precision is given to the conservation of names of certain genera to avoid disadvantageous changes by strict application of laws of priority ; the nomenclature of hybrids and half-breeds is rendered more explicit ; also the rules governing valid and effective publication, and those determining the selection of names when groups are divided, remodelled, transferred or united. An important addition is the insistence on nomenclature types as determining the names of taxonomic groups—

the type is that element of a group with which the name of the group is permanently associated. An alteration, the effect of which had not been adequately appreciated, was introduced into the rule dealing with homonyms. A saving clause was an addition to the final rule by which modifications accepted at one Congress remain on trial until the next, at which they will receive sanction unless undesirable consequences show need for further amendment or rejection. A supplement provides a list of proposed additions to the names of genera to be conserved and also lists of standard species typifying such genera.

The volume as published by Messrs. Fischer conforms in size and character of text with the two previous editions emanating respectively from the Vienna and Brussels Congresses of 1905 and 1910.

Epidemics and Crowd-Diseases

Epidemics and Crowd-Diseases: an Introduction to the Study of Epidemiology. By Prof. Major Greenwood. Pp. 409. (London: Williams and Norgate, Ltd., 1935.) 21*s*. net.

THE value of a scientific treatise lies not so much in the information which it imparts as in the inspiration which the reader derives from it to inquire further into the matters with which it deals. We have read "introductions to the study of" subjects, which left the impression that nothing remained worth inquiring into, and even destroyed all desire for such exercises. In his work on "Epidemics and Crowd-Diseases"—which will become a classic—Prof. Greenwood, far from doing this, introduces his readers to the study of epidemiology in such charming fashion that, as the tale unfolds, each chapter seems to end on a note of lively interrogation.

The volume is divided into two parts, general principles and methods, and special illustrations. The first four chapters, dealing with the history of epidemiology from Hippocrates and Galen through Graunt and Farr to the present time, and two chapters in the second part dealing with Jenner and Creighton, provide continuous entertainment as well as instruction, this being due to their literary style rather than their subject matter. The chapters on experimental epidemiology, artificial immunisation, nutrition, and the influence of occupation and of psychological factors upon crowd-diseases, are masterly essays, all too brief, on our knowledge of these matters. The special illustrations chosen are the typhoid group, cholera, typhus, measles, diphtheria, scarlet fever, smallpox, plague, epidemic diseases of the central nervous system, influenza, venereal diseases, tuberculosis and cancer. It is impossible to do more than enumerate these chapters, each of exceptional interest and critical value. A wealth of satire, not overdone and certainly salutary in its effects, pervades these chapters, as indeed that whole work, and adds pleasure to the re[illegible]and should [illegible]

The greatest living exponent of the application of the statistical method to epidemiology might be pardoned if he exaggerated the services which statistical research has rendered to the progress of medical knowledge; but Prof. Greenwood might rather be accused of under-estimating the achievements of statistical epidemiology and of undue pessimism as to the possibilities of such research in the future. In the opening chapter, for example, he tells us that so far as epidemics of catarrhal disease, common colds and pneumonias are concerned, we know scarcely any more than Hippocrates did about their general etiology. Again, in his account of "The Age of Pasteur and Galton", he asks whether the new statistical calculus has yet solved any of the age-old problems of secular variation, change of type or method of spread of infectious diseases; and having answered this with an emphatic negative, passes to the depressing conclusions that "we do not know enough of the elements of the subject to be fit to ask questions" of Dame Nature, and "at present, with all our knowledge of detail, we shall not reach the general 'laws' which Sydenham failed to discover".

It is difficult for us in this analytical period to 'see the wood for trees' sometimes. Our knowledge of the individual factors which combine to make the general etiology of crowd-diseases so complex becomes every year more complete, and when analysis has proceeded far enough—a tedious process seeming to our foreshortened vision to lead us farther from the solution of the general problems rather than nearer—the time will come when to some fresh mind with a genius for synthesis the fitting together of the carefully sorted pieces will appear amazingly simple. Perhaps the first steps in this synthesis are not so far away as Prof. Greenwood thinks; without doubt they will be brought nearer by the inspirations derived from the publication of such a work as this.

Discoveries: Old and New

Unrolling the Map: the Story of Exploration
By Leonard Outhwaite. Pp. xiv+351. (London: Constable and Co., Ltd., 1935.) 16*s*. net.

THE appearance of yet another history of exploration may be taken to indicate a popular demand for such works and, if one may judge from some of his remarks, Mr. Outhwaite writes primarily for the general reader. He disarms criticism by confessing that he does not "pretend to refinement in historical scholarship" and generously acknowledges help both from distinguished scholars and from previously published works. As he frankly admits, there is little originality in his book. Its facts are in the main accurate, but he seems to have found the limitations of space very hampering, and many parts of the later chapters are little more than notes on explorers grouped under a general heading, such as "Others in Africa". This limitation has other curious results, such as the inclusion of all the work of the Duke of the Abruzzi in the chapter on the Arctic, and the relegation of "mountain explorers" to an appendix to that chapter. These are perhaps mere faults of arrangement.

There are, however, two serious criticisms to make of this work. Its title suggests a progressive development of the knowledge of the world which is not in accordance with facts. Until quite recent times, there were too many 'secret' discoveries and too many national or personal jealousies to make it possible for anyone to say how much of the world was known at any one time. Mr. Outhwaite may know now—but explorers, like, say, Columbus on his fourth voyage, would have given a good deal to see a map of the world as it was known to their contemporaries.

Mr. Outhwaite further attempts to illustrate his ideas with a series of maps. It is not quite clear what these maps are intended to show, but if the general statement in the introduction is applicable to all maps then there are many serious errors in the book. On many of them the whole of Newfoundland is shown as 'known', whereas in fact inland journeys were practically unknown until relatively recent times. There is much more of the world 'known' in 1490 than there is when Vasco da Gama made his voyage to India. In some of the maps showing the exploration of Africa in the nineteenth century there are similar errors. In short, the map does not unroll itself in quite the way Mr. Outhwaite intended, and when, as sometimes happens, his own statements do not agree with the maps, the reader is left in confusion. Nor is he helped in his search for a solution by the bibliography, which in the main consists of "a few volumes that will tempt the fireside explorer". Some at least of the distinguished authors quoted would perhaps be a little suspicious of such comfortable popularity.

It has been necessary to criticise Mr. Outhwaite's book partly because the publishers claim that it will be welcome to "students in need of a work of reference". It will, in fact, give them little help. On the other hand, the "schoolboy eager for one of the greatest true stories of adventure" and the "general reader" will find it, despite its awkward format, interesting, readable, and, up to a point, instructive. Even the student may study with profit the admirable drawings of ships, contributed by Mr. Gordon Grant, which combine art and scholarship in a manner which is much to be commended.

J. N. L. B.

Ornamental Shrubs and Trees: their Selection and Pruning
By Arthur J. Sweet. Edited by Walter P. Wright. Pp. xiii+64. (London and Toronto: J. M. Dent and Sons, Ltd., 1935.) 5*s*. net.

OWNERS of gardens, large and small, will find this book very useful, for many people fail to get the best results from their shrubs and trees owing to their indifferent knowledge of pruning. All ornamental shrubs and trees do not need annual pruning; some give better results without it, others require an annual light thinning out of the older wood, and some respond most satisfactorily when the flowering branches are cut back each year after the flowers are over and entirely new wood is relied upon for future flowers. Moreover, some shrubs and trees can be pruned when they are dormant in late autumn or winter, but if the same treatment were given to others the flowering wood for the following season would be cut out; that is why the autumnal clean up of gardens should not be made the time for the annual pruning of shrubs and trees.

In the book under notice all the little peculiarities of different shrubs, regarding pruning, are dealt with, and by the aid of descriptive lists and diagrams it need not be difficult for the most casual amateur to find out the proper time and most approved method for pruning his shrubs and trees.

Theoretische Grundlagen der organischen Chemie
Von Prof. Walter Hückel. Band 2. Zweite Auflage. Pp. viii + 338. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1935.) 15.60 gold marks.

VOL. 1 of the second edition of Prof. W. Hückel's work was recently reviewed (NATURE, March 9, 1935, p. 384); vol. 2, divided into two main sections, contains a not inconsiderable amount of new material and there are certain changes in the presentation of the subject.

The first section (Book 3) on "Constitution and Physical Properties" contains the larger proportion of the new material included in the volume. This new material deals with dipole moment and with colloid problems in organic chemistry which, apart from the polysaccharides, are chiefly concerned at the present time with polymerisation of unsaturated simple compounds to products of high molecular weight. The author has purposely omitted to include the consideration of the physical basis of optical activity, a subject in which so much original work is being carried out particularly in England and in Germany at the present time.

Book 4 is concerned with various aspects of "Constitution and Velocity of Reaction" treated largely from the kinetic point of view. In this, not very much new matter is included, although there has been a rapid increase in our knowledge, particularly of the mode of reaction of simple organic molecules in the gaseous phase, since the publication of the first edition.

There is no doubt that Hückel's "Theoretical Principles" is a most stimulating work, in spite of the necessary restrictions which the author evidently feels it desirable to impose in a work of this kind; in his *Ausblick*, after referring to the work of Heisenberg and Schrödinger, the author indicates the importance of the application of quantum mechanics to the organic chemistry of the immediate future.

C. S. G.

An Introduction to Experimental Embryology
By Dr. G. R. de Beer. Second edition. Pp. xii + 148. (Oxford: Clarendon Press; London: Oxford University Press, 1934.) 7*s.* 6*d.* net.

THE appearance of a second edition of de Beer's "Introduction to Experimental Embryology" is evidence of its well-deserved popularity. The book deals with the whole subject of modern research into the form changes of animals. The field is so wide and the subjects touched on so varied, that perforce a very large number of experimental facts have to be included. It is Dr. de Beer's particular merit to have provided an exposition which is at once perfectly clear as to the actual data and also never loses sight of the main principles involved.

The achievement is the more remarkable as in point of fact there is no generally recognised set of principles extant which can be applied over the whole field. The author has had to select boldly, from the conflicting hypotheses which are available, one main thesis to which he can refer his experimental data. Dr. de Beer chooses the axial gradient theory, which has the somewhat dubious advantage of being so flexible that it can be more widely applied than many of the more specialised theories. Apart from any consideration of its ultimate scientific worth, however, it fulfils very well the function it is called upon to play in this book—the function of providing a connecting thread on which the data of experimental embryology can be strung together to make an interesting and not too mysterious story for beginners. If the vagueness which still attaches to the theory stimulates the reader to try to make precise in his own mind some of the questions which are raised, that too will have been not without its usefulness.

A Bibliography of Two Oxford Physiologists: Richard Lower 1631–1691, John Mayow 1643–1679.
By Prof. John F. Fulton. Pp. 62 + 7 plates. (Oxford: Printed at the University Press, 1935.) n.p.

THIS work is a reprint from the *Proceedings of the Oxford Bibliographical Society and Papers* (4, 1; 1935). Prof. Fulton states that he has chosen this subject owing to the recent interest caused by Dr. K. J. Franklin's studies on Lower and Prof. T. S. Patterson's critical discussion of Mayow's work. In a short introduction to Lower's bibliography, Dr. Franklin adds some supplementary matter to his previous studies, and maintains that the pre-eminent position occupied by Oxford in scientific achievement during the seventeenth century was due among others to Lower, who was alike great as an anatomist, physiologist and medical practitioner. Dr. Fulton himself has an equally high opinion of Lower, whom he regards as the foremost English physiologist of the seventeenth century after Harvey. On the other hand, he agrees with Prof. Patterson that Mayow has been credited with many things which had been definitely mentioned by other people, though he emphasises the fact that Mayow was the second English writer after Glisson to publish a treatise on rickets with novel and praiseworthy suggestions concerning orthopædic treatment.

The bibliographies of the two physiologists are each divided into three sections devoted respectively to their separate works, of which facsimiles of the title pages are inserted, contributions to other works, especially the *Philosophical Transactions*, and biography and criticism.

La Tchécoslovaquie: étude économique
Par Prof. André Tibal. (Collection Armand Colin: Section de géographie, No. 183.) Pp. 224. (Paris: Armand Colin, 1935.) 10.50 francs.

PROF. TIBAL'S economic survey of Czechoslovakia is mainly concerned with agriculture and the country's industries, but reference is incidentally made to educational, cultural and scientific matters. The book is most noteworthy for its account of the influence of the world economic crisis upon national life, and the methods that are being pursued to overcome the general stagnation. It is significant that the industrial and political leaders have sought the aid of men of science and have adopted some of their suggestions in attempts to surmount their difficulties. They are already meeting with a measure of success.

Solar Magnetism

By Dr. George E. Hale, For. Mem. R.S., Mount Wilson Observatory, Pasadena, California

THE recent celebration of Prof. Zeeman's seventieth birthday offers a favourable opportunity to describe current applications of his powerful method of research to the study of solar magnetism. Our latest results include the completion of the first observed 23-year magnetic cycle of sunspots and the conclusion of a long investigation of the sun's general magnetic field, made for the purpose of checking beyond question the original measurements begun in 1912.

Zeeman Effect in Sunspots

As explained eleven years ago in NATURE[1], I was led in 1908 to the discovery of magnetic fields in sunspots by a hypothesis based upon the results of two series of studies, begun at the Kenwood Observatory in 1890, and continued at the Yerkes and Mount Wilson Observatories. The first of these related to the nature of various phenomena of the solar atmosphere revealed by spectrographs and spectroheliographs. The hydrogen flocculi, as first shown by the $H\alpha$ line at Mount Wilson in 1908, indicated the existence of immense vortices surrounding sunspots, and suggested that electrically charged particles might be whirled within the spots in such a way as to produce appreciable electric currents. Such currents would set up magnetic fields, possibly of sufficient strength to be detected by a powerful spectroscope. Zeeman had shown how the spectrum lines of luminous metallic vapours between the poles of a magnet are widened or split into several components, polarised in distinctive ways. Meanwhile our studies of sunspot spectra, supplementing those made with less powerful spectrographs by Young, had reached a point where many lines on our photographs were not only widened but also separated into apparent doublets or triplets. These had previously been regarded as reversed lines, due to the superposition of two vaporous layers of different temperature and density. Such reversals actually exist in certain cases, notably in the lines of hydrogen and calcium. Thus, the true understanding of the sunspot spectrum had been obscured.

In the hope of disentangling the question, a new attack on sunspots was begun. Aided by the 60-foot tower telescope on Mount Wilson, equipped with a 30-foot grating spectrograph and suitable polariscopic apparatus, it was easy to test my hypothesis. The presence of magnetic fields was readily established in all the sunspots observed, and the polariscopic phenomena of the sunspot lines, varying as the solar rotation changed the angle between the lines of force and the line of sight, was quickly found to harmonise with Zeeman's laboratory results on the spectra of vapours. My solar work was greatly facilitated by experiments made in our own laboratory by King, provided with a Du Bois magnet and all the essential equipment.

Magnetic Polarity of Sunspots

The sunspot spectrum contains many thousands of lines, and its complete investigation is an extensive task. After a sufficient number of these lines had been examined in order to establish the existence, strength and general character of the magnetic fields, another phase of the problem was attacked.

Speaking broadly, sunspots in the northern hemisphere of the sun were found to be opposite in polarity to those in the southern hemisphere. But occasional apparent exceptions indicated the need for a more careful analysis. The earliest drawings of sunspots, made by Galileo and Scheiner, suggest their complex character. They often appear at first as single spots, but soon develop into groups, frequently containing many components, large and small. No observer could fail to detect, however, a remarkable tendency of spots to occur in pairs, consisting of large spots with small companions, or of two groups of small spots. Here was an interesting chance for polarity tests, which showed that such pairs are almost invariably bipolar: that is, they consist of two spots or groups having opposite magnetic poles. The smaller spots that frequently cluster about the preceding (western) and following (eastern) major spots usually agree in polarity with the larger spots they accompany, though this is not an invariable rule.

From such characteristics a scheme of magnetic classification developed, which has been used ever since on Mount Wilson in recording the magnetic phenomena of thousands of spots examined with

the 150-foot tower telescope and the 75-foot spectrograph. This long task, in which Nicholson, Ellerman, Joy and many others have taken part, has now covered more than two of the well-known sunspot cycles of approximately eleven years duration.

Law of Sunspot Polarity

It is well known that the first spots of each of these 11-year frequency cycles break out in comparatively high latitudes some time before the last of the spots of the previous cycle disappear near the equator. From 1908, the spots of the then existing cycle continued to show the same polarity, opposite in the two hemispheres, while slowly decreasing in mean latitude. Not long before the minimum of solar activity in 1912, the forerunners of the next 11-year cycle began to appear. To

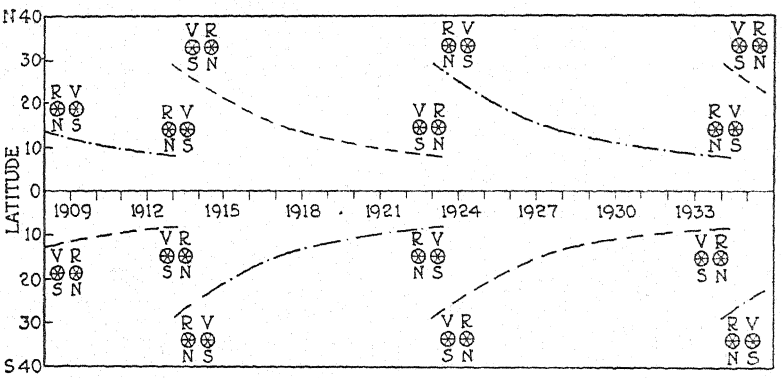

Fig. 1. Law of sunspot polarity. The curves represent the approximate variation in mean latitude and the corresponding magnetic polarities of sunspot groups observed at Mount Wilson from June 1908 until January 1935. The preceding spot is shown on the right.

our surprise, their polarity was opposite to that of the spots of the preceding cycle. Moreover, the succeeding spots of the new cycle, which overlapped for a time the remnants of the old cycle in lower latitudes, retained the same reversed polarities for approximately eleven years. Then another frequency cycle commenced, with another reversal of polarity. Thus the complete magnetic cycle, bringing back spots of the same polarity as those first observed, occupies some twenty-two or twenty-three years, and comprises two frequency cycles. The northern and southern hemispheres represent this novel effect with opposite signs. The diagram shown in Fig. 1 summarises the changes of latitudes and polarities during the period 1908–35.

A more detailed examination of the observations, many of which have been published in the *Astrophysical Journal* and the *Publications of the Astronomical Society of the Pacific*, would suffice to show that occasional exceptional phenomena complicate the explanation of these changes. About ninety-seven per cent of consistent results, however, obviously point toward some general solution, applicable to the sun and countless other stars, but still remaining in the form of the empirical law illustrated in Fig. 1.

General Magnetic Field of the Sun

Soon after the detection of strong magnetic fields in sunspots, I began to wonder whether the sun as a whole might possess a general magnetic field. There was no very promising theoretical ground for such speculation, but the magnetic field of the earth, with poles not far removed from the poles of rotation, was at least suggestive. Schuster had queried in 1891: "Is every rotating body a magnet?" and the structure of the solar corona resembles that of a magnetic field*. Thus while it was a far cry from the solid earth to the vaporous sun, it seemed worth while to undertake a trial.

The first attempts, made with the 60-foot tower telescope, were fruitless. In 1912, with the completion of the 150-foot tower telescope and 75-foot spectrograph, a better opportunity offered itself. Obviously no such widening and complete splitting of lines as had been found in sunspots existed in regions away from spots. But by using a purely differential method, comprising a compound quarter-wave plate overlying a long Nicol prism on the slit, it seemed barely possible that minute magnetic displacements of suitable lines might be detected by measurements on successive strips. Assuming the magnetic poles of the sun to correspond with the poles of rotation, and mounting the quarter-wave strips with their principal sections alternately at angles of $+45°$ and $-45°$ with the slit of the spectrograph, the displacements on

* In the present brief statement no attempt is made to enumerate other speculations and theories.

odd and even strips should attain maximum values on the central meridian at about 45° north and south latitude, and decrease to zero at the poles and equator.

In the search for such minute displacements, every precaution was taken to obviate any possible bias on the part of the measurers. Thus the quarter-wave plates were frequently inverted, and the measurer was never allowed to know in advance in which position they stood, nor the hemisphere or latitude of the photographs under measurement.

Great difficulties attended this investigation, which was continued for several years. Many members of the Mount Wilson staff joined me in the task, including Seares, Anderson, Ellerman and van Maanen, together with Miss Lasby, Miss Richmond and Miss Felker, while check measures and tests were made by Adams, Babcock and others. Several different types of measuring machines were employed, and every possible means of avoiding personal or instrumental errors was adopted. The results, fully described in a series of papers in the *Astrophysical Journal*, seemed to leave no room for doubt regarding the existence, polarity and approximate strength of a weak general magnetic field of the sun, having poles lying within a few degrees of the sun's poles of rotation.

The fact remains, as pointed out in these papers, that some of the many measurers engaged in the work could not detect the general field, though the results of all those who succeeded were in agreement regarding its polarity and order of magnitude. The difficulties of measurement can be appreciated only by those who have endeavoured to detect such minute displacements of lines, rendered broad and diffuse by the great dispersion employed. The observed displacements ranged from zero near the equator and poles to maximum values of 0·001 A. at mid-latitudes.

Several years ago I renewed this investigation with the cœlostat telescope (equivalent focal length 150 feet) and the 75-foot spectrograph of my solar laboratory in Pasadena. Having made a new series of photographs of the same dispersion as those previously taken on Mount Wilson, I endeavoured to measure them by several different instruments, including a Zeiss microphotometer and a tipping plate micrometer of the form used in our earlier work. The results showed little, if any, general magnetic field, and finally I thought it advisable to undertake new check measures of the plates made more than twenty years ago on Mount Wilson. More difficulties were encountered, and most of the experienced measurers who had overcome them before were no longer available. However, others kindly enlisted, and a study lasting four years has at last yielded a sufficient number of independent confirmations to satisfy us of the validity of our former conclusions.

As before, some of the measurers have been unable to detect the general magnetic field shown by our old plates. On the contrary, Dr. John Strong with an improved Zeiss microphotometer, used visually, and Dr. R. M. Langer with the original tipping plate micrometer, have found systematic average displacements of the same sign. Mr. J. Evershed, who very kindly volunteered to assist, obtained excellent confirmatory measures of our original plates at his observatory in England, using his own admirable method of measurement. Within the last few weeks [date of communication, September 14, 1935], Dr. Langer has obtained two more unmistakable confirmations with the aid of a new type of combined measuring, recording and computing machine, built in my laboratory after a design due chiefly to himself. The chief advantages of this machine are its speed of operation, permitting a very large number of measures to be made in a short time, and its complete freedom from any possibility of bias.

Taken altogether, the evidence is overwhelmingly in favour of the existence, polarity and order of magnitude of the general magnetic field of the sun given in our original papers. There is thus far no evidence of change of polarity at sunspot minima. As for any possible changes of intensity, every single determination is necessarily based upon thousands of measures, and hence represents mean values for many points on the sun. Thus much time may elapse before the question of variability can be settled.

The striking magnetic phenomena of sunspots, and the evidence we have offered that the entire sun is a magnet, would seem to have important bearings on the problems of terrestrial magnetism and the fundamental nature of magnetism itself. It is difficult to avoid the belief that the strong magnetic fields of the spots, and the much weaker general magnetic fields of the sun and the earth, arise from the same general cause, namely, the rotation of bodies carrying electrically charged particles. Many different hypotheses based upon this view have been tested, but there is much room for further work. While this will naturally deal at first with the simplest general assumptions, a detailed study of such anomalous phenomena as are presented by about three per cent of all sunspots should not be overlooked.

The Schools and Pre-Medical Studies

IN NATURE of July 20, 1935 (136, 90), appeared an article upon the recent report on the medical curriculum* dealing with the report from the point of view of clinical studies, but making no reference to the pre-medical studies and their relation to the work carried on in public and other secondary schools. The present article, which deals with this section of the report, is intended to be supplementary to that previously published.

The third section of the report deals with the pre-medical studies and may be briefly summarised as follows :

1. The period of pre-medical studies is spent with increasing frequency at school and only too often general education is stopped at too early an age in order to permit specialisation in science for passing the pre-medical examination.

2. In some cases, this has resulted in the formation of small groups working solely for this object, and thus segregated some, not only from the rest of the school, but even from other boys studying science.

3. The early specialisation is undesirable and could be avoided if a reasonable proportion of time was spent on science throughout the school period.

4. Greater use should be made of the Higher School Certificate examinations as a means of obtaining exemption from the First M.B. examination.

5. A common syllabus in chemistry, physics and biology is desirable for all First M.B. examinations, and suggestions for such a syllabus are given in the appendix to the report.

6. To ensure sufficient time for general education, and to avoid too early specialisation, medical studies proper, that is, anatomy and physiology, should not be begun before the age of eighteen.

It appears desirable to examine these criticisms and the suggestions, and to do so it is necessary to review briefly the work carried on in public and other secondary schools at the present time.

In the majority of schools, the work of the pupil is directed to attaining the standard of a School Certificate examination at the age of 15–16 years, and up to this stage in most schools there is little or no specialisation, each pupil commonly offering English, at least one other language, elementary mathematics, and from two (minimum) to five (maximum) additional subjects, usually including some science subjects.

A large number of pupils leave school when they have passed the School Certificate examination, but those intending to study medicine stay for an additional one or two years, and naturally their academic interests are centred mainly on their first professional examination. If these candidates have offered chemistry and physics (and possibly biology) for the School Certificate examination, and assuming they are about 16 years of age, it should be a matter of comparative ease for them to reach the standard of the First M.B. examination at the end of a further two years work without any intensive preparation, and the formation of special M.B. classes appears quite unnecessary.

Unfortunately, there are frequently complications so far as individual pupils are concerned. For some reason, it may be ill-health, slower development, or failure to pass the School Certificate examination at an earlier attempt, a pupil may already have reached the age of 17 years before becoming a post-certificate student. The tendency then will be for him to endeavour to pass his First M.B. examination at the end of a further year's work, a proceeding which must entail some intensive preparation and which probably segregates him to some extent from the rest of the science students.

In large schools, there is often also the difficult problem of a boy, who, having spent his time on the classical or modern side up to School Certificate stage, decides to study medicine. He has probably done little or no science, but is now transferred to the science side, and the problem becomes one for the science masters. To expect the boy to work with students of the science side who have already spent about three years working at science subjects is unreasonable, and therefore a special course of study has to be planned for him. Since this boy is endeavouring to pass in two years (or in extreme cases in one year) the same examination over which the preparation of the science side student has taken four or five years, the course of study is necessarily intensive, and demands all the time of the student, and even then the knowledge gained is in many cases superficial, and the examination is passed through the cultivation of a retentive memory rather than of scientific method. The general education of such a student must suffer, and if there is more than one pupil in such

* Report of the Conference of Representatives nominated by the Universities of Oxford, Cambridge and London, the Royal College of Physicians of London, the Royal College of Surgeons of England, and the Society of Apothecaries of London, on the Medical Curriculum. Pp. ii+34. (London: University of London, 1935.) 1s.

an unhappy position, it is easy to see how special M.B. classes arise.

As the report points out: "If all schoolboys and girls devoted a reasonable proportion of their time throughout the school period to the natural sciences there should be less need for a prolonged period of intensive preparation at the end of school life".

Putting on one side the special cases considered in the preceding paragraphs, one may now inquire: What provision is made for the continuation of the general education of post School Certificate students? Some specialisation is now inevitable, and as the report states "may not be undesirable", for those remaining at school usually have some definite objective, either a professional examination or a university scholarship, and the general work of these students is usually directed towards a Higher School Certificate examination. In this, a candidate is required to satisfy the examiners in a particular group of studies, for example, classical studies, modern studies, mathematics, or natural sciences, but, in addition, he has also to satisfy the examiners in at least one subsidiary subject which is quite outside the group in which he has specialised. This avoids, to some extent, undue specialisation, and it is probably in recognition of this fact that "the Conference would, however, approve of greater use being made of the Higher School Certificate Examinations as a means of obtaining exemption from the Examinations for the 1st M.B. or Basic Sciences".

Here again arise difficulties which could easily be removed. In some cases, a university will not recognise the possession of the Higher School Certificate of another university for exemption from the First M.B. examination. To take a definite illustration, a boy attending a school taking the Oxford and Cambridge Joint Board examinations can obtain exemption from London Matriculation by a suitable School Certificate of the Joint Board, but finds that he has no means of gaining exemption from the First M.B. examination at London by the Higher Certificate of the Joint Board, and his easiest course is to work for the First M.B. examination. There is no incentive for him to work at subjects other than the science subjects of the First M.B. and therefore his general education virtually ceases. If greater recognition was given by all universities to Higher School examinations for purposes of exemption from their own examinations, difficulties such as these could be avoided.

The need for a common syllabus for all First M.B. examinations has long been apparent to teachers who have been faced with the preparation of individual members of the same class for different First M.B. examinations. The difficulty may be made clearer by a consideration of the biological syllabuses of the First M.B. examinations of Cambridge and London. Since the introduction of the new syllabus in 1935 into the Cambridge examination, there is more in common than there was formerly. Thus in each syllabus the following types are mentioned: *Amoeba*, *Monocystis*, *Paramecium*, *Lumbricus*, *Scyllium*, *Rana*, *Lepus*; *Spirogyra*, *Pythium*, *Saccharomyces* and Bacteria. Peculiar to London are *Obelia*, *Hæmatococcus*, malarial parasite amd the flower structure of *Lilium* and *Pisum*; and to Cambridge: *Chlamydomonas*, *Protococcus*, *Polytoma*, *Pandorina*, *Eudorina*, *Volvox*, *Fucus*, *Hydra*, cockroach, and frog embryology. Truly, as is stated in the report, "the training would be more efficient if these differences, none of them great or important, could be removed".

Appendix A of the report presents a suggested common syllabus for the subjects of the First M.B. examination. It may not be out of place at this point to pause and consider the proposed syllabuses. In the preparation of the report, the representatives consulted various authorities from medical schools, and also headmasters and representatives of the Science Masters' Association; and it may be assumed that pre-medical studies were fully discussed, and the syllabuses given in Appendix A are the outcome of those discussions. The standard of work outlined by the syllabuses appears to be roughly that of the present First M.B. examinations, that is, somewhat lower than that of the Higher School Certificate examination in the separate subjects. This is probably wise, for whilst it will allow a candidate who has offered science subjects in the School Certificate examination to take his First M.B. examination with fair prospects of success at the end of a further year's work (a benefit to the older post-School Certificate student already referred to), it will probably require two years' careful work from a candidate who has previously done little or no science, unless he is 'crammed' for this particular examination, a deplorable event, but practically impossible to eradicate, since parents' wishes must be respected.

If the recommendation that medical studies proper should not be begun before the age of 18 years is carried into effect, then there will be little incentive for the post-School Certificate student of 16 years to take the First M.B. examination the following year, and he can continue the normal school course for a further two years and attain the somewhat higher standard required from Higher School Certificate candidates, providing his success will gain for him exemption from the First M.B. examination. The syllabuses will probably be well received by teachers, to whom the

adoption of the syllabus by all authorities is of greater importance at the present moment than the details of the contents.

It may be predicted, therefore, that the recommendations of the report so far as they are concerned with the pre-medical studies and the age for commencement of medical studies proper will receive the enthusiastic support of teachers in public and other secondary schools. If the recommendations are carried into effect, the complaints of undue specialisation and too low a standard of general education will largely disappear, and the medical students produced by the schools may be better fitted to "acquire that kind of culture which survives the forgetting of facts".

W. J. R. D.

Geology as a School Subject

AT the Norwich meeting of the British Association, a discussion was held in Section C (Geology) on "Geology in Schools". It was certainly appropriate that this subject should be discussed during the year in which Prof. W. W. Watts is president of the Association, for during a period of more than thirty years he has repeatedly pressed the claims of geology as a school science subject, and his presidential address to Section C in 1903 dealt comprehensively with the functions of geology in education. For various reasons, little progress has been made with the introduction of the subject into schools, although in the meantime there has been a great extension of science teaching.

The Norwich discussion may be summarised the more easily since it revealed a remarkable unanimity of opinion, practically all who spoke emphasising their agreement with the previous speakers. It was keenly felt that geology does not occupy the place to which it is entitled in the educational system, in schools, universities or in the wider field of adult education. Dr. A. K. Wells showed that the number taking geology in the University of London General Schools Examinations has fallen almost to zero. On the other hand, many speakers emphasised the fact that geology proves one of the most attractive sciences when once a student is introduced to it. As Prof. Watts said: "there are many types of mind to whom this science appeals as no other one does": it gives a new interest which frequently lasts beyond school days, and which gives meaning to every piece of country visited, an important fact in these days of wider travel. Prof. P. G. H. Boswell stressed the value of geology as a cultural subject, and quoted Mr. Ramsay MacDonald's statement that "if any one of the sciences were selected as the key to all the other sciences—as that which in its subject-matter and its history, the history of its evolution, enforces the true scientific method—geology might be selected as that science".

In the course of the discussion, many advantages of geology as a school subject were touched upon. Among these the most important appears to be that geology is perhaps the very best training ground in the collection and co-ordination of observed facts. It was also emphasised that the equipment necessary for teaching (more abundant and more easily obtained now than at any time) is probably less expensive than in any other science. Many rural schools are situated in areas which can be described as natural laboratories, and it is preposterous that scholars do not learn something of the meaning of these surroundings. On the other hand, Dr. H. D. Thomas referred to the valuable work in geology done in a London school, so that the teaching of the subject by no means needs to be confined to rural areas. Prof. A. Hubert Cox spoke of the excellent work now being done in some Welsh schools, and Mr. A. N. Thomas gave an account of the courses provided at Caerphilly.

It was also pointed out that in several sciences taught in schools the teaching has become increasingly dogmatic: even the experiments performed are "carefully designed to eliminate all confusing and collateral elements". At least some teachers of chemistry and physics consider that the elementary parts of those subjects must be mastered as quickly as possible, and that it is impossible for a student until he approaches the standard of an honours graduate to begin to assess for himself the real value of experimental evidence or to develop his originality and critical ability. There is a real danger that a pupil finishing his science training in school may have acquired a vast body of scientific information, but may have had little chance of developing that scientific outlook which is likely to make him a more valuable member of most communities. In geology, on the other hand, it is still possible for a beginner to feel the excitement of making new discoveries; a fossil or a dip observation in a temporary section may be vitally important. The co-ordination of such observed facts, and the examination of alternative hypotheses concerning which the

teacher is prepared to admit his own uncertainty, are all part of the training of the most elementary student.

Other changes in school organisation in late years have, however, affected the question of what sciences ought to be taught. In the first place, the great extension of the senior classes in elementary schools has opened up a new field. The teachers in these schools, to a large extent freed from the tyranny of examinations, have opportunities of devising courses in science on more original lines; often limited by lack of laboratories and apparatus, the teaching of science must become even more dogmatic unless it is extended to include subjects such as geology in which the provision of simple equipment offers no difficulties: moreover, as Prof. Watts emphasised, it is possible to do a considerable amount of geology without any special knowledge of other sciences.

In the secondary schools the position presents greater difficulties. The teaching is frequently dominated by examinations; the needs of the small proportion of pupils who may eventually proceed to the university to a large extent determine the subjects chosen; the curriculum is already crowded, at least so far as the School Certificate stage. But many educationists feel that all is not well with science teaching at this stage and that the tendency to early specialisation imposes serious limitations on the teacher. Recently the panel of investigators appointed by the Secondary Schools Examinations Council concluded that "at present the practice is to confine Science work too narrowly and this practice is encouraged by our examination system". They believe that "there is a general body of knowledge . . . which ought to be known both by the ordinary citizen and by those who may ultimately specialise" in some narrower field, and recommend the institution of a course in elementary or general science to be made obligatory for practically all candidates desiring a pass in science at the School Certificate examination. The scheme now proposed involves some physics, chemistry and biology; in the course of the discussion at Norwich the view was very strongly expressed that some geology should be included in this general course.

The difficulty, already widely discussed, of making a homogeneous subject out of this new group would not necessarily be made greater by the inclusion of geology. For geology occupies a central position among the sciences, having close contact with all, and it was suggested that the geology would help to synthesise the scheme. In many cases it would form a suitable basis for the study both of science and of the external world. In this connexion, Prof. H. H. Swinnerton referred to a Nottingham school where a course in local geology and biology forms the starting point of all science work.

Several speakers felt that the introduction of geology as a separate subject after the School Certificate stage, for Higher School Certificate pupils, was highly desirable. The higher work done in school represents for some pupils the last stage of organised study, for others it forms the basis of subsequent university work; but for both these groups the inclusion of additional science subjects in the curriculum of most schools is greatly to be desired. Usually not more than three subjects are studied to this higher stage, and often in smaller schools no more than that number of science subjects is available: the pupil's choice at best is limited, and he may be excluded from any course in 'science' because, for example, of a distaste for physics or mathematics. For those who are not likely to proceed to university work in science, the advantages of a scheme which includes geology will be apparent from the remarks already summarised.

It was pointed out that the case of the student who intends to go to a university to read science calls for still more consideration, for the position has been greatly altered by the growth of the Higher Certificate courses. In most universities satisfactory school work at the higher stage gives exemption from first year university courses. But whereas in the past a matriculated student going to the university had to choose (usually) four science subjects from a list of seven or eight, which mostly involved taking up at least one subject which he had not studied at school, the present student has already made his narrower choice at school. There is a probability, therefore, that students who may have marked abilities in sciences not taught at school may never discover that bent, and may indeed be deterred from reading science at all. The effect of these conditions on the geology departments at the universities was commented on, although obviously this in itself is no strong reason for instituting geology courses in schools.

The relations of geology to the geography taught in schools were also discussed by several speakers. Prof. A. Gilligan emphasised the importance of geological work as a basis for school geography, and Dr. M. E. Tomlinson gave her experience, as a geography teacher, of the great interest taken by both boys and girls in the geology which she had, of necessity, introduced into her geography lessons.

The president of the Section (Prof. G. Hickling) mentioned that a sectional committee had been appointed to consider questions affecting the teaching of geology in schools. A. E. T.

Obituary

Mr. A. Thorburn

WITH the passing of Archibald Thorburn, who died on October 9, at the age of seventy-five years, ornithology has suffered a grievous loss. For a generation his pictures of bird-life held a supreme place in the presentation of our native birds; and this because he combined the rare gift of scientific accuracy with a sense of composition and colour-values, rarely attained by any other artist in this field. He knew his birds and loved them, and this goes far to explain his success.

Some of Thorburn's finest work is seen in his pictures of birds which appealed to the sportsman. His illustrations in Lilford's "Coloured Figures of the Birds of the British Islands" made him famous, for they were gems of the first water. He also painted a large number of pictures of pheasants for a great monograph on these birds published in the United States many years ago, as well as most of the coloured plates in the fine monograph of our British game-birds, written by his old friend J. E. Millais. This was no small tribute to his genius, for Millais himself had won fame in this field.

From his own pen followed two sumptuous books, each in two volumes, illustrated by himself. One of these was devoted to British birds. The other, in every way worthy of its predecessor, followed later, on British mammals. His exquisite pictures of field-mice and other small rodents and insectivores have never been equalled; and his wonderful drawings of whales seem to vibrate with life. These two books will remain an enduring monument to a great artist. His sure grasp of colour-effects he probably inherited from his father, who in his day enjoyed fame as a painter of miniatures.

The world is the poorer by Thorburn's death. To the wife and son who survive him, his friends and that great host who knew him only by the treasures from his pen and brush, will extend their profoundest sympathy. W. P. P.

Mr. E. G. Hooper

MR. EGBERT GRANT HOOPER was born at Bath on July 2, 1855, and died on September 17, 1935. As a pupil of Frankland at the Royal College of Science, he was a brilliant student and acquired that knowledge of chemistry which he used to such advantage in his later career. In 1878 Grant Hooper joined the Government Laboratory at Somerset House, and was transferred with it to its present quarters off the Strand. While in the Laboratory, he was engaged in food, drug, and water analysis, and assisted the late Dr. James Bell in his pioneer work on the analysis of foods.

In 1881 the tax on malt was changed to a tax on beer, and this gave Grant Hooper the opportunity of utilising his knowledge of the chemistry of brewing. It is not too much to state that Grant Hooper's small textbook, the "Manual of Brewing", was one of the earliest to consider the art of brewing in the light of the chemical knowledge at the date of its publication. It continued in use by students up to the present century and passed through several editions. It was fortunate too, in this connexion, that Grant Hooper was an expert microscopist. His wide experience enabled him to carry through many official chemical investigations of importance, ranging from the determination of arsenic, to lead in paints.

In 1912 Grant Hooper was appointed Deputy Government Chemist, a position he occupied during the difficult War period until his retirement in 1919. He was an active member of the principal chemical societies, on which he served by acting on their councils and committees. Among his various offices were those of vice-president of the Institute of Chemistry and chairman of the London Section of the Society of Chemical Industry. Those who worked with him will always remember his readiness to help in difficulties and to place his wide knowledge at their service. J. J. F.

Dr. P. K. Kozloff

THE death is reported of Dr. Petr Kuzmich Kozloff, the well-known Russian explorer, which took place at Leningrad on September 27 at the age of seventy-two years.

Kozloff was a pioneer in the band of travellers, who, combining geographical and archæological exploration in the objective of their expeditions, during the last forty years have traversed the Gobi Desert from end to end, and have restored to Western knowledge the vanished civilisations of Central Asia. Among these, the greatest honour will always be due to Sir Aurel Stein and Sven Hedin; but the Russian expeditions to Turkestan at the close of the last century were among the first to show the way to the sand-buried cities of these now desert lands, from which English, French, German and Swedish expeditions have brought back a priceless store of the treasures of ancient Asiatic art and culture.

Kozloff had already been a member of two important expeditions when he led his own first expedition to Central Asia in 1899. This was followed by a number of explorations in the Gobi Desert in the years preceding the War, of which the most fruitful was that of 1907–9, when he discovered the dead city of Khara Khoto, with its well-preserved remains of buildings and its evidences of an unknown race, from which he brought back the relics of a library, including writings in an unknown language. Under the Soviet Kozloff made several further expeditions to the Gobi Desert, of which the last was in 1926. In 1923, with the assistance of the Soviet Government, he published a fully illustrated account of his explorations and of Khara Khoto.

News and Views

Prof. Hans Spemann

THE Nobel Prize for Medicine for 1935 has been awarded to Prof. Hans Spemann, professor of zoology in the University of Freiburg-im-Breisgau. The presentation is a fitting recognition of a series of investigations which have transferred a large group of phenomena from the domain of metaphysics to that of science, in a way which we are more used to associate with the eighteenth century than with our own. Since his earliest papers, written at the turn of the century, Spemann has devoted himself to the problem of why one part of an egg develops into a certain organ in the adult, another part into something else. When he began his investigations, there was no scientific answer to such questions; one had the choice of invoking, with Driesch, a non-material entelechy, or of putting one's trust, with Roux, in the physics and chemistry of the future. Spemann refused such theoretical flights. He restricted his speculation to the actual data he could obtain from experiment, and his experimentation again to an intensive study of the development of one group of animals, the Amphibia. After twenty years of research, remarkable alike for the clarity with which the problems were envisaged and the beauty and skill of the technical means by which they were attacked, he was able to demonstrate that, in the amphibian egg, the way in which any part develops is dependent on its position relative to a certain region which he named the organisation centre. The formulation of this concept provided the first step in the causal analysis of the differentiation of the several regions of the egg. But Spemann was not content to leave the organisation centre as an unanalysed biological entity. He proceeded to show that some, at least, of its effects are due to its chemical properties, the nature of which he is still actively investigating, in company with his pupils and many others who have followed him in the exploration of the rich country which he has opened up for science.

Prof. E. Maitland Wright

DR. EDWARD MAITLAND WRIGHT, who has been appointed to succeed the late Prof. H. M. Macdonald in the chair of mathematics at the University of Aberdeen, is only twenty-nine years of age. He took his degree at the University of London in 1926 with first class honours in mathematics. He was a scholar of Jesus College, Oxford from 1926 until 1930 and has been a research student in mathematics at Christ Church since. He gained both the Junior and Senior Mathematical Scholarships of the University and first classes in each of the mathematical 'schools'. He has also been a University Senior Student and, for one year, lecturer in mathematics at King's College, London. He was trained in research work in mathematics under Prof. G. H. Hardy in Oxford and Prof. Landau in Göttingen. He has published nearly twenty papers, mainly on the additive theory of numbers and especially on Waring's theorem. A book by Prof. Hardy and him will shortly be published by the Oxford University Press; it will be accurately, though, perhaps, deceptively described as "An Introduction to Arithmetic".

The New Physics

IN the Sir Halley Stewart Trust Lecture delivered on October 24, Sir William Bragg said that an important factor in the rapid progress of science, so marked in recent years, has been the discovery that in one of her chief aspects Nature's constructions are essentially 'particulate'. In the first place, matter is particulate. The atomic theory as now understood dates from the time of Dalton, who established the fact that atoms, of a limited number of kinds, combine in definite numerical proportions to form the substances of the world. This great generalisation is the foundation of chemistry. Forty years ago it was shown that electricity is also particulate, the ultimate unit, when of negative sign, being called the 'electron'. These two generalisations have prepared the way for a third; it has been found that energy may also be described as 'particulate'. The transfer of energy is effected in units, known as 'quanta'. It is now possible to demonstrate the single atom, though a hundred million in line cover only an inch, the single electron and even the single energy quantum. Accurate maps of various molecules can be drawn, showing the signs and positions of the atoms of which they are composed: just as an architect draws the plan of a building. We may study the single ring of six carbon atoms which, with attached hydrogens, forms the molecule of benzene, or the double ring of naphthalene and the treble ring of anthracene, these being of great importance in the dye industry; or the five-ringed structure which is typical of most of those substances that are known to produce cancer. We can examine the details of the long protein molecule which plays so great a part in animal life, or the cellulose molecule of plants, or the arrangements of the atoms in metals and rocks. Nature builds all the substances that we know on certain definite structural lines. It is because we have learnt this fact, and are learning how to follow, very haltingly it may be, that physical science is making such rapid headway.

Atmospheric Electricity

IN the third of the series of Sir Halley Stewart Trust Lectures on "Scientific Progress", on October 29, Prof. E. V. Appleton dealt with recent advances in the study of atmospheric electricity. The surface of the earth is negatively charged in fine weather, while the air immediately above possesses a positive

charge. Measurements made over the oceans by American observers in the non-magnetic ship *Carnegie* showed that there is a maximum effect all over the world at the same universal time (7 p.m. G.M.T.). It is now believed that the maintenance of the earth's charge is due to thunderstorms, which send an appreciable amount of negative electricity into the ground. In the upper atmosphere, the electrification is a thousand times denser than it is in the lower atmosphere. The marked solar control of the density indicates unmistakeably that the ionisation is due to solar radiation, and radio observations show that the cause of the electrification is ultra-violet light. A difference in the behaviour of the lower and upper levels of the ionosphere has been recognised recently. The lower stratum is found to be about twice as dense in summer as in winter, due to the more direct influence of sunshine. This is exactly the amount of variation predicted by theory. But for the higher region there is not the expected increase in summer. To account for this anomaly the theory has been put forward that, at a height of 150–200 miles, the atmosphere is raised to a high temperature by the sun. Expansion results from this heating, so that the electricity is attenuated in density. To account for the observed facts it appears necessary to assume that at this level the summer noon temperature is at least 2000° F. The density of the ionosphere appears to follow the sunspot cycle of 11 years. The minimum of solar activity occurred about the latter half of 1933, and both magnetic and radio observations now show that activity is increasing again. It is expected, as a result, that the radio-engineer will find substantial differences in the wireless wave-lengths best suited for long-distance communication.

Science Exhibition at Liverpool

THERE was a record attendance at the fifth public exhibition and soirée arranged by the Associated Learned Societies of Liverpool and District at the Liverpool Technical College on October 26. The exhibition was opened by the Lord Mayor of Liverpool, and the Mayor of Bootle attended; they were received and shown round the exhibition—twenty-six rooms arranged by twenty-three societies comprising more than two thousand members—by the president, Dr. H. J. W. Hetherington; chairman, W. Mansbridge; deputy-chairman, W. S. Laverock, and the secretary, Miss E. Warhurst. Lectures included: "Race, Place and Nationality in Europe" by Prof. P. M. Roxby; "Value of Milk in Nutrition" by Prof. H. J. Channon; "Spiders and their Silk" by S. T. Burfield; and "Recent Work on Vitamins and Hormones" by Dr. R. A. Morton. The Society of Chemical Industry showed films of crystal growth by H. Emmett, and citrous fumigation with cyanides. The bird room arranged by Eric Hardy included a working scale model of a proposed bird observatory or ringing-station for migration study in the area, the first photographs taken of the grey phalarope in Great Britain—by members of the Ornithological Section of the Liverpool Naturalists' Field Club—and a working model of a ship's oil separator as the solution to the waste oil menace to sea-birds. Dr. C. T. Green of the Liverpool Botanical Society exhibited an extensive series of hand-coloured photographic prints of British orchids, similar to his noted collection recently accepted by the British Museum. Diagrams and photographs from Bidston Observatory were shown by the Liverpool Astronomical Society, and short talks were given on meteorology and astronomy. Dr. W. B. Wright, district geologist of H.M. Geological Survey, showed his results of spore analysis of coals at the Liverpool Geological Society's room. There were also demonstrations and exhibits by the leading scientific firms and the Liverpool Corporation Electric Department.

Recent Acquisitions at the Natural History Museum

AMONG the recent acquisitions to the Department of Zoology is the Bird collection of reptiles and amphibians from eastern Asia Minor. This collection, consisting of 196 specimens, contains representatives of one new subspecies of lizard and of two others not previously represented in the Museum's collections. It is of especial interest as coming from a region which is comparatively little known and which is intermediate, both geographically and faunistically, between the better-known regions of Iraq and western Asia Minor. A collection of 280 land snails from Cyprus has been purchased and is of interest in connexion with an intensive study which is being made of insular variation in the land Mollusca of various Mediterranean islands. The Department of Geology has received the Pleistocene vertebrate remains (chiefly mammals) which have been collected by Dr. L. S. B. Leakey in considerable quantity and from a large number of localities in East Africa in the course of his recent expedition. Purchases for the Department include a number of rare fossil fishes from the Middle Eocene of Bolca, Italy. The Mineral Department has received by gift from Mr. V. Koren a specimen of gold in quartz from Tanganyika Territory; from Mr. E. E. A. Leach a large crystal of platinum, showing magnetic poles, from Potgietersrust, Transvaal; from Dr. R. Kirkpatrick a series of moldavites, mostly collected by himself, from Czechoslovakia; and from Dr. Germaine Joplin a series of rocks from Ben Bullen, New South Wales. The purchases include a series of Brazilian minerals, among them being a large, pale blue and white, zoned, tabular, and waterworn crystal of topaz, a cut citrine (yellow quartz), weighing 647·35 carats, a large cut, pink and green tourmaline weighing 57·47 carats, a golden beryl crystal, and several specimens of quartz. A cut lemon-coloured orthoclase, weighing 31 carats, has also been bought.

THE Department of Botany has received from Mrs. E. G. Wheelwright the bryological herbarium of the Rev. H. E. F. Garnsey (1826–1903). The collection contains 2,300 mosses mostly British. Though Garnsey's name is best known on account of his association with the translations of German botanical textbooks issued by the Oxford Press, he had a high reputation

as a bryologist. The herbarium of Robert Paulson has been presented by his widow. It contains more than six hundred flowering plants, but its value is in its 269 British and 200 foreign lichens, for Mr. Paulson was one of our best known amateur lichenologists. Mr. A. H. G. Alston, assistant keeper in the Department, recently visited southern Albania in company with Mr. N. Y. Sandwith, of the Kew Herbarium. About 550 numbers were obtained. The Lunxheriës Mountains and Mount Tomori were explored, and further collections were made about Voskopoj. A visit to Gur-i-Topit was forbidden by the authorities because of a revolution. The main interest in the collection is that it was made at a late season of the year when little exploration has been done in the region. It also supplements the previous collections made in Albania by these botanists. The herbarium of Maurice Depierre has been purchased. It consists of about 23,000 specimens representing the flora of Mont Blanc and the other mountains in the Haute Savoie, collected in the first half of the last century. It contains specimens collected by the Curé's friends, MM. Puget and Chevalier, and some of the labels are made out or verified by the celebrated Prof. Reuter, who published a catalogue of the plants of Geneva.

Trees and Health

As the subject of his Chadwick Public Lecture on October 23, Mr. R. St. Barbe Baker discussed "The Contribution of Trees to National Health and Efficiency". He commenced by tracing the history of trees on the globe, showing that in early times trees of certain species were regarded as sacred, a superstition of man—if indeed it were a superstition—which survives to the present day, since many jungle races still worship the forests, or trees in the forests. Mr. Baker correctly states that man has been a destroyer of trees and the forest for a long period in his history. This destruction in the early days of man was justified to enable him to obtain space for pasturing his flocks and raising crops; with the increase in numbers, however, the destruction and wasteful utilisation of the forest proceeded apace, resulting in the disappearance of ancient civilisations owing to the former prosperous lands becoming a desert. As Mr. Baker shows, this wanton waste of the resources of the earth is continuing at an increased pace, owing to the greater demands being made upon the lands for agriculture and other purposes by an increasing population at the expense of the forest. Mr. Baker's remarks on the subject of the French and British in West Africa concerning the forests and the advance of the Sahara are somewhat misleading. The French are in fact carrying out forestry work of considerable importance and high technique in West Africa. In Nigeria a very considerable recognition exists of the problems connected with agricultural methods, forests, the increasing desiccation, and so forth.

Two other points in connexion with Mr. Baker's lecture are worthy of note. Under certain conditions, trees and the health of man are closely connected. In most of the temperate parts of the world under salubrious conditions of land and climate this is true. Mr. Baker must, however, be aware that in certain parts of the globe it is far from the truth. Medical opinion in West Africa, for example, now holds that sleeping sickness due to the tsetse fly is increased by the presence of trees on the ground. Large belts of trees around towns and along main roads are now felled, and the area kept clean with the object of reducing the disease. Generalities are always dangerous. Many have welcomed the 'Men of the Trees' and the effort the Society stands for. At times, however, Mr. Baker would seem to forget that a Forestry Commission has been established in Great Britain and has now been carrying out excellent afforestation work for some fifteen years; also that many landowners throughout the country possess parks containing beautiful trees. It is not that the love of the tree is not deeply implanted in the British peoples. The trouble arises from the fact that the general public does not know or understand how to raise young trees. One has only to look at the trees upon some of the arterial roads to realise that there is little use in planting trees in Great Britain unless proper provision is made for their supervision. It would be a fine thing if the members of the Society which Mr. Baker represents would, individually, plant twenty-five trees on Armistice Day in this Jubilee year. But who is going to look after these trees for say the next fifteen years? Without such attention, how many will be alive at the end of two to three years? If the 'Men of the Trees' can solve the question of how young trees, planted in public localities in Great Britain, are to be properly tended until they have reached a size and height beyond the ordinary dangers to which the young standards are exposed, we shall be on the road to replacing in our generation what our forefathers have given us in the wonderful old trees to be found in this island.

Births and Deaths in England and Wales, 1934

PART I, consisting of Tables (Medical), of the Registrar-General's Statistical Review of 1934 has just been published (London: H.M. Stationery Office. 6s. net). The number of live births in England and Wales registered in the year was 597,642, giving a birth-rate of 14·8 per 1,000 persons living. This rate was 0·4 above that for 1933, which was the lowest ever recorded. The death-rate was 11·8 per 1,000 persons living, 0·5 below the rate for 1933. When allowance is made for the fact that the average age of the living population is increasing every year, the resulting corrected or standardised death-rate was the lowest ever recorded both for men and for women, the rate for the sexes together being just half of the corresponding rate in 1881–90. Mortality from infectious and parasitic diseases in general reached a low record of 1·3 per 1,000, notwithstanding increases for scarlet fever and diphtheria, and the tuberculosis rate declined once again to a new low record of 763 per million. Pneumonia gave the lowest rate save in 1930, which was also a very healthy year. The

cancer rate, corrected for the increasing age of the population, rose slightly to 1,003 per million, but was still below the levels reached in 1928 and 1929. A new feature of the review is the tabulation of a 'comparability factor' for each separate town and rural district, which shows at a glance whether the distribution of persons by age and sex in the population of that area would lead to the expectation of a death rate above or below that of the country as a whole, and makes it possible to correct the death rate by a simple multiplication for valid comparison with that of any other area similarly corrected. After correcting in this way, the administrative County of London and the south eastern counties of Kent, Surrey, Sussex, Hampshire, Isle of Wight and Berkshire gave a combined mortality rate after correction only 84 per cent of that of the country as a whole, compared with 113 per cent for the north of England, namely, Durham, Northumberland, Cumberland, Westmorland, Yorkshire, Lancashire and Cheshire.

Archæological Investigation under the Soviets

ARCHÆOLOGICAL activities in Russian territory, in which the work of the Historical Museum of Moscow has been reinforced by the co-operation, financial and other, of museum authorities in the United States, have produced results of no little historical importance. Archæologists on the staffs of the various Russian museums are now engaged, according to a report from the Moscow correspondent of the *Observer* in the issue of October 27, in examining material brought in by expeditions to the Crimea, Kazakstan in Central Asia, the Georgian Republic in the Caucasus and the Ural Province. From the Crimea comes further evidence relating to Neanderthal man in the form of stone implements from a settlement site—not a cave—on the Katcha River, while in the neighbouring village of Pychka rock-paintings in red, depicting battle scenes, were discovered, which are attributed to a pre-Scythic culture of the third millennium B.C. The expedition of the Historical Museum to Kazakstan was occupied in excavating a site of the Bronze Age, on which a communal hut, measuring twenty-five metres in length, has been uncovered, as well as an altar about which were the charred bones of domestic animals, vessels containing the remains of food and bone cubes, which are said to resemble modern dice. In the Caucasus, cave deposits were examined, which yielded a number of flint implements of the palæolithic age.

Illuminating Engineering

IN his presidential address to the Illuminating Engineering Society, delivered on October 8, Mr. A. W. Beuttell took an optimistic view of the future of illuminating engineering. He based his claim on the inevitable demand for more artificial light which must approximate more and more to daylight. At the moment, the cost of this light is prohibitive, and the problem is to produce more light whilst using no more energy. The keeping low of energy costs will increase the cost of equipment. It is now realised that having incandescent metals near their melting point does not give the solution. On the other hand, vapour discharge lamps, although we are only at the threshold of these fields of discovery, whilst giving cheaper light, do not give white light. The question is now being thoroughly explored. The disturbance of electrons causing light is produced by heat, but at present much energy is lost in the non-visible spectrum. This problem is of great importance owing to the future great demand for light and the well-defined field with which we have to deal, and the fact that the production of light is based on the fundamental principles which physicists study. In considering the production and use of light, the psychological aspect has also to be considered. Mr. Beuttell expressed the view that in both the physiological and psychological processes concerning light, cause and effect hold good. Whilst we are learning rapidly, it is necessary that specialists should pool their knowledge.

The Internal Combustion Engine and its Fuel

ON OCTOBER 9, Mr. H. R. Ricardo received the Melchett Medal of the Institute of Fuel, and after the presentation delivered his Melchett Lecture on the "Progress of the Internal Combustion Engine and its Fuel". This progress he characterised as one of the most startling developments of the last fifty years, and now, he said, more than eighty per cent of the total power output of prime movers is based on petrol. He traced the development of the views held on the cause and character of the phenomenon of 'engine knock' and the formulation of the well-known method of evaluating 'knock-tendency' by means of the variable compression engine. The value of aromatic hydrocarbons was established by this machine and later the practice of rating fuel by an 'octane-number'. The production of fuels with high 'octane-numbers' has permitted the use of higher compression ratios with consequent greater engine efficiency, culminating in the 60 horse-power per litre attained by the Schneider engines. Further increase in the octane-number of petrols is not anticipated, nor the use of supercharging in pleasure cars. The Diesel engine is displacing the petrol engine in heavy commercial vehicles, and will continue to do so even at the same cost of fuel per gallon, owing to the 70 per cent advantage in the figure of miles per gallon.

The King's Fund Miniature Hospital

IN order to make known more widely the great work of the voluntary hospitals, Mr. Saxe Wyndham in 1929 suggested to the King Edward's Hospital Fund for London that a model of a modern hospital, complete in its smallest details, would be likely to arouse the interest of the public and so help the King's Fund. The Propaganda Committee of the Fund decided to undertake this work, and a design for the model was commenced by the late Mr. Percy Adams, and completed after his death by Mr. Lionel Pearson. At first, there was some difficulty in obtaining the necessary funds, but eventually Messrs.

Humphreys, Ltd., of Knightsbridge, generously undertook the responsibility, and a number of other firms collaborated in the construction and equipment. The model is to a scale of one sixteenth of full size, and includes adults' and children's wards, complete with bathrooms, lavatories and sink rooms, and with circular solarium at the end, operating theatres, X-ray apparatus, staircases and working electric lift, board room and kitchen, balconies and garden, together with figures of doctors, nurses and patients. The work was executed by a staff of skilled craftsmen, and so far as possible every detail essential to a building of this kind has been reproduced in the model—furniture, bedding, screens, radiators and others too numerous to mention. The model is on view until further notice at British Industries House, Hereford House, Oxford Street, London.

Agricultural and Horticultural Research

THE year 1934, coming after a period of monetary anxiety, brought financial stability to the National Fruit and Cider Institute and Research Station at Long Ashton, Bristol. This gratifying state of affairs has allowed the completion, or further prosecution, of several important pieces of investigational work. Some results of these are published in the annual report of the Station for 1934 (Long Ashton, pp. 312, July 1935). A foreword by Prof. B. T. P. Barker, the director, outlines the administrative changes of the organisation, and also of the Berkeley Square Advisory Centre, Bristol. The principal contributions of research results are three papers on the maturity of fruit by Dr. J. C. Hinton (NATURE, Oct. 26, p. 687), whilst numerous studies of pests and plant pathology have been prosecuted. The cider investigations include a consideration of the suitability of various containers for apple juice, the role of pectin in cider-making, experiments on clarification of the juice, and preservation with sulphur dioxide. A soil survey of the Teart Land areas of Somerset is also being made.

Television in Australia

BAIRD TELEVISION, LTD. announces that as the result of negotiations with the Australian Radio Manufacturers' Patents Association, Ltd., of Sydney, the Association has been appointed the exclusive representatives in Australia of the Baird Company, both for the construction and operation of television transmitting stations and the manufacture of television receivers under the Baird patents. The Australian Radio Manufacturers' Patents Association, Ltd. is composed of a majority of the leading radio manufacturers throughout the Commonwealth of Australia, and they propose to develop television as an adjunct to sound broadcasting. Experimental transmitters will, it is expected, be erected in Sydney and Melbourne in the near future, with the view of providing ultimately a commercial high-definition television service.

Louis Lumière Celebrations

A MEETING to celebrate the fortieth anniversary of the invention of the *cinematographe* by Louis and Auguste Lumière will be held in the Hall of the Sorbonne, Paris, on November 6 at 9 p.m. The meeting will be held under the presidency of M. Mario Roustan, Minister of Education; and M. Albert Lebrun, President of the Republic, will be present. Among the discourses will be one given by Prof. C. Fabry, professor of physics in the Sorbonne and president of the French Society of Photography and Cinematography. During the celebrations, certain films made in 1894, and colour photographs of 1907–1935, will be exhibited. Further information can be obtained from the Secrétaire Général, 11 Avenue Casimir, Asnières (Seine).

Awards of the Institution of Civil Engineers

THE following awards of the Institution of Civil Engineers have recently been made for papers read and discussed at ordinary meetings: a Telford Gold Medal to B. M. Hellstrom (London); a Telford Premium jointly to F. W. D. Davis (London) and William Mackenzie (Hull); a Telford Premium to G. L. Groves (London); a Telford Premium jointly to C. Seager Berry (Baldock) and A. C. Dean (Manchester); a Telford Premium to E. J. Buckton (London); a Telford Premium to W. J. H. Rennie (Singapore); a Telford Premium and the Coopers Hill War Memorial Prize to A. W. H. Dean (New Delhi); a Telford Premium and the Indian Premium to M. G. Platts (Madras); a Telford Premium jointly to J. A. K. Hamilton (Cleveland, York) and J. Tudor Graves (Middlesbrough); a Telford Premium to Alexander Gray (St. John, Canada); a Trevithick Premium to George McIldowie (Newcastle, Co. Down); a Trevithick Premium jointly to W. T. W. Miller (Sheffield) and R. J. Sargant (Sheffield); a Manby Premium to M. A. Ravenor (London); a Crampton Prize jointly to V. F. Bartlett (London) and W. H. Cadwell (Mellor, Derbyshire). For papers published without discussion as 'Selected Engineering Papers': a Telford Premium to T. H. Hopkins (Bromley, Kent); a Telford Premium jointly to Prof. E. G. Coker (London) and G. P. Coleman (London); a Telford Premium to Ralph Poole (Bradbury, Cheshire); a Telford Premium to W. H. Weston (Glasgow); a Telford Premium to C. G. Watson (London). For papers read at students' meetings: the James Forrest Medal and a Miller Prize to James Halliday (Dunbar); Miller Prizes to R. S. Cogdon (Sunderland), Geoffrey Wood (London), R. G. Rowbotham (Buenos Aires), G. R. Coles (St. Albans, Herts) and J. L. Matheson (Stafford). The Charles Hawksley Prize has been awarded to Frank W. Curry (London).

Announcements

AT the annual statutory meeting of the Royal Society of Edinburgh held on October 28 the following council was elected: *President:* Prof. D'Arcy Wentworth Thompson; *Vice-Presidents:* Prof. C. G. Darwin, Prof. R. A. Sampson, Principal O. Charnock Bradley, Prof. P. T. Herring, the Marquis of Linlithgow and Prof. E. B. Bailey; *General Secretary:* Prof. J. H. Ashworth; *Secretaries to Ordinary*

Meetings: Prof. F. A. E. Crew and Prof. J. P. Kendall; *Treasurer:* Dr. James Watt; *Curator of Library and Museum:* Dr. L. Dobbin; *Councillors:* Lieut.-Col. A. G. M'Kendrick, Prof. James MacKinnon, Prof. W. Peddie, Dr. A. C. Aitken, Principal J. C. Smail, Sir Harold J. Stiles, Prof. J. Walton, Prof. Edwin Bramwell, Prof. T. H. Bryce, Prof. I. de Burgh Daly, J. A. Inglis and Prof. A. D. Peacock.

THE council of the Royal Society of Edinburgh has made the first award of the David Anderson-Berry Prize to Dr. C. M. Scott, lecturer in materia medica in the University of Edinburgh, for his essay "On the Action of X- and Gamma-Rays on Living Cells". This prize, which consists of a gold medal and a sum of money, was founded by the late Dr. David Anderson-Berry in 1930, and is awarded triennially to the person who, in the opinion of the council, has recently produced the best work on the nature of X-rays in their therapeutical effect on human diseases.

THE first evening meeting of the 1935–36 series to be held in the house of the Pharmaceutical Society of Great Britain, on November 12, will be the occasion of the presentation of the Harrison Memorial Medal to Prof. Arthur Smithells, director of the Salters' Institute of Industrial Chemistry, who will deliver the Harrison Memorial Lecture. The title of the lecture is "The Teaching of Chemistry". Prof. Smithells was chief chemical adviser (Anti-Gas Training) G.H.Q. Home Forces 1916–19 and was closely associated with the late Colonel E. F. Harrison, director of Chemical Warfare, in anti-gas work.

DR. BERNARD SMITH will deliver the Cantor Lectures of the Royal Society of Arts on November 18 and 25, and December 2, at 8 p.m. The subject of Dr. Smith's lectures will be "Geological Aspects of Underground Water Supplies".

DR. HERBERT DINGLE, assistant professor of astrophysics in the Imperial College of Science, South Kensington, is giving a course of ten Lowell Institute Lectures at Boston, Mass., beginning January 3. Dr. Dingle's subject will be "Through Science to Philosophy".

DR. W. H. MILLS, the Right Hon. Lord Riverdale, Prof. A. Robertson, and Mr. H. B. Shackleton have been appointed members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research. Dr. E. J. Butler, Sir Kenneth Lee, and Prof. N. V. Sidgwick have retired from the Council on the completion of their terms of office.

AT the ordinary meeting of the Institution of Electrical Engineers to be held at 6 p.m. on November 7, Lieut.-Col. K. Edgcumbe will, on behalf of Colonel R. E. Crompton, Faraday medallist, honorary member and past-president, present to the Institution an oil painting of Colonel Crompton by Mr. George Harcourt. The painting was subscribed for and presented to Colonel Crompton by a group of 'Old Cromptonians' and other admirers on the occasion of his ninetieth birthday; but, at his express desire, it is now to become the property of the Institution.

THE Rockefeller Foundation has recently awarded 14,000 dollars to the University of Michigan for the application of spectroscopic methods in medicine.

FOR many years the late Mr. Archibald Thorburn (see p. 710 of this issue) has presented the Royal Society for the Protection of Birds with a painting for the illustration of its annual greetings-card. The subject for Christmas 1935 is the goldcrest, the smallest of all British birds, alighted on a twig of oak. Copies may be obtained from the Royal Society for the Protection of Birds, 82 Victoria Street, London, S.W.1, price 4*s.* 8*d.* a dozen, inclusive of envelopes and postage. All proceeds from the sale of the cards are devoted to the funds of the Society.

MESSRS. CHAPMAN AND HALL, LTD. announce that they have been appointed sole British Empire agents for the publications of the Reinhold Publishing Corporation, which is the successor to the Chemical Catalog Company, Inc. In addition to numerous well-known scientific and technical books, the Reinhold Publishing Corporation controls the issue of volumes appearing under the auspices of the American Chemical Society. This scheme of publication was undertaken by arrangement with the Interallied Conference of Pure and Applied Chemistry, which met in London and Brussels in July 1919, when the American Chemical Society and the National Research Council mutually agreed to care for certain fields of chemical development. A complete catalogue (150 titles) is now available and can be obtained from Messrs. Chapman and Hall, Ltd., 11 Henrietta Street, London, W.C.2.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

Assistants in the Departments of Mechanical Engineering, Electrical Engineering and Physics, and Mathematics of the Coventry Technical College—The Director of Education, Council House, Coventry (Nov. 8).

A principal of Aston Technical College—The Chief Education Officer, Education Office, Margaret Street, Birmingham, 3 (Nov. 11).

A professional assistant at the Royal Observatory, Hong-Kong—The Director of Recruitment (Colonial Service), 2 Richmond Terrace, Whitehall, London, S.W.1 (Nov. 23).

An inspector of mines and petroleum technologist for service in Trinidad and Tobago—The Director of Recruitment (Colonial Service), 2 Richmond Terrace, Whitehall, London, S.W.1 (Nov. 30).

A librarian at the Institution of Automobile Engineering—The Director, 5 Bolton Road, Chiswick, W.4.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 723.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Helium Content of the Stratosphere

IT is often assumed that the absence of any systematic temperature gradient in the stratosphere is incompatible with large-scale mixing; winds, which in the troposphere ensure a constant composition of the permanent atmospheric constituents, are supposed to fall off rapidly as the boundary between the troposphere and stratosphere is passed, and above the level at which mixing ceases the composition of the atmosphere should therefore vary with the height. Over England, the boundary between troposphere and stratosphere lies between 10 km. and 11 km.; so far, however, we do not know where the large-scale mixing in the stratosphere becomes negligible. Chapman and Milne[1], therefore, in their well-known tables, provide for four cases in which effective mixing ceases and diffusion commences, at heights of 12 km., 20 km., 30 km., and 50 km. respectively. Maris[2] has suggested that effective mixing takes place up to about 100 km.

The most direct method of finding the level where diffusive separation actually begins is the chemical analysis of air samples; up to this height the composition must necessarily be the same as at the surface of the earth; above this level the lighter constituents of the air should be present in higher percentage. The lightest gas, hydrogen, would be the ideal indicator, but its proportion in air is so low that there is at present no method of sufficient sensitivity available. The gas which, owing to its lightness, is next best suited is helium, which has the additional advantage that no complication due to chemical reactions are to be feared. From the calculations of Chapman and Milne, it follows that the amount of helium should increase by 1 per cent in the first 75 metres of the undisturbed layer of the stratosphere.

Oxygen as an indicator is eight times less sensitive. Of the air samples brought back from an altitude of nearly 19 km. over Russia by the stratosphere flight of Prokofiev, Godunov and Birnbaum on September 30, 1933, only the oxygen content has been analysed separately; it showed no deviation[3]. The same result was found by Lepape and Colange[4], so far as the main constituents of the atmosphere are concerned; in nine samples of air, taken between 9·0 km. and 16·8 km., the content of oxygen, of nitrogen and of argon + neon + helium, was identical with that at the level of the earth. The proportion of helium + neon to the total of rare gases, however, was found on the average to be 27 per cent higher than at the surface, a result which the authors apparently regard as real, and not due to the inaccuracy of their method; this would mean a still greater change in the percentage of helium alone, without neon.

We decided to investigate the problem of the mixing of the stratosphere by measuring directly its helium content. With the co-operation of Sir George Simpson, director of the Meteorological Office, several sounding balloons have been sent up by the Upper Air Section of Kew Observatory and samples of the air obtained. Much greater heights can be reached in this way than in manned stratosphere flights. To reach high altitudes by such balloons, it is essential to keep the weight as low as possible, a fact which made it imperative to develop a method for finding the helium content in small samples of air with high accuracy. We can now separate the helium of a few cubic centimetres of air from all other constituents; the amount of helium so obtained is measured by a procedure described in previous publications on the micro-analysis of helium[5]. Details of the method, which enables us to determine the helium content of 2 c.c. of air with an accuracy of 1 per cent, will be published elsewhere.

For the automatic sampling, a device was used which comes into operation after the sounding balloon, at the top of its flight, has burst; an extension of an evacuated glass bulb is then broken, and while the vessel, attached to a parachute, begins to fall, air is sucked in; after an interval of 10–15 sec. the extension is sealed again. If the mechanism functions satisfactorily, the pressure of the air inside the vessel should correspond within certain limits to the highest value of the barographic record. In the following table the figures in each row are derived from one sample of air; at least three portions of each sample have been separately analysed with accordant results.

Helium content of the atmosphere at different heights over England.

Height in km. (Dines baro-thermograph)	Height in km., as measured by pressure inside vessel	Helium in 10^{-6} c.c. per c.c.	Helium surplus, compared with London air (per cent)
—	0	5·27 ± 0·05	
16·8	14·0	5·35 ± 0·07	1·7 ± 1·4
18·5	18·4	5·31 ± 0·05	0·7 ± 1·0
21·0	20·4	5·69 ± 0·06	8·0 ± 1·0

From our analyses, it seems to follow that, up to 18 km., we are not yet above the ideal boundary considered by Chapman and Milne, where mixing ceases and diffusion becomes effective; this is in good agreement with the results of the Russian explorers. At a height of 21 km., however, the helium content is already distinctly increased. So far, nothing definite is known about its constancy in different parts of the earth's surface, and the first analyses of a survey begun by us indicate that local variations actually occur. The value found for London, however, agrees within 0·3 per cent with the average of analyses from eight different places in Germany, Sweden, the United States, Central America, and over the Atlantic, and the 8 per cent helium surplus in the air from 21 km. height appears to be outside the range of these variations; but more samples are needed before it will be clear whether the helium found is characteristic for this height.

We hope to apply our method of analysis to samples from still higher levels of the stratosphere. We are continuing our own experiments with sounding balloons, but as for this purpose England is neither geographically nor climatically very favourable, we should welcome the co-operation of others interested in stratosphere research. Air samples of volume about 6 c.c. (N.T.P.) would permit us to carry out three independent analyses of the helium content.

In conclusion, we would express our gratitude to Sir George Simpson, director of the Meteorological Office, London, for the assistance he has given us in arranging for the collection of samples of air from the stratosphere.

Vertical Intensity of Cosmic Rays by Threefold Coincidences in the Stratosphere

A YEAR ago we communicated the results of an ascent with a Geiger-Müller tube counter by registering balloons into the stratosphere to a height of 28 km.[1]. We found that the curve of the number of impulses obtained with the counter is identically the same as the intensity curve obtained with an ionisation chamber.

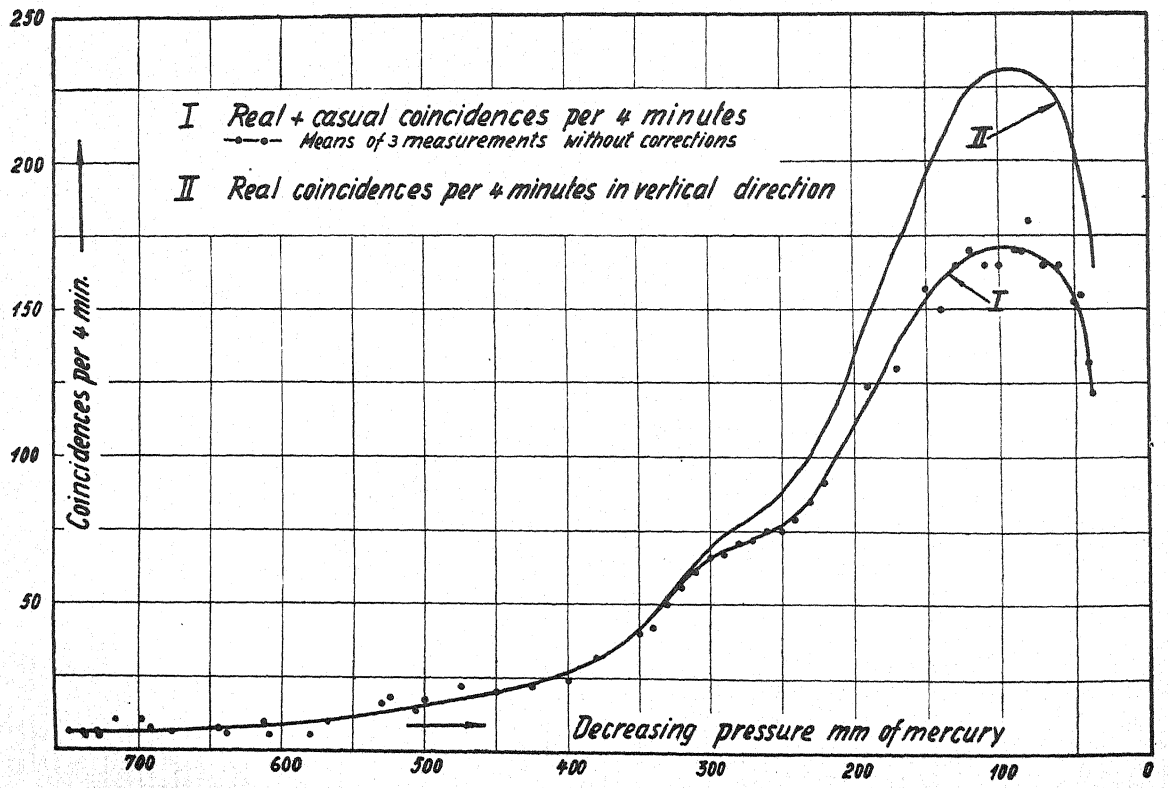
Recently, we succeeded in sending up a *threefold*-coincidence apparatus by balloons to a height of 22 km. (37·5 mm. mercury). The three counters had been arranged one above the other in such a manner that the area, 45 mm. × 50 mm., of the outer counters subtended a solid angle of only 20° about the zenith. Therefore, only the nearly vertical rays producing coincidences are recorded.

The data for pressure, temperature and counting rate were recorded every four minutes in the same way as previously described on a photographic plate[1]. The coincidence arrangement gave a high resolving power even at a high counting rate of a single counter. The apparatus was protected against the low air temperature by a case of 'cellophane'[2]. The temperature in the case varied only between + 25° C. and + 17° C. Therefore there was no influence of temperature on the recorded data.

Curve I (Fig. 1) shows the means of the results from two ascents and one descent. This curve requires correction according to the known probability of coincidence counting and of casual coincidences. Curve II shows the values thus reduced. There is to be seen a maximum at a pressure of 100 mm. of mercury and a well-marked hump at a pressure of 300 mm. The humps are obviously to be attributed to the components of the cosmic rays of primary or of secondary origin. It is remarkable that the same humps appear in the curve earlier found with one counter, if we transform the earlier curve indicating impulses from all directions to that showing impulses in the vertical direction by the method of B. Gross[3].

The curve tends to zero with decreasing pressure. But because of the latitude effect, it is not probable that the continuation of the curve will really pass through the zero. On the contrary, it is to be expected

FIG. 1.



that further ascents to greater heights will give a definite intensity of coincidence-producing rays near the top of the atmosphere.

A more detailed report will be published in the special number of the *Zeitschrift für technische Physik* for the Physikertagung, 1935.

We wish to thank the Deutsche Forschungsgemeinschaft for providing the means enabling us to make these investigations.

Radioactivity of Samarium

SEVERAL workers have investigated the radioactivity of samarium, and it is established that this element emits short-range α-particles. Mäder[1] has also reported the existence of a group of particles of range 1·37 cm., which he believes to be protons. To obtain fuller information about these particles, I have introduced samarium sulphate into the emulsion of an Ilford '*R*' plate, and examined the tracks which are produced. The technique of this method has been previously described[2].

After seven weeks exposure, numerous tracks are observed on the plate, most of which clearly belong to the short-range α-particle group. The accuracy with which the range in air can be determined from measurements of the length of the tracks is now known, and an account of the method used in making this determination will shortly be published. The range so determined is

$$R = 1{\cdot}13 \pm 0{\cdot}02 \text{ cm. standard air.}$$

This value is in good agreement with those previously published.

In addition to these short tracks, we have observed tracks which correspond to particles of much longer range, up to at least 3·5 cm. air. These are much less numerous than the short tracks, the relative frequency being of the order 1 : 100. So far, some 150 such tracks have been measured. The distribution curve of the measurements does not show any well-defined maximum, such as is always found with a group of α-particle tracks, and the 'scatter' of the measurements is much greater than is found, for example, with the tracks of uranium α-particles, for which numerous measurements have been made. This alone is strong evidence that we are not dealing with a group of α-particles. Furthermore, the mean separation of the grains is found to be 2·0μ for the whole group, and many of the individual tracks show greater values. The mean separation for the short-range α-particle tracks, obtained on the same plate, is 1·6μ. It has been pointed out previously[2] that this forms a criterion for distinguishing between α-particle tracks and proton tracks. It appears, therefore, that the long tracks cannot be attributed to α-particles, and we must conclude that samarium emits singly-charged particles.

It is not yet possible to make any accurate statement as to the range of these particles. The distribution curve suggests that more than one group may be present, but the greatest range must be in the neighbourhood of 3·5 cm. air. It is hoped that further observations will make it possible to decide these points.

I am indebted to Prof. Hevesy for supplying a specially pure sample of samarium, and to Mr. Dabholkar of this Department for help in the measurements.

Emission of Positrons from Radioactive Sources

WITH the improved apparatus, already used by us in the investigation of positrons from thorium-active deposit, we have repeated our measurements of the positron spectrum, emitted by a thin-walled radon tube; a new determination of the ratio of the positron number to that of the β-particles of RaC was also made. The positron spectrum is shown in Fig. 1: for each point about 1,000 particles were counted. The ratio N_+/N_β was found to be $2\text{–}3 \times 10^{-4}$ (N_+ = number of positrons, N_β = number of β-particles of RaC). Surrounding the source with a 1 mm. lead sheet, we could compare the number of positrons emitted by the source with that produced by the γ-rays of RaC in lead: it was found that N_+/N_+ (Pb) = 0·9–1.

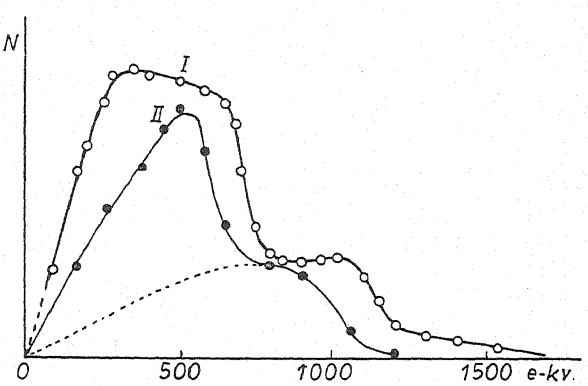

FIG. 1.

In the positron spectrum from the source, two discontinuities are observed at 760 and 1,100 e.kv., which correspond to the internal conversion of two strong γ-rays of RaC with energies 1,760 and 2,200 e.kv. The general shape of the spectrum does not correspond, however, either to the theoretical spectrum of internal conversion of γ-rays from RaC, or to the positron spectrum, produced in the thin (25) lead foil by γ-rays (curve II). By a method similar to that used in our analysis of the positron spectrum from thorium[1], it is possible to separate the portion of the spectrum due to the internal conversion of γ-rays from the total spectrum. The remaining main portion of the spectrum has the features of a continuous spectrum extending in energy up to 1,700 e.kv. The number of positrons belonging to this portion of the spectrum is of the same order of magnitude as that in the spectrum of

thorium-active deposit, that is, about 1–1·5 per 10^4 β-particles of RaC, and exceeds the number of positrons due to the internal conversion of the γ-lines 1,760 and 2,220 e.kv. by a factor of about 2.

Placing aluminium plates 0·5 mm., 1 mm. and 3 mm. thick in front of the source, we tried to reveal positrons produced by β-particles from RaC in traversing the aluminium. According to D. Skobelzyn and E. Stepanowa[2], these positrons greatly exceed (50–70 times) in number those originated by the action of γ-rays in the same substance. Our measurements showed a small difference in the positron number when passing over from the thin (0·5 mm.) to the thick (3 mm.) plate; this effect arising from the partial transmission of the positrons from the source through the thinner plate.

Having placed in our apparatus a strong radon source so that positrons of the source could not reach the counters, we irradiated by γ- and β-rays and also by γ-rays only a 25μ-thick lead foil. In this experiment the positrons going from the lead strip to the slit of the apparatus made an angle of 90° with the direction of β-particles and γ-rays. The number and the spectrum (II, Fig. 1) of positrons observed indicate clearly that most of the positrons are produced by γ-rays of RaC. Thus we are led to the conclusion that the cross-section for the production of pairs by γ-rays of RaC is at least several times greater than the cross-section for β-particles of RaC; as in the case of lead, so in that of aluminium.

'Extra' Rings in Electron Diffraction Patterns

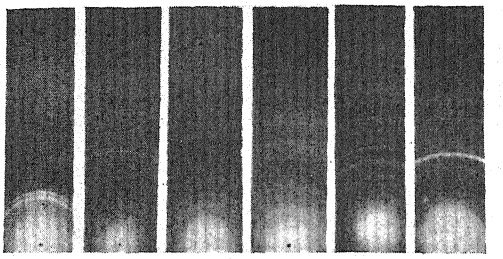
Mark, Motz and Trillat[1] have shown that traces of grease can give rise to 'extra' rings in electron diffraction patterns from metal films. In agreement with them, we have found that the spacings of these grease rings are as given in col. 1 of the accompanying table, and are independent of the nature of the metal substrate. The spacings of 'extra' rings obtained by

'Extra' Ring Spacings in Angström Units

1	2	3	4	5	6
4·02	4·81	3·85	4·49	3·75	4·93
3·62	4·00	3·46	2·57	2·93	4·09
2·90	2·79	2·81	1·69	2·44	3·37
2·43	1·83	2·45	1·50	1·81	3·24
2·30	1·61	2·31		1·57	2·85
2·17	1·49	2·15			2·57
2·01		2·05			1·70
1·92		1·83			
1·81		1·62			
1·71		1·49			
1·58		1·40			
1·47		1·29			

heating a metal in a gas are, however, quite different in that they depend not only upon the metal but also upon the gas and the nature of the heat treatment[2]. Thus, for example, we have obtained different 'extra' ring systems by drawing gold leaf through a Bunsen flame (col. 2) and by heating in oxygen at 540° C. during 30 minutes (col. 3). The reproductions 1–6 are from the corresponding electron diffraction patterns.

We have also found that amalgamation gives rise to 'extra' ring systems which, like those due to absorbed gases, have spacings dependent upon the metal. The spacings found for some gold, silver and copper amalgams, and given in cols. 4, 5 and 6 respectively, are quite different from those due to either grease or absorbed gases. The gold and silver amalgams were prepared by suspending the metal leaf in the vapour above a warmed drop of mercury until signs of amalgamation were visible at the lower edge of the leaf. Copper amalgam was obtained by immersion in a mercuric chloride solution.



1 2 3 4 5 6

In studying the absorption of gases by metals, it is therefore important to exclude the formation of 'extra' rings due to grease or amalgamation; whilst the former should, for the reasons given above, always be easy to recognise, the amalgam 'extra' rings appear to have much in common with absorbed gas 'extra' rings, at least in so far as the spacings of both vary from metal to metal.

Structure of Solid Oxygen

As is well known, solid oxygen appears in three modifications: α (below 23·5° K.); β (23·5°–43·5° K.); and γ (43·5° K. and melting point). In connexion with our investigations on the structure of solidified nitrogen and other gases, extensive work has been done with the object of determining the structure of the various forms of solid oxygen.

Already in 1927, McLennan and Wilhelm[1] published a powder diagram of α-oxygen which they tried to interpret by means of a rhombic cell. We found, however, that their interpretation could not account for the intensity distribution of the spectrum. Later on, powder diagrams of α- and β-oxygen were given by Ruhemann[2]. The two forms gave similar diagrams, which he tried to interpret by means of the rhombic cell proposed by McLennan; the result was not satisfactory.

In 1929 and following years, we obtained powder diagrams of β-oxygen, showing a large number of lines, but we found that the rhombic cell of McLennan could not account for the lines appearing in our diagrams. They were, however, satisfactorily interpreted by means of a trigonal (rhombohedral) cell, containing six molecules ($a = 6·19$ A., $\alpha = 99·1°$) corresponding to a density $\rho = 1·395$.

In spite of considerable efforts, we have not yet been able to determine the arrangement of the molecules within the cell; but I think we can say safely that only the space groups C_{3i}^2, C_{3v}^5 or D_3^7 can come into consideration.

We have also been able to obtain quite good powder diagrams of γ-oxygen. The spectrum shows those features which are typical for a lattice with rotating molecules. The diagrams were interpreted by a *cubic* cell ($a = 6{\cdot}83$ A.) containing 8 molecules, corresponding to a density of $\rho = 1{\cdot}30$. In this case we have also been able to find the arrangement of molecules within the cell which satisfies the intensity distribution.

The lattice belongs to the space group T_h^6. The position of the individual atoms are not fixed by this space group, but only the molecular centres. The molecules rotate in the lattice, and they are grouped into pairs along the trigonal axis. The distance between the two molecules of a pair (3·48 A.) is somewhat smaller than the minimum distance (3·68 A.) between neighbouring pairs. This indicates that the molecules of the pair are tied up with stronger forces than molecules of different pairs.

The study of the absorption bands of liquid oxygen by Ellis and Kneser[3] also indicates the existence of groups (O_2–O_2). This tendency to form groups explains the fact that γ-oxygen, although it possesses rotating molecules, does not appear in a closest spherical packing of molecules, as in the case of β-nitrogen. The centres of the pairs (O_2–O_2), however, form a face centred lattice, and we may, therefore, say *that γ-oxygen forms a closest cubical packing of pairs of oxygen molecules.*

γ-Oxygen may also be regarded as belonging to the space group T^4. In this case we arrange the molecules in two fourfold equivalent positions with parameters x_1 and x_2. Putting $x_1 = -x_2$, the symmetry of the lattice is raised to that of the space group T_h^6.

As shown in previous papers also, the lattices of α-N_2 and α-CO approximately fulfil these conditions, and they are therefore closely related to that of γ-oxygen.

The lattice of γ-oxygen is obtained when in α-nitrogen or in α-CO each atom is replaced by a rotating oxygen molecule (O_2), and the parameters are subject to the relation $x_1 = -x_2$.

Cinematographic Record of the α⇄γ Iron Transition, as seen by the Electron-Microscope

RECENTLY E. Brüche and W. Knecht[1] described the electronoptical observation of the transition of α- into γ-iron. In their beautiful experiments, however, the emission of the test-piece (after activation by means of an evaporated barium layer) at the transition temperature of about 900° C. was so small that the actual occurrence of the process could not be observed on the fluorescent screen without sufficient adaptation of the eye. In order to obtain a fluorescent image clear enough to be photographed, the temperature of the test-piece had to be raised to about 1000° C. A photographic record of the transition could therefore only be obtained by observing whether, after lowering the temperature to the neighbourhood of the transition point and raising it again at 1000°, the texture of the test-piece had changed or not.

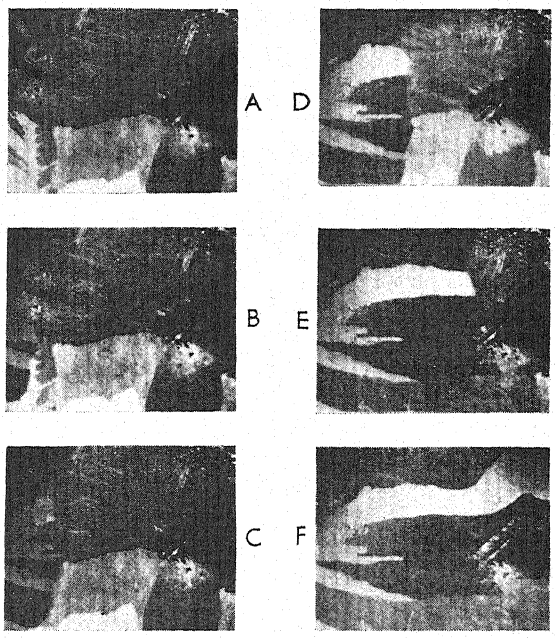

FIG. 1. Growth of α-iron crystals in the original γ-phase.

Using an 'electron-microscope' with one magnetic lens, similar to that described by other authors[2], we succeeded in obtaining even below 900° C. an intensive emission from a strip of iron after careful activating by means of evaporated barium or strontium oxide, so that the fluorescent image could easily be photographed with a film camera (N.A. 1 : 2·7; $f = 4$ cm.) after an exposure of 1–2 sec. Since by slowly lowering or raising the temperature through the transition point the growth of the new crystals could be made to take place in 5–10 minutes, it was thus possible to obtain a cinematographic record of the transition process (a photograph was taken every 4 seconds). In Fig. 1, *A–F*, six separate photographs have been reproduced. They show clearly the growth of α-crystals (starting at the left) in the original γ-phase. It is of interest to remark that the progressive growth of the newly-formed crystals observed here is essentially different from the sudden formation of martensite needles in austenite, of which a cinematographic record by means of ordinary microphotography has been made by Wiester[3].

Statistical Tests

I HOPE some space will be afforded me for comment on Prof. Karl Pearson's letters[1], since I fear that Prof. Pearson's expressed opinions are not calculated to engender trust in modern statistical methods. These have proved, however, to be of almost universal practical service in minimising the number of times an observer may be misled by his observations.

To commence with, I must answer Prof. Pearson's attack on the logical position of Prof. Fisher and myself. No doubt Prof. Fisher will have something to say on the matter. For myself, I would point out that I never assume that data are capable of proving either the truth or the untruth of a hypothetical cause of our observations. The hypotheses being tested by the data are the following: Do the data indicate that a stipulated hypothesis is not likely to be true; and the reverse hypothesis—do the data *not* indicate this? All statistical tests appear to me to be of this kind. If the data do not indicate—I am not using the word prove—that the stipulated hypothesis is false, the simplest explanation of the data is often that the hypothesis is true. This holds good especially in cases where the stipulated hypothesis is *known* to be a simple and a likely explanation of the data. Such cases are very numerous.

To attempt to cover all hypothetical frequency distributions under the term 'graduation formulæ' is to overlook the fact that, as used, such distributions are of two radically different kinds. The first kind contains those which may be *expected* to have given rise to our observations. Of this kind is the binomial distribution as used for testing bias in dice or throwing of dice. The 'limit' approximations, the normal distribution, Prof. Pearson's Type III, the Galton-Macalister, and the Poisson series, for example, may often be justified as 'expected' explanations; also the straight line, the parabola and the hyperbola and the aggregate of two or more samples. The manner in which they arise in theory may be assumed reasonably to resemble the manner in which they arise in practice in many cases. They are reasonable explanations of our data unless these themselves indicate that they are not. They are not mere graduation formulæ. Of the second kind are the distributions mentioned, together with a host of empirical distributions without simple theoretical basis, when they cannot *explain* the origin or cause of the data. These are truly mere graduation formulæ. They may be very useful as such but do not increase our knowledge of the work of Nature. Of such a kind is Makeham's formula. To use such formulæ to cover a combination of simple *explanations* of observations is to obscure the workings of Nature, not to elucidate them. Yet as mere graduation formulæ they may be ideal.

Prof. Fisher's school of statisticians aims at disentangling combined simple explanations of observations from each other and thus showing up likely *causes* of the data. It is true that in their work it is assumed generally that the observations or simple functions of them are samples from a normal population since the processes of analysis used are then more readily applied. It has been shown, however, that these processes of analysis are often fully justified where the fundamental assumption is not strictly justified, and that the methods are most valuable in minimising the number of times an observer may be misled by data. Mere graduation formulæ cannot ever perform this practical service.

My plea for the use of different levels of significance as criteria of judgment whether data do or do not indicate the unlikelihood of a given hypothesis has an analogy in engineering practice. I mean the use of the 'breaking strain' and the 'working load' of a given kind of rope. At strains near the breaking strain the rope is likely to break: at strains near the working load it is unlikely to break. At intermediate strains the likelihood of breaking cannot be expressed. With full knowledge the 'likelihood' could be expressed as a probability, but such full knowledge is not assumed. Reasonable safety is what is required. My aim is to make a safety-gap between "not shown to be an unreasonable explanation" and "may be considered a likely explanation". The notion does not apply to graduation formulæ, but only to expected causes. If no particular cause is expected it would appear safer to consider always that the sample exactly represents the form of the population. No other population is shown to be even *possible* by the sample itself. This does not preclude the use of a graduation formula to express concisely the general form of the sample and to provide parameter-distributions of very similar form to those applying to the sample-population.

The Accessibility of Discoveries

WE are indebted to NATURE (**136**, p. 606) for an admirably sharp picture from Dr. Royds setting out his discovery (by its emission spectrum, which is in excess of its absorption as an atmosphere) of a layer of oxygen about a thousand miles deep at the base of the solar chromosphere. As he hints, his graph of intensities gives data for the law of distribution of oxygen-density with height: and he refers to a forthcoming *Kodaikanal Bulletin* for a discussion of this fundamental problem. But where is one to find it? When I was a member of the Indian Observatories Committee, the *Bulletin* came to me regularly, and was often of intense observational interest, which I sometimes exploited: but about twenty years ago my place on the Committee was vacated, and I have never seen a *Bulletin* since, nor do I know how to find one. Yet I am still favoured with personal copies of American and French astronomical reports. I am, moreover, by way of contrast, often overloaded with astronomical theory coming from the Royal Society and the Royal Astronomical Society, in the main too complicated analytically for my slow rate of appreciation, as an amateur no longer young. The brief accounts in *Science Abstracts* come therefore as a relief.

This note is presented mainly by way of illustration of current methods, especially in Government publications, against which I used to protest in vain when I had a seat in the House of Commons, of fixing prices on a scale that will recover the expense if all the copies of the edition are sold, regardless of the consideration that this price may prohibit the sale of any copies at all. And then what is the use?

JOSEPH LARMOR.

Surface Structure Beneath the Pacific

IN *Science Abstracts*, *A*, July 25, 1935, No. 2944, which reached here yesterday, one reads that calculations by R. Stoneley from data for an earthquake in Mexico at Apia point to an upper layer of granitic material beneath the Pacific about 10 km. thick resting on ultrabasic rock.

A month ago I came here to relieve Mr. J. Wadsworth (director), on furlough, and have since interpreted records of a few minor shocks with origins less than 10° from Apia. I found, unexpectedly, that velocities given in Jeffreys' "The Earth" (second edition, par. 6–9, p. 116) very closely fit particularly the transverse waves, for upper, intermediate and lower layers, as for thicknesses cited therein. *P* phases are much fainter, but phases corresponding to longitudinal wave velocities appropriate to these three layers do seem to exist too, on some records studied so far.

Such layers exist in New Zealand, but publications read there created the impression that these layers may be absent near Samoa. My deductions, both in method used and as an attempt, have been quite independent of those by Stoneley. However, both results are favourable to a 10 km. granitic layer. References available here so far leave a doubt as to common agreement on the intermediate layer, because some writers call only the lower layer "ultrabasic". In my judgment, Wiechert records here are as clear on this point as are some published by Jeffreys cited earlier.

Oct. 15.

Points from Foregoing Letters

In order to find out at what height of the atmosphere large-scale mixing (winds) ceases to occur, Prof. F. A. Paneth and E. Glückauf have determined the percentage of helium in samples of air obtained by means of sounding balloons sent up from Kew. Up to a height of 18 km., the percentage remains practically constant, but at 21 km. a noticeable increase (8 per cent) was observed. The authors ask the co-operation of stratosphere investigators in various parts of the world in order to obtain small samples of air from high altitudes.

The intensity of cosmic rays in the upper atmosphere—up to a height of 22 km., corresponding to an atmospheric pressure of 37·5 mm. mercury—has been determined by Prof. E. Regener and G. Pfotzer with an apparatus recording only vertical rays. The curve shows a 'hump' in the intensity at a height corresponding to 300 mm. pressure, and a maximum at 100 mm. pressure, apparently due to primary or secondary components of cosmic rays. At greater heights there is a rapid fall in the intensity of vertical cosmic rays, but the authors expect that a certain definite intensity of cosmic rays (coming from interplanetary space) will be found at the top of the atmosphere.

By means of the new technique of registering the tracks of ionised particles upon photographic plates in the emulsion of which a small amount of a suitable substance (in this case, samarium sulphate) has been incorporated, Prof. H. J. Taylor has confirmed the emission of α-particles by samarium. The element also emits particles of greater penetrating power, which appear to be positively charged hydrogen atoms (protons).

The energy and relative number of positive electrons from a radioactive source has been determined by Prof. A. I. Alichanow, A. I. Alichanian and M. S. Kosodaew, and compared with the similar 'positron spectrum' produced by γ-rays in thin lead foil. From these, and from further results obtained by irradiating lead with γ- and β-rays together and with γ-rays alone, the authors conclude that when lead (or aluminium) is submitted to rays from such a source, most of the positrons produced are due to the γ-rays of radium C.

Dr. G. I. Finch and A. G. Quarrell submit photographs and measurements of 'extra' rings obtained by electron diffraction—by passing electrons through thin films of metals. The rings differ according to the nature of the metal and the treatment it has received. The authors emphasise that when studying the absorption of gases by metals by this method, it is important to exclude the formation of 'extra' rings due to the presence of grease or to amalgamation.

Prof. L. Vegard states that he has obtained good X-ray diffraction photographs by the powder method with γ-oxygen, one of the three forms of solid oxygen. He deduces that its crystalline structure may be represented by a cubic cell containing eight rotating oxygen molecules grouped into pairs (O_2–O_2), the distance between the two molecules of a pair being somewhat smaller than the minimum distance between neighbouring pairs. γ-Oxygen, Prof. Vegard states, represents the closest cubical packing of pairs of oxygen molecules, and its structure is similar to that of α-nitrogen and α-carbon monoxide.

Cinematographic records showing the transition and growth of crystals of α-iron (magnetic) in the original γ-iron (non-magnetic) in the neighbourhood of the transition point 900° C. have been obtained by Dr. W. G. Burgers and J. J. A. Ploos van Amstel, by means of an 'electron-microscope' with one magnetic lens.

Sir Joseph Larmor directs attention to the difficulty and expense involved in obtaining scientific periodicals and other publications with restricted circulation, and protests against the high price of certain Government publications.

Research Items

Kisi of Liberia

AMONG ethnographical papers presented to Section H (Anthropology) at the Norwich meeting of the British Association was an account by Miss E. D. Earthy of the Kisi of Liberia, a tribe little known to anthropologists, which speaks a semi-Bantu language, although surrounded by peoples of the Sudanic linguistic group, and has been little affected by European culture contact, being economically independent of foreign civilisation. Their villages are built on hill-tops in the forest, where the borders of Liberia, French Guinea and the Sierra Leone Protectorate meet. The people are probably of mixed Hamitic-Negro stock with a strong pygmy strain in some of the villages. The ruling class are of fine physique, and live by hunting, fishing and agriculture. Their chief food is rice seasoned by palm oil. Their currency is twisted iron rods, used for the bride-price and commerce in the markets. The paramount chief rules over a large number of clans and sub-clans. The tribe is totemic, and inter-totem marriage is forbidden. Polygamy prevails. Names up to the sixth child of either sex show the order in which the children are born. Both sexes have to undergo a severe course in the bush initiation school. Their religion is a mixture of animism and totemism. An important sacrificial rite takes place when the rice harvest is over. The sacrifice is performed on the top of a high and inaccessible mountain, of which the name is never divulged to strangers. The office of priest, as is that of trumpeter, is hereditary. The sacrifice is a sheep, which is slain by the priest, the blood being collected in a bowl held by a member of a special family, in which the office is hereditary, who touches the hand of each worshipper with the blood, which the latter must then rub over his face, especially the forehead. The priest then prays for the prosperity of the people and country. In returning, no one must look back at the mountain or fall, otherwise he will die.

Prehistoric Copper and Bronze

SOME further results of the analyses of copper and bronze from excavations in Sumeria and from other archæological sites in the Near and Middle East are given in the report of the Committee on Sumerian copper presented to Section H (Anthropology) at the recent Norwich meeting of the British Association. A chronological arrangement by Dr. Plenderleith of the results of the Committee's examination of specimens from Ur shows that the single object examined from the al'Ubaid period is of nearly pure copper; of eleven objects from the Royal cemetery, nine are bronze, while two contain only small proportions of tin; and that while both copper and bronze occur in the Sumerian period, objects of the Sargonid period are either of copper or contain only a small proportion of tin. To these must now be added four objects from Jemdet Nasr in which copper varies in percentage from 48·18 to 67·23; all show arsenic, varying from 0·20 to 0·93, and two show nickel in the proportion of 0·02 and 0·075 respectively. A copper rod from the same site, which was less corroded, gave percentages of copper, 82·33, nickel, 0·05, arsenic, 0·34, sulphur, 0·11. In none of these was tin present. In twenty-two specimens supplied by the Oriental Institute of Chicago from Tell Asmar, Khafaje and Alishar Huyuk, nickel was absent in two samples only, from Alishar. The Akkadian material from Tell Asmar showed no tin, and this metal was also absent from two objects of early dynastic age from Khafaje, and present only in the proportion of 0·40 in an early dynastic chisel from Tell Asmar. Some interesting results were obtained from copper objects from Tell Duweir (Lachish), Palestine. The metal had clearly come from sources other than those from which the Mesopotamian metal had been derived. It was, therefore, of special interest to examine ores and slag obtained from the Arabah district by Mr. J. L. Starkey. The ores proved to be a mixture of azurite and malachite with no tin, arsenic, nickel or lead.

The 'Rain Frog' of China

THE egg-laying habits of the rain-frog, *Kaloula borealis*, are correlated with amount of rainfall and temperature, so that under proper temperature conditions (something over 20° C.) a minimum threshold of about 40 mm. of rainfall is necessary. This amount of rainfall does not indicate the depth of the pools needed for egg-laying, since these may be drainage centres of larger areas (Ju-chi Li and Chang-shan Lin, *Pekin Nat. Hist. Bull.*, **10**, 45; 1935–36). Larval development provides another aquatic complication, for unless the pool in which the eggs are laid lasts through three weeks, the larvæ cannot complete their development. Furthermore, the larvæ feed upon unicellular organisms, and so are dependent upon the influx of organisms and their multiplication, which again depend upon washings from the heavy rainfall and appropriate temperature. The food habits of the adults are somewhat similar to those of frogs and toads, and since they prey upon injurious ants belonging to the Formicidæ, it is possible that thereby they benefit mankind.

Malformation in Adriatic Copepods

FOLLOWING his previous work on the same subject, Dr. Fritz Früchtl summarises his records of malformation in various appendages of several marine copepods in his paper "Beitrag zur Kenntnis der Missbildungen adriatischen Planktoncopepoden" (*Sitz. Akad. Wissen. Wien.* Math.-naturwiss. Klasse. Abt. I. Mineralogie, Biologie, Erdkunde, **143**, 5 bis 7 Heft; 1934). These include abnormal antennæ, caudal furca and legs, the last being most frequently affected. *Temora stylifera* has been found by the author to vary considerably in both the absolute and relative length of the caudal furca and the relation of the branches to one another; but there are also abnormalities in the setæ, and a peculiar form is here shown in *Temora longicornis*, in which one branch is quite unlike the other and much shorter, the armature differing greatly. A table is given of all the malformations seen, with dates and localities, involving ten species of the genera *Calanus*, *Calocalanus*, *Aetidius*, *Temora*, *Acartia*, *Sapphirina* and *Corycoeus*. It is evident that such malformations are of not infrequent occurrence, and it is of importance to note these carefully when observed.

Deterioration of Cut Sugar Cane in Egypt

ALTHOUGH the loss in sugar value of the cane during a delay between harvesting and milling has been mentioned by investigators in other sugar-producing countries, the observations made by Dr. Rosenfeld in the Egyptian field cannot be over-emphasised from the planter's point of view (Bull. 155, Ministry of Agriculture, Egypt). Certainly the fact that a four days delay in delivering the cut cane means the evaporation of all the profits on the harvest serves to give point to the investigations at Mallawi. Though the extent of loss varies with the type of cane grown, yet in no case is it small enough to make a delay in delivery anything but a serious risk—even in the coolest harvest time when deterioration is least. At the same time, in cases of unavoidable delay, certain elementary precautions will minimise the loss. Of the actual manner of deterioration, the 'masking' of the remaining sucrose by the invert sugar, glucose, is perhaps the most interesting, for it means that loss is not only due to inversion but also to the formation of the glucose on the sucrose crystals, so that the latter cannot be extracted. From the facts put forward it seems that a delay in harvesting, until immediate transport of the cut cane is assured, is at any time preferable to a hold-up between the harvest and delivery of the cane.

Production of Vegetables for Canning

SOME problems in the growing of vegetables for canning was the subject of a paper read on September 6 by Mr. W. B. Adam to Section M (Agriculture) at the Norwich meeting of the British Association. The canning industry in England has developed rapidly since 1928, and although the present output is still about one twentieth of that in the United States, it has now reached approximately 100 million cans per year. The research work, conducted at Campden, deals with all aspects of the industry, selection of variety being one of the most important lines of work, particularly as vegetables for canning are grown under contract, and a steady supply throughout the season is essential. Biochemical investigations are also being carried out to determine the age at which the vegetables can satisfactorily—the sweetness of green peas, for example, is lost after a certain stage in their development owing to the sugars being replaced by starch. Technical problems inevitably play a prominent part in the industry, questions of colouring being among those which have received special attention, and a new process for the treatment of green vegetables has been evolved at Campden. Vegetables are canned within a few hours from picking, so that they are actually preserved in a fresher condition than those bought on the market for home cooking. Further, biological investigations in the United States have shown that canned vegetables generally have a higher vitamin value than those cooked in the usual fashion, so that from a dietetic point of view the vegetable canning industry is entirely justified.

Air Seasoning of Indian Timbers

WITH the increasing demand for timber, the great waste due to the common use in the tropics and sub-tropics of green timber has gradually received recognition. If insect attack is left out of the question, the material in log form is subject to splits, shakes, end-cracks and decay, whilst converted timber owing to bad stacking and other evils incurs even greater loss by depreciation. Furthermore, the climate itself, with the great degree of variation in temperature and moisture throughout the year, results in enormous waste, both before and after the finished article has been turned out. The difficulties in India, as is pointed out in Dr. S. N. Kapur's "Manual on the Air Seasoning of Indian Timbers" (Forest Research Institute, Dehra Dun. Delhi: Manager of Government Publications, 1934), are due to the absence of any large-scale wood-using industries in the country other than railway workshops and ordnance factories, most of the wood-working industries in India being carried on in a small way, usually employing manual labour, their requirements of timber being small and consisting of a variety of species and thicknesses which preclude the installation of any expensive plant like seasoning kilns. It is for this reason that the author holds the opinion that an improvement in the general wood utilisation in India can only be brought about by the introduction of proper methods of air seasoning. It is, therefore, with this question of air seasoning that the manual deals under sections devoted to moisture, shrinkage, the mechanism of wood seasoning, seasoning defects and their causes, the practice of girdling trees before felling (as is usually done with teak), water seasoning, green conversion, requirements of seasoning such as sheds, etc., practical methods of stacking timbers for seasoning, and the seasoning of railway sleepers. In a second part, the author deals with the air seasoning characteristics of various species.

Caledonian Orogeny of North-East Greenland

IN his preliminary report on this subject, C. E. Wegmann presents a discussion of the problems involved which is a model of its kind (*Medd. om Gronland*, 103, No. 3, 1935). He shows that the sediments of the East Greenlandic geosyncline (up to 9000 m. thick over a width of not less than 200 km.) indicate a deep-going interruption of the Greenlandic shield on such a scale that the geosyncline must be looked upon as a tectonic element of first order in the architecture of the earth's crust. In Caledonian times, immense migrations of sub-crustal material due to igneous activity took place. In part, the material penetrated the rocks by a process of 'molecular migration', leading to the formation of large felspar phenocrysts, 'augen gneisses' and migmatites in great variety. Wegmann draws a distinction between a migration of elements through a stationary framework and a migration through a framework undergoing internal and external movements. He points out that where quartzites and schists are interwoven with felspar, not all the material has migrated, but only the part of it which rendered possible the formation of the felspar. When crystallisation outlasts the movements, the relict structures disappear, and the result is a granite of more or less massive character which nevertheless is itself only a mixed rock that has migrated as a mobile mass from its original place of development. Such granite is not to be regarded as the source of the migrating elements. The conclusion is reached that igneous phenomena so transformed the infra-structure of the Caledonian material that the conception of the mountain complex as being of germanotype character is deprived of support based on the opinion that the basement rocks are rigid, undeformed Archean masses. Every

line of evidence indicates that the mountain chain must be regarded as a deep-going interruption of the Pre-Cambrian shield. The later history is briefly summarised; further problems are indicated; and a detailed memoir on the whole—which will be eagerly awaited—is promised at a later date.

Geography of the North Sea Bed

A BATHYMETRICAL map of the North Sea floor compiled from the Admiralty Charts accompanies a paper on the subject by Mr. R. G. Lewis in the *Geographical Journal* of October. The map brings out a number of features that are often overlooked and raises a number of problems. River erosion explains many of the features, and Mr. Lewis traces what he calls the Silver River, the extended Rhine, to the west of the Dogger Bank and then northwards by changing courses. But more difficult to explain are certain features that are not clearly the outcome of river work, and suggest tectonic movements. There are a number of narrow elongated depressions. In the English Channel there are comparable troughs not connected with the river that once flowed there. Mr. Lewis suggests that these may be due to folds on the floor which have disappeared. A fold would hold up the water behind it. The water would flow along the course of the fold in a deepening channel until it found an outlet. Eventually the flow of water would destroy the anticline. Another problem that awaits explanation is the failure of the sand and gravel which lies over most of the floor to fill these depressions. The small elevations south-east of the Dogger Bank suggest not erosional features so much as heaps of moraine matter.

Specific Heats of Crystals

THE August 1 issue of the *Proceedings of the Royal Society, A*, contains the Bakerian Lecture by Prof. R. H. Fowler on "The Anomalous Specific Heats of Crystals". The lecture contains a general survey of the theoretical position and gives a new tentative theory of the contribution made by molecular rotation. The theory of specific heats is primarily the construction of the free energy function of the solid in terms of an assumed model for the crystal lattice, and this in turn involves the construction of a 'partition function' giving the probability of the different energy states. Assumptions were made by Einstein and by Debye which led to partition functions and to specific heat formulæ, and Debye's work has been recently extended by Blackman in a detailed consideration of cubic lattices. Fowler classifies as 'anomalous' any variation of the specific heat which does not arise from normal modes of vibration (small oscillations) of the atomic lattice. Such anomalies must arise in any case in which there is not a monotonic increase of specific heat with temperature. He classifies them into three types. In the first type the anomalous specific heat occurs around a certain temperature and, in some cases, in any event, the extra specific heat is used in exciting the atoms, for example, to states of higher orientational energy. The second type is distinguished by sudden disappearance of the anomaly above a certain temperature, and its explanation involves co-operative interactions between atoms of the lattice. Examples are the ferromagnetic interaction disappearing above the Curie point and the order-disorder transitions recently described by Bragg and Williams. The rotational contribution specially discussed by Prof. Fowler is of this type. The third type is the discontinuous absorption of heat at a transition temperature between phases.

Use of Electron Lenses for β-Rays

O. KLEMPERER (*Phil. Mag.*, Oct.) has applied to β-ray spectroscopy the known focusing effect of a short coil on electron beams passing axially through it. A short coil, with or without an iron mantle to concentrate the field, was used to focus the β-rays from a small radioactive source (Th *C*) on the window of a Geiger counter placed about a metre away. By varying the current in the coil, the power of the lens may be varied, and different β-ray energy groups brought into focus. This method is analogous to the focal isolation of light according to the method of Rubens and Wood, and good β-ray spectra could be secured. A further development was the construction of a magnetic analogue of an ordinary spectroscope, with magnetic lenses for telescope and collimator and a uniform magnetic field for a deflecting prism, but the experiments have not yet been completed.

Cerin and Friedelin

By extracting ground cork with alcohol, Chevreul in 1807 obtained a material which he believed to be a wax and called cerine. In 1898, Thoms obtained it in a pure state and believed it to be related to the phytosterols because of its colour reactions. Another constituent of cork extract was prepared in 1899 by Istrati and Ostrogovich who, in return for the interest taken by Friedel in their investigation, named it after him. N. L. Drake and R. P. Jacobsen (*J. Amer. Chem. Soc.*, **57**, 1570; 1935) have now reinvestigated these materials. They find that the empirical formulæ of friedelin is $C_{30}H_{50}O$ and that of cerin $C_{30}H_{50}O_2$, plus or minus 2H, within the limits of error. The hydrocarbon to which friedelin is related is $C_{30}H_{52}$. The molecular weight was determined by the saponification of several enol esters. The colour reaction was not due to pure friedelin but to a sterol present as impurity. The presence of a double bond in friedelin is inferred from molecular refraction data and the colour reaction with tetranitromethane. Addition of bromine and hydrogenation were not effected, but one of the double bonds of ergosterol behaves in this way.

A Rectifying Valve for Radiological Work

MESSRS. PHILIPS METALIX, of 145 Charing Cross Road, W.C.2, have sent us a booklet on high tension rectification which should prove useful to the radiologist and the radiological engineer. They will find in it an explanation of the functioning of rectifying valves and the relative efficiency of various types. There is also given an account of the gas-filled valve, their latest production. They point out that every operation in the production of radiograms, from the time of switching on the mains until the removal of the film from the fixing bath, must be performed with the highest efficiency, if consistently good results are to be obtained. As a rule, the rectifying valve does not receive the consideration it deserves, and yet its performance is essential to good work. It often causes additional expense by wastage of films, and its failure can irremediably damage the X-ray tube and other valves in the circuit. The technical matter contained in this booklet will assist the radiologist in understanding present-day equipment.

International Institute of Documentation

COPENHAGEN CONGRESS

MICROPHOTOGRAPHY, as a means of distribution of data, rivalled such veteran subjects as decimal classification and cataloguing in discussions at the Copenhagen Congress of the International Institute of Documentation, on September 10–14. Marking the fortieth anniversary of the world bibliographic or documentation movement that arose out of the 1895 International Congress of Bibliography, this thirteenth Congress in a part of its programme provided, in effect, a 'clearing house' for current progress upon microphotographic duplication as visualised or practised in many lands.

Nearly fifty reports were presented to the Congress, and the advance volume of the Congress is an important addition to the literature of finding, classifying, preserving and distributing written information.

Held under favourable weather conditions of Copenhagen's waning summer and arranged with Danish hospitality by the local committee, of which Oscar Thyregod was the leader, the Congress brought together representatives from about a dozen countries to discuss problems of mutual interest in a medley of German, English and French.

The president of the Congress, Dr. J. Alingh Prins, president of the Dutch Patent Office, said in an opening address that documentation has three stages: (1) investigation as to what has been written about a subject or put into the form of a document; (2) filing the material so that the place of each subject may be determined instantly; (3) placing the material at the disposal of those who need it.

With regard to filing and classifying material, Dr. Prins said: "Collected material, which is not filed, is of little importance. What system of classification should be adopted? In theory this does not matter; the main thing is, that *one and the same* system is used nationally and internationally. We are convinced that the most serviceable system is the decimal system, invented by Melvil Dewey, and considerably improved in Brussels by Lafontaine and Otlet and since then brought to a high stage of development by the international classification committee of our Institute under Donker Duyvis, with the co-operation of a large number of prominent persons from different countries."

Decimal classification, and the sessions of the committee charged with keeping the system in step with advancing knowledge, bulked large on the programme, with reports on its use in Germany, Switzerland, England, America, Holland, Norway, Sweden, Denmark, Finland and other countries.

Of fundamental importance was the paper presented by Dr. S. C. Bradford, keeper of the Science Library, London, which analysed the situation surrounding library service in the general field of science, including societies, research institutions, business and industrial organisations, etc., and came to the conclusion that a central library of science and technology would alleviate many of the disabilities under which scientific and technical work is carried out at the present time. A communicated paper by E. Lancaster Jones explained the classified bibliography operated by the Science Library. A paper by Watson Davis, director of Science Service, Washington, told of suggested applications of microphotographic duplication in making available existing literature in libraries and publishing scientific papers and monographs that cannot at present be issued promptly or in full.

Television was foreseen as a future tool in library service by Dr. Walther Schürmeyer, director of the Library of Art and Technology at Frankfurt, whose paper stressed primarily the possibility of applying photographic methods to the distribution of information from libraries.

How photographing of library cards upon motion picture film, and making enlargements from these convenient and inexpensive negatives, is done was the subject of a paper presented by Paul Vanderbilt, librarian of the Pennsylvania Museum of Art, who used this technique experimentally in connexion with a union catalogue of Philadelphia libraries. Experience with use of film copies and microphotoprints at the Huntington library in America was reported in a communication from Dr. L. Bendickson, and there was also a communicated report on photographic methods in connexion with documents and libraries by Dr. H. Joachim, director of the Zeiss Ikon concern at Dresden.

The question of the photocopying of books and literature in view of the copyright laws and rights of authors was the subject of one session. The standardisation of the format for film copies so as to simplify the exchange of film copies between different countries was urged in resolutions, with a recommendation for the use of 35 mm. film, perforated both sides, with width of image of 24 mm. and a reduction of approximately 12 to 1.

The International Institute of Documentation reaffirmed at the Congress its desire to "work with every international organisation which pursues related aims, for example, in the field of publication and of the working organisation of special publication such as film".

Several related efforts in the field of documentation were made known and explained by documents distributed at the congress. The International Institute of Intellectual Co-operation of the League of Nations reported the progress in its endeavour to co-ordinate world efforts in the field of documentation, and the International Office of Chemistry, Paris, made available a report, "L'Utilisation du Film comme Support de la Documentation", giving proceedings of its April conference.

The prevailing spirit of the meeting was the hope that there would be co-operation effected through the International Institute of Documentation with both international organisations dealing with particular fields of knowledge and national organisations that bring together the documentation activities in various geographical areas.

Mingled with the meetings there were visits to libraries, publishing firms, schools and places of historical interest. These events and lunches arranged in famous Copenhagen restaurants allowed informal discussions of mutual problems in many languages, a function of any Congress that is often even more important than the set and formal proceedings.

International and Absolute Electrical Units

AT the recent meeting in Paris of the International Committee of Weights and Measures, the subjoined draft memorandum relating to international and practical absolute electrical units was approved for publication. The document makes clear the position of the Committee and shows that for practically all engineering purposes the change to the suggested new units involves no difficulty.

1. In accordance with the authority and responsibility placed upon it by the General Conference of Weights and Measures in 1933, the International Committee of Weights and Measures has decided that the actual substitution of the absolute system of electrical units for the international system shall take place on January 1, 1940.

2. In collaboration with the national physical laboratories the Committee is actively engaged in establishing the ratios between the international units and the corresponding practical absolute units.

3. The Committee directs attention to the fact that it is not at all necessary for any existing electrical standard to be altered or modified with a view to making its actual value conform with the new units. For the majority of engineering applications the old values of the international standards will be sufficiently close to the new for no change even of a numerical nature to be required. If for any special reason a higher precision is necessary numerical corrections can always be applied.

4. The following table gives a provisional list of the relations between the international units and the corresponding absolute practical units, to the fourth decimal place. Since differences exist between the standards of the international units held by the various national laboratories affecting the fifth decimal place, and, further, because all the laboratories which have undertaken determinations of the values of their standards in absolute measure have not yet obtained final results, the Committee does not consider it desirable for the present to seek a higher precision. At the same time it hopes that it will be possible to extend the table of these ratios with a close approximation to the fifth decimal place well before the date fixed for the actual substitution of the practical absolute system for the international system.

Sixth International Congress of Entomology

THE Sixth International Congress of Entomology, attended by some four hundred delegates, was held at Madrid on September 6–12. On account of the financial restrictions, some of the mid-European countries were not so fully represented as at past Congresses, but despite these difficulties, entomologists from practically every country were present. The opening session had as its chairman His Excellency the President of the Spanish Republic, who greatly impressed the Congress by his personality and warm welcome.

The Congress itself was presided over by that veteran entomologist, Dr. I. Bolivar Urrutia, director of the Museo Nacional de Ciencias Naturales, Madrid. A heavy programme, divided into sections devoted to general, ecological, agricultural, forest, medical and veterinary entomology, with, in addition, sessions allotted to apiculture and nomenclature, provided something of interest for everyone, and considering the warm weather and the variety of languages in which the papers were presented, the meetings were very well attended. As these papers will be published and may then be read and digested in the quiet of the study, it is unnecessary to detail them severally by name here, but we might say that some of the illustrated ones, as, for example, Dr. F. W. Edwards's account of the British Museum Expedition to Ruwenzori, Dr. B. Mayne's film of the life-cycle of the malarial parasite in the body of the mosquito, Dr. Escalera's one on apiculture, and Dr. Kamal's 'talkie' of *Prodenia littoralis* seemed to be much enjoyed. The Sunday sessions were held at El Escorial, and though most of the delegates spent their time exploring the beautiful and historic buildings and collecting their favourite families of insects in the neighbourhood, the meetings were well attended by the more enthusiastic seekers after knowledge.

Only a small part of the time, however, was devoted to serious scientific matters. The President of the Republic received and entertained the Congress at the Palace, and entomologists must have felt just a little awed on walking up the grand staircase between the lines of fully-accoutred lifeguards; the Mayor of Madrid entertained it to music, and during the subsequent proceedings, outlined to some of the members in excellent English the town-planning schemes of the city; the organisers, to a charming *fiesta* of Spanish art, to lunches and *merienda* and a final evening banquet, and bore the expenses of excursions to such historic places as El Pardo, El Escorial (as mentioned above) and Toledo. A whole day was devoted to a sight-seeing trip to the Guadarramas, the Alpine Biological Station being visited *en route*, the Forest of Valsain, San Ildefonso (La Granja) and Segovia, where members gazed with delight on the beautiful west façade of the cathedral lit up by the setting sun. An afternoon visit to

Aranjuez provided an opportunity of viewing the luxuriant growth produced by irrigation.

Honorary doctorates were conferred by the University of Madrid on Prof. M. Caullery, University of Paris; Dr. R. Goldschmidt, director of the Kaiser-Wilhelm-Institut, Berlin-Dahlem; Dr. R. Jeannel, Muséum Naturelle d'Histoire, Paris; Prof. F. Silvestri, Portici, Italy; and Mr. B. P. Uvarov, Imperial Institute of Entomology, London.

During the week preceding the meeting some of the members went on an excursion through the Picos de Europa under the guidance of Dr. F. M. de la Escalera, and after the Congress others visited southern Spain and the Canaries.

It is to the admirable organisation of the secretary, Dr. C. Bolivar y Pieltain, and his committee that the success of the recent Congress was due, and the lavish hospitality set a standard which few countries could hope to live up to, but there will remain in our memories also the courtesy and helpfulness of the people of Madrid to those who were ignorant of both customs and language.

It was decided to hold the seventh International Congress of Entomology in 1938 at Berlin under the presidency of Dr. E. Martini, and it is expected that the ninth will be held at Amsterdam in 1945 to coincide with the centenary celebrations of the Dutch Entomological Society.

Tercentenary of the University of Budapest

THE recent celebration of the tercentenary of the Royal Hungarian Péter Pázmány University of Budapest was worthy of a people that has played a great part in the intellectual and political life of Central Europe. The Hungarian nation began its corporate life in 896 when the Magyars entered the country from the plains of southern Russia and the slopes of the Carpathian mountains. In the fourteenth century, and again in the fifteenth century, universities were founded, but they lasted only a comparatively short time and none survived more than a few years after the disastrous Turkish victory in 1526. In 1635, when the greater part of Hungary was still under Turkish rule, Péter Pázmány, Archbishop of Gran (Esztergom) and later Cardinal, Prince Primate, founded a new university at Nagyszombat; more than a hundred years later it was transferred to Buda and in 1783 to Pest. The two cities Buda and Pest were united in 1872. Since 1922 the University has been known as the Royal Hungarian Péter Pázmány University of Budapest. This leading university of Hungary has now more than 5,000 students: its success is a remarkable demonstration of the intellectual aspirations and the national spirit of a nation which was deprived by the Treaty of Versailles of the greater part of its territory.

Unfortunately no list of delegates was given to the representatives of foreign universities and academies who assisted at the celebrations, and it is therefore impossible to mention the names of the foreign delegates. The celebrations began in the evening of Wednesday, September 25, with a reception in the Hotel Gellért. On the Thursday morning, the delegates and the university staff met in the great hall of the University and went in procession to the neighbouring University Church, where his Eminence the Cardinal Prince Primate, Dr. Jusztinian Serédi, assisted by a brother cardinal from Vienna and several bishops, celebrated Mass: Liszt's music was beautifully rendered. It was a memorable service. At the conclusion of the service the foreign delegates signed their names in a special commemorative book and, after visiting the University library where a collection of charters and old books relating to the Péter Pázmány foundation was exhibited, were entertained at luncheon in the Grand Hotel Hungaria, where several speeches were made by foreign ministers and some of the delegates. In the evening an invitation performance at the Opera House, illustrative of Hungarian drama and national life, was followed by a reception given by the Minister of Education.

On Friday morning, September 27, the delegates of the University staff met under the central dome of the Parliament House to take part in the principal academic event of the celebrations. His Serene Highness, the Regent of the Kingdom of Hungary, their Royal Highnesses the Archduke Joseph and his son, the Archduke Francis Joseph, were present. The Rector Magnificus, Dr. Julius Kornis, opened the proceedings and, after other members of the University had spoken, a representative of the University of Bologna spoke on behalf of the foreign universities, and the foreign secretary of the Royal Society of London was asked to speak on behalf of the whole body of academies. The latter paid a special tribute to the memory of one of the greatest sons of Hungary, the founder of the Hungarian Academy, Count István Széchenyi, "a man whose enlightened attitude towards learning, breadth of vision and spiritual ideas are worthy of our most respectful and grateful homage". Delegates were then called upon to present their addresses: English, Scotch and Welsh universities were represented, universities of the Irish Free State, of Austria, Belgium, Egypt, Denmark, Latvia, France, Finland, Germany, Greece, Holland, Italy, Norway, Poland, Spain, Sweden, Switzerland, the United States of America, and other countries.

In the afternoon some of the delegates were present at the laying of the foundation stone of a new University hospital for lung diseases. Each medical professor has his own University hospital. An informal entertainment was given by students in the evening.

In the morning of September 28 a large number of honorary degrees were conferred. Unfortunately, the two English graduands, Sir Charles Sherrington and Sir F. Gowland Hopkins, were not able to receive their degrees in person.

In the afternoon the Regent received the delegates in the Royal Palace and talked with many of them with equal fluency in German, French and English. In the evening the visitors had the privilege of hearing Beethoven's "Missa Sollemnis" with an impressive accompaniment of a liturgical drama produced by the director of the National Theatre.

The celebrations were admirably organised: the attractive Hungarian national uniform worn by the University officers, the brilliant robes of the cardinals, the white, brown and black vestments of members of monastic orders, and the variety and wealth of colour represented by the gowns and hoods of delegates contributed to the gaiety and splendour of a great occasion. The celebration was an important national event which made a very favourable impression upon the international company and created a feeling of sympathetic interest in the welfare of a courageous nation. Delegates who had the good fortune to be guests of the University in one of the most beautiful of European cities will long retain the pleasantest memories of the friendliness of the Rector Magnificus, the Ministers of State and the University officers with whom they came into contact.

Educational Topics and Events

CAMBRIDGE.—The managers of the Balfour Fund have made a grant of £100 to F. R. Parrington, of Sidney Sussex College, for researches on the fish fauna of the Achenarass quarries.

It is proposed to confer the degrees of M.A. and M.D. *honoris causa* upon Dr. J. A. Ryle, regius professor of physic, and the degree of M.A. on Dr. G. P. McCullagh, University demonstrator in pathology.

LEEDS.—Mr. Frank Stuart Atkinson has been appointed to the chair of mining, in succession to Prof. Ritson, who takes up his appointment at the Royal School of Mines at the beginning of January next. Mr. Atkinson is a qualified mining engineer. He was educated at Chesterfield Grammar School and the University of Sheffield, and has had a long and varied experience of practical work; he has been manager of the Hatfield Main Colliery since February 1927.

LONDON.—The title of Edwards professor of Egyptology in the University has been conferred on Mr. S. R. K. Glanville, in respect of the post held by him at University College.

The title of emeritus professor of bacteriology in the University has been conferred on Dr. J. W. H. Eyre, formerly University professor of bacteriology at Guy's Hospital Medical School; and that of emeritus professor of civil engineering in the University on Mr. A. H. Jameson, who has retired from the University chair of civil engineering at King's College.

OXFORD.—Dr. John Mellanby, professor of physiology in the University of London, has been appointed to the Waynflete professorship of physiology, to hold office from January 1, 1936.

The Council of the Institution of Naval Architects has made the following awards: 1851 Exhibition Commissioners post-graduate scholarship in naval architecture, £250 per annum for two years, to Mr. Harrison Lackenby, of Armstrong College, Newcastle-upon-Tyne; Sir William White post-graduate scholarship in naval architecture, £150 per annum for two years, to Mr. Ian C. Bridge, of the University of Glasgow; Earl of Durham Prize, to Mr. D. H. Burnett, of H.M. Dockyard, Devonport.

Science News a Century Ago

Meeting of the Entomological Society

AT a meeting of the Entomological Society held on November 2, 1835, the president, the Rev. F. W. Hope, being in the chair, several communications were read, one of which was a notice of the ravages of the black caterpillar upon the leaves of the turnip in Kent, by W. W. Saunders. "Relative to this communication Mr. Yarrell stated some additional circumstances regarding the destruction of the turnip last summer and autumn, by the insect in question, which were the larvæ of a species of Saw-fly (Tenthredinidæ) termed by the farmers 'the blacks'. In the dry summer of 1818 these insects were equally destructive, and so rapid is the destruction caused by them, that in a couple of days a fine field of turnips is reduced to the mere skeleton of the leaves. Mr. Hope gave an account of some other insects which had this year been equally injurious to the turnip in Shropshire, Herefordshire and Worcestershire and suggested several plans for their destruction."

Beginning of Faraday's Researches on Electrostatics

"HAVE been thinking much lately," wrote Faraday in his Diary on November 3, 1835, "of the relation of common and voltaic electricity; of induction by the former and decomposition by the latter, and am quite convinced that there must be the closest connexion. Will be first needful to make out the true character of ordinary electrical phenomena. The following notes are for experiment and consideration.

"Does common electricity reside upon the surface of a conductor," he went on, "or upon the surface of the electric in contact with it? I think upon the electric, and must work out the results on that view. It will make a great difference in the collation and connexion of the various electrical phenomena and also in their explication."

Then follow a dozen or so pages, written on the same day, of speculation on such points as the effect of the form of a conductor on its electrical behaviour, on the relation of two surfaces under induction, and on the state of the dielectric, or as he called it, the "electric", during the persistence of inductive action. Together with the queries are ideas and suggestions for experiments by which they may be tested.

This was the beginning of Faraday's researches on electrostatics. The work on electrochemistry had been completed early in the year, and very little had been done during the summer months. Now, in the autumn, he was ready to begin again, and the first step was to put down on paper the ideas for experiment that had come crowding to his mind; next, in a few weeks time, he would be devising the necessary apparatus.

New Session of the Geological Society

ON November 4, 1835, the Geological Society held its first meeting of the session. A paper by Dr. Buckland was first read on the discovery of the beaks of four extinct species of fishes, referable to the genus *Chimæra*, and found in the Oolitic and Cretaceous series of England. The paper was accompanied by an appendix by M. Agassiz, describing the distinctive characters of each species.

A communication by Mr. Murchison was next read, containing an account of the quarry in the new red sandstone at Rhone Hill, near Dungannon, in which

numerous ichthyolites had been found, and of the geological structure of the adjacent district. A slab of the sandstone, presented to the Society by Mr. Greer, the proprietor of the quarry, was laid upon the table, and exhibited on a surface not exceeding two feet square impressions of above 250 fishes.

M. Agassiz afterwards gave a succinct account of his researches on English fossil fishes. The number of species which he had noticed amounts to about 400, of which 300 were new, and he stated that the specimens, too imperfect to be described at present, announce the existence of a still greater number of species.

King of Denmark's Medal for Astronomers

IN the *Athenæum* of November 7, 1835, was a statement regarding the founding by the King of Denmark of a gold medal, of the value of twenty ducats, to be given to the first discoverer of a telescopic comet. The discoverer who desired to be considered for the award, if in any part of Europe except Great Britain, had to send immediate notice of his discovery to Prof. Schumacher, of Altona, and if in Great Britain, or any other quarter of the globe except the Continent of Europe, to Francis Baily, of Tavistock Place, London. The medal was to be adjudged twelve months after the discovery of the comet, and no claim could be admitted after that period had elapsed. Prof. Schumacher and Mr. Baily were to determine whether a discovery was to be considered established or not, but if they differed in opinion, Dr. Olbers, of Bremen, was to decide between them.

Societies and Academies

PARIS

Academy of Sciences, September 30 (*C.R.*, 201, 533–572). CHARLES CAMICHEL, LÉOPOLD ESCANDE, ETIENNE CRAUSSE and JEAN BAUBIAC: Linear hydraulic elements and the resistance of immersed bodies in permanent or transient regime. RAYMOND MINDLIN: Contribution to the problem of equilibrium of elasticity of an indefinite solid limited by a plane. BERNARD LAFFAILLE and FLORIN VASILESCO: The *flambage* of thin cylindrical plates. JOHN ELLSWORTH: The asymmetry of the light curves of variables with eclipses attributable to a tide lag. F. DUSCHINSKY: The bands in the neighbourhood of spectral lines in the ultra-violet. GASTON DUPOUY and PIERRE JACQUINOT: The proportionality of the deviations in the field in the Zeeman effect of three mercury levels. HORIA HULUBEI: New "*hors diagrammes*" emissions in the $K\alpha$ spectra of elements included between Cu(29) and Rh(45) inclusively. MLLE. O. HUN: The cryoscopic study of the total hydration of the ions of sodium bromide. MLLE. MARGUERITE QUINTIN: The heat of dilution of cadmium chloride. MLLE. SUZANNE VEIL: The electromotive forces due to bringing together metals in gelatine, and the importance of the Volta effect in batteries. JEAN CHÉDIN: The Raman spectrum of nitric anhydride. The Raman spectra of nitric anhydride in organic solutions (chloroform, carbon tetrachloride) differ from those given by the same substance in nitric acid or in sulphuric acid. PIERRE LAURENT: A new compound of phenol and aniline. From measurements of the dielectric capacity of mixtures of phenol and aniline in various solvents (benzene, carbon tetrachloride, cyclohexane and ether) the existence of the compound ($C_6H_5NH_2,2C_6H_5OH$) is deduced, and this has been isolated in the form of colourless crystals melting at 29·2°C. ANDRÉ LÉAUTÉ: The capillary separation of tars. When studying the ascent in capillary tubes of tars and bitumens, it has been noticed that two liquids appear in the tube, the upper a clear yellow fluid, the lower black tar. This explains the appearance of yellow exudations on the surface of tarred roads. ANDRÉ CHRÉTIEN and GEORGES VARGA: Two new compounds of titanium tetrachloride and hydrochloric acid. The cryoscopic study gives indications of the existence of the compounds $TiCl_4$, 6HCl, and $TiCl_4$, 2HCl. The first of these is a new type. JOSEPH HOCH: A new general method of preparation of the *N*-carboxethylketimines, $RR'.C{=}N.CO.OC_2H_5$. The diethylacetals of the ketones are condensed with ethylurethane in the presence of a trace of aniline hydrochloride. JACQUES FROMAGET: The upper Trias of the western border of the Tran Ninh (Haut Laos). CHARLES FRAIPONT: A skull of *Homo neanderthalensis* from the grotto of Engis (Liège). A detailed examination of the small skull found along with the celebrated Engis skull in 1828. ANGEL H. ROFFO: The action of solar rays (ultra-violet) on the skin, and the accumulation of cholesterol. The effect of the sun's rays, especially the ultra-violet rays, produces a local accumulation of cholesterol under the skin. W. KOPACZEWSKI and S. MARCZEWSKI: Anaphylaxy from the point of view of altitude. A study of the effects of reduction of atmospheric pressure, corresponding to an altitude of 10,000 metres, on animals sensitised by an injection of protein. RAYMOND-HAMET: The physiological inversion of the hypotensor effects of adrenaline.

ROME

Royal National Academy of the Lincei, May 19. V. NOBILE: The possibility of new trends in the theory of astronomical refraction and of incidental contributions to the physics of the atmosphere (2). F. SBRANA: Monodrome parallelism on a surface. U. CASSINA: The construction of the plane osculatory to a quartic of the first species. A very simple linear construction of finite character is given. N. SPAMPINATO: (1) Functions totally derivable in a real or complex algebra endowed with modulus (2). (2) A characteristic property of totally derivable functions. B. SEGRE: The bi-relations on the non-developable surfaces of space and the geometric conditions for projective equivalence between them (2). G. BOZZA: The deposition of crystalline suspensions. (1) General theory. The general relationships between the various factors involved in the deposition and separation of crystalline granules from suspensions are deduced for the case when the granules are of such dimensions that the surface influences between granules and liquid are negligible. C. SCHAEFER and L. BERGMANN: A new optical method for the determination of the elastic constants of crystals. Diffraction centres may be formed in a quartz cube by exciting this to rapid elastic oscillations by means of a field which oscillates 10^7 to 10^8 times a second. If monochromatic light is passed through the vibrating crystal, a diffraction figure is formed which depends on the elastic properties of the crystal and on the direction of the rays, but is independent of the form of the crystal and of the type of the excitation. Various examples are described. G. WATAGHIN: The theory of protons and neutrons. By a slight modification of

Dirac's equations, these may be made capable of indicating some of the known properties of protons and neutrons. G. C. WICK: The oscillation and rotation spectrum of the molecule HD. M. SAVIANO: Water metabolism. (9) Variation of the diuresis and urinary *p*H in animals on acidogenic and alkalogenic diets. The more abundant the diuresis, the more nearly does the reaction of the urine approach that of the blood. With animals on an alkalogenic diet, the urine may even become less alkaline than the blood. V. FAMIANI: The development of Jensen's sarcoma in certain particular conditions of nutrition.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Monday, November 4

SOCIETY OF CHEMICAL INDUSTRY (LONDON SECTION), at 8.—Prof. I. M. Heilbron: "Chemical Elixirs of Life—the Recent Developments in the Chemistry of Sterols, Lipochromes and Related Compounds" (Jubilee Memorial Lecture).

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Prof. Kenneth Mason: "The Himalaya as a Barrier to Modern Communications".

Tuesday, November 5

ROYAL HORTICULTURAL SOCIETY, at 3.30.—(in the Society's New Hall, Greycoat Street, Westminster, S.W.1).—Sir William Wright Smith: "Problems connected with the Classification of Plants". (Masters Memorial Lectures. Succeeding lecture on November 26.)

BEDFORD COLLEGE FOR WOMEN, at 5.15.—Prof. W. Neilson Jones: "Notes on a Biologist's Visit to Southern California".*

HALLEY STEWART TRUST LECTURE, at 6.—(in the Memorial Hall, Farringdon Street, E.C.).—Prof. J. B. S. Haldane.*

INSTITUTION OF CIVIL ENGINEERS, at 6.—J. D. Watson: Presidential Address.

Wednesday, November 6

UNIVERSITY OF LONDON, at 5.—(at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C.1).—Sir Daniel Hall: "The Improvement of Native Agriculture in Relation to Population and Public Health" (Heath Clark Lectures. Succeeding lectures on November 11, 13, 18 and 20).*

ROYAL SOCIETY OF MEDICINE (HISTORY OF MEDICINE SECTION), at 5.—Dr. E. J. Holmyard: "The Pharmacology of Mediæval Islam".

WARBURG INSTITUTE, at 5.30.—H. Mattingly: "The First Age of Roman Coinage" (succeeding lectures on November 13 and 20).*

UNIVERSITY COLLEGE, LONDON, at 5.30.—I. C. Gröndahl: "Norwegian Life in Town and Country".*

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION), at 6.—R. A. Watson Watt: Inaugural Address.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.30.—(at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1).—M. J. Leahy: "Stone Age People of the Hagen Area, Mandated Territory of New Guinea" (Film).

INSTITUTE OF CHEMISTRY (LEEDS AREA SECTION).—Dr. C. H. Desch: "Metals in the Chemical Industry" (Jubilee Memorial Lecture).

Thursday, November 7

ROYAL SOCIETY, at 4.30.—F. W. G. White and L. W. Brown: "Some Measurements of the Reflection Coefficient of the Ionosphere for Wireless Waves".

J. P. Gott: "On the Electric Charge collected by Water-Drops falling through a Cloud of Electrically Charged Particles in a Vertical Electric Field".

HALLEY STEWART TRUST LECTURE, at 6.—(in the Memorial Hall, Farringdon Street, E.C.).—Prof. Julian Huxley.*

Friday, November 8

BEDSON CLUB, ARMSTRONG COLLEGE, NEWCASTLE-UPON-TYNE, at 6.30.—Prof. J. W. Cook: "The Synthesis and Biological Effects of Carcinogenic Hydrocarbons" (Bedson Lecture).

ROYAL INSTITUTION, at 9.—S. R. K. Glanville: "Weights and Balances in Ancient Egypt".

Science and Political Responsibility

AS these pages pass through the press and come to the hands of our readers, Great Britain once more lies under the stress of one of those periodically recurring emotional crises in which the future policy of government of the country for a period of greater or lesser duration is determined by popular vote. The gravity of the issues involved on this occasion needs no stress ; but it may well raise the question whether the machinery of democratic government is such as to adapt itself to that scientific approach to the solution of the problems of government and administration, which the course of events in the last ten or fifteen years has shown to be a necessity of this modern age. In the hundred years which have elapsed since the introduction of the Reform Bill, thanks in great measure to the British political genius for compromise, the ultimate control of the destinies of the nation has passed from what was virtually an oligarchy to the people as a whole without the more violent pangs which marked the birth of democracy in less fortunate conditions. No longer, however, is the electorate confronted with the relatively simple issues of 'party'. The problem of the future in an increasing degree must be the manner in which, and at what stage, the scientific and technical considerations, which it would seem must enter more and more largely into the shaping of public action, are to be brought home to democracy.

John Stuart Mill, with the characteristic optimism which underlay the logical exactitudes of the Philosophic Radicals, declared that the individual exercise of the franchise was to be preferred to all the advantages that might accrue from the most benevolent despotism ; and the nineteenth century, also holding to the belief in the ultimate perfectibility of the individual through education, elected to follow him. The Great War struck the final blow at the barriers, comparatively few as they were, which still stood in the way of equality of status and opportunity for all. Of these the most formidable, perhaps, was the inequality of the position of women. By the irony of circumstances, however, that great upheaval also destroyed the conditions in which these opportunities were to come to fruition. The War revealed the enormous forces which it was possible to set in motion and direct to a given end by organisation, especially on a national basis, and the complexity of the problems arising from day to day, which could no longer be localised and isolated, but were liable to affect the whole world, even to its remotest parts, through the speeding up and improvement of communication and transport.

The optimism of the post-War period of reconstruction was short-lived. The stability of civilisation had suffered a shattering blow ; and throughout the world it was apparent that it was no longer possible to meet the issue by the traditional methods of party politics. The situation called for measures that were at once more drastic and more flexible, if the methods of science were to be applied to the problems of government. Action, when once a logical conclusion had been attained, was not a matter for further debate.

Even now it is too early to pass judgment on the means, some of them drastic, which have been adopted to cope with the crisis, and are still in some measure on their trial. The extended application of the results of scientific research in every field of production to meet human needs—this, too, has given rise to problems all its own—and the more highly organised methods of industry and commerce in the pursuit of efficiency and the

elimination of waste, have led by analogy to the concept of the corporate State, highly organised on scientific lines as a unit, bringing with it the inevitable consequence of the institution of a dictator as a condition of success, whether that dictatorship were held by an individual, as in Italy and Germany, with limitations as in the United States of America, or more or less in commission as in the early stages of the National Government in Great Britain, or, in theory, in Russia.

The outcome, as is familiar to all, through the repercussion of economic and political factors, has been the intensive cultivation of the national spirit, to which concessions were made at the close of the War in the interests of justice and peace, but which has now become a source of irritation and danger greater than the injustices which it was fostered to remove. To the justification of political and economic exclusiveness has now been added the doctrine of race, with the implication of racial superiority and inferiority, which in Germany has been made the basis of internal policy to subserve the purpose of commercial and economic rivalry between Jew and Christian, and in the United States has served as an argument in favour of discriminatory laws regulating immigration and imposing disabilities on certain classes of the population in social legislation.

If, however, exclusive nationalism claims to base itself upon a scientific racial theory, over against it must be set the movement towards internationalism, which has found material expression in the League of Nations. If, according to the one school, the nation is regarded as one stage in what is claimed to be a Darwinian struggle for existence, in the view of the other, it represents a phase from which we are said to be on the point of emerging in an evolution of the social organism in an ascending scale of complexity, which begins with the family, passes to the tribe and will culminate in some form of great commonwealth vast enough and elastic enough to embrace the whole of mankind.

If those who claim to speak with the authority of science may voice views so widely divergent, the puzzled layman may well ask where in all this controversy does science itself stand. Now science as such is not concerned with 'moral values', which in the long run determine the policy of the statesman, but with truth; and the man of science, as such and apart from his standing as a citizen, has no special claim to speak on the issues of political controversy, except in so far as his standing and the interests of his pursuits are affected as constituent elements of the community. When, however, the name and principles of science are invoked in support of political policy, it is to the interests of himself and of science in general—and indeed it is his duty—to examine and test the theories which have been invoked and their application, and to see not merely that they are correctly stated in accordance with the facts, but also that in their application they have not been distorted to fit the views of the partisan.

A lesson as to the true function of the man of science in relation to political controversy may perhaps be drawn from two recent publications dealing with the theories and practice of anthropological science. Of these one, "We Europeans" by Dr. Julian Huxley and Dr. A. C. Haddon, is the subject of notice in another column of this issue of NATURE (see page 736), but it may be pointed out here that in this book the authors have effectually pricked the bubble of 'race' as applied in justification of the nationalism rampant in Europe to-day. They track down the 'Aryan Race' theory to its origin in a misinterpretation—it might indeed be said a perversion—of ethnological theory, and finally cut away the ground from under 'racial' theory by demonstrating that, when examined in the light of modern methods and modern doctrines of genetic studies, race becomes virtually a meaningless expression.

In the second of these publications*—an excellent review by Mr. Penniman of the history of anthropological thought from its beginnings with the investigations of Herodotus down to the present day—the racial fallacy is traced to its origins in the writings of de Gobineau and others in the last century. It is instructive to note how, from the earliest times and long before anthropology had become an organised discipline, philosophers and political thinkers were drawing from the more or less systematic observations of travellers and historians the formularies upon which to base theories of the political and ethical ends of man.

At present, the trend of events is that the statesman must rely, in an increasing degree, on the findings of science in the interests of good government. If freedom and democracy are to endure, this constrains the man of science to hold a watching brief, lest the name of science be taken in vain and the power of the franchise abused in an uninstructed electorate.

Industrial Reorganisation and International Obligations

The Next Five Years: an Essay in Political Agreement

Pp. xvi+320. (London: Macmillan and Co., Ltd., 1935.) 5*s*. net.

LAST year two manifestos appeared in the Press under the title "Liberty and Democratic Leadership". They represented in effect the expression of large schools of thought in all political parties of their abhorrence of *il-liberal* and undemocratic forms of government, and their determination to solve present-day problems by methods of persuasion and without curtailment of liberty. Not content with mere manifestos of good intentions, a number of the signatories have now published this book which, they claim, presents a far-reaching but attainable programme of action for the next five years. Apparently, the signatories would welcome the formation of another National Government, the centre of gravity being nearer the left-centre than the one we have known since 1931. As to how this coalition is to be brought about, the book is silent. Be that as it may, it will be welcomed in all quarters as a successful attempt to display the vast agreement which exists as to the programmes that are necessary for the organisation of a world order freed from the menace of war, the development of an economic system freed from poverty and unemployment, the safeguarding of political liberty and the revitalisation of democratic government.

In the economic sphere, a Cabinet Planning Committee is advocated of ministers without portfolio aided by an Economic General Staff composed of the best brains in the ranks of industrialists, financiers, trades unionists and experts to survey the resources of Great Britain and recommend the reorganisation of our industries to meet present-day needs. The authors set great store on the increase of our export trade, and this they believe to be possible by our participation in the formation of a 'low-tariff club'. By this means, they maintain, it will be possible in five years to return to the 1929 level of trade and thus reduce the number of unemployed by about a million. They also attach considerable importance to the inauguration of large schemes of public works, including housing, road construction and the electrification of suburban railways, as an immediate method of coping with the problem.

In view of the present international crisis, however, the reader will probably turn first to the four excellent chapters dealing with international relations. In a well-reasoned statement, the authors reject the policies of armed isolation, balance of power and alliances as being impracticable or dangerous, or both, and pin their faith to the collective system based on the Covenant of the League of Nations as the only sure method of achieving a lasting peace.

It is emphasised that peace can only be secured if international anarchy is replaced by law and order, and furthermore that if peace is to be lasting, the state of law and order from which it results must be founded not on the *status quo* as it exists at any one time, but on justice. The prime necessity for the observance of international obligations is recognised and for sanctions to enforce those obligations, and also the necessity for adequate machinery for the peaceful settlement of disputes and the revision of the law to meet new conditions.

First, then, as to sanctions: it is agreed that they are morally justifiable, "used solely to prevent or put a stop to breaches of the peace with the minimum of lasting injury". Further, they are politically necessary and desirable if collective security is to be made effective. But to do this, sanctions must possess three essential qualities. "They must be *predicable* enough to serve as a deterrent to a would-be aggressor and as an assurance to those in fear of attack". "They must be *potent* enough to stop the peace breaker, surely, quickly and with a minimum of lasting injury". "They must be so conditioned and *limited* as not to impose an intolerable burden upon those who have to contribute to them".

At the present time, the sanctions on which international law depends fall far short of these requirements. They are not predicable because they depend for their use on the whims and vagaries of national Governments. Would Italy have attacked Abyssinia if she had known for a certainty that she would have to resist the moral, economic and physical strength of the combined nations in the League?

The question still remains, How are sanctions to be organised so as to fulfil these conditions? There is only one answer. The League itself should be endowed with an International Police Force. That is the key to the problem of sanctions. It is also the key to the problem of security and therefore of disarmament. Indeed, the authors recognise that if military aviation and the menace of aerial bombardment are to be abolished, it may be necessary to establish an

international air police force. The dangers of rearmament which Europe is to encounter during the next five years may yet convince even the most reactionary of us that it is only by transferring force from national control and placing it at the disposal of international justice that peace can be preserved.

The authors recognise "that provision for peaceful change of the status quo is indispensable". "The society of nations, like society within a nation, must find peaceful means of adjusting conflicts between rigid law and the changing needs and conceptions of justice". They recognise the need for a settlement of Hungary's territorial claims, of Japan's case for expansion, of some alterations with regard to Danzig and the Polish Corridor. War, or the threat of war, is the very worst instrument for settling such disputes or affecting such changes.

The authors do not consider that the Permanent Court at The Hague is a suitable body for deciding political, as distinct from legal, issues. "The most radical method is, of course, for states to entrust to an international authority the task of giving a binding decision not simply on the basis of existing law but on broad grounds of equity and balance of advantage"; and for this purpose they recommend the appointment of *ad hoc* commissions to deal with such questions.

This marks a great advance. It is a step towards endowing the League with a permanent tribunal in equity composed of men who by their uprightness, character and disinterestedness are capable of giving a just and impartial decision as between the disputants and in consonance with the interests of the international community as a whole.

These are undoubtedly the necessary instruments of the reign of law—a court and a policeman. When the League is so equipped, the world will enter upon an era of just and lasting peace such as it has never enjoyed in the past.

DAVIES.

The Racial Myth

We Europeans:
a Survey of 'Racial' Problems. By Dr. Julian S. Huxley and Dr. A. C. Haddon. With a Chapter on Europe Overseas, by Prof. A. M. Carr-Saunders. Pp. 299 + 4 plates. (London and Toronto: Jonathan Cape, Ltd., 1935.) 8*s*. 6*d*. net.

THIS book, the result of a happy collaboration, comes as an opportune prophylactic against the spreading virus of racialism. Its nine chapters contain a historical survey of the development of anthropology and racial ideas, a simple but sufficient account of human genetics, an examination of the bases and follies of ethnic classification, a review of European ethnic groups considered broadly and nationally, a careful demographic summary of European emigration and a recapitulation of the practical applications of the inquiry.

Its uniform excellence leaves little room for criticism, but the chapter on the "Ethnic Composition of European Nations" could have been improved by more systematic treatment; and that by Prof. Carr-Saunders creates the unfortunate impression that Australia, New Zealand and North America form a series of overseas Europes, practically untouched by other immigrant and endemic mores and genes. Yet the North American population, regarded as a whole, is somewhat obviously Eur-Afro-Asiatic, and one fails to follow the curious argument that the indigenes of these areas can be "disregarded" as they "have played no part in the building up of the communities which now inhabit" them.

The main utility of the book is that it demonstrates with incontrovertible clarity (and it is a reflection on human sanity that such demonstration should still be necessary) that the racial concept is a myth, and *race* "a pseudo-scientific rather than a scientific term". It has been so extensively used "to rationalize emotion, and to bolster up the appeals of prejudice" that the authors employ the expression *ethnic groups*, an advance on Prof. Boas's proposal to substitute 'populations' for 'race'. Of course, all this has been said before, but it bears saying again; and it is to be hoped that it will have a restrictive effect on the growth of ethnomania and proposals to elevate the primary, phenotypic divisions of mankind to specific rank. A large section of exploited humanity should be grateful to Drs. Huxley and Haddon for helping to deprive this prospective taxonomic exuberance of any semblance of biological foundations. For even its limited acceptance would help to relegate the Negro, already regarded by numerous morons as 'subhuman', to the category of the gorilla in the Western mind; and it would stimulate a revitalised outbreak of social ineptitude.

Other fallacies associated with racial mythology are also exposed, such as Nordic superiority,

measurable differences in innate group ability, the biological evils of miscegenation, and the equation of 'race' with 'nation', which Sir Arthur Keith is still fond of emphasising from his sylvan retreat at Downe. "The idea," they write, "of a British, a French, a German or an Italian 'race' is a political fiction, and a dangerous one at that".

In dealing with miscegenation, however, the authors express themselves 'cautiously'. They say, boldly enough, that supposedly biological reasoning against ethnic mixture is a cloak for aggrandisement and discrimination; they show, with significant lack of emphasis, that the unfortunate characteristics so often observed in 'hybrids' are associated with economic, social and cultural factors of which prejudice is perhaps the most effective; they almost follow Mr. Bernard Shaw in the timid statement that from "a purely biological standpoint it might conceivably be a good thing to undertake mass crossing between say the British and the Bantu . . ." One expects the obvious conclusion that a rational attitude towards miscegenation would be concerned with the improvement of the factors affecting it, rather than egocentric attempts to prevent relations which have proved to be unpreventable at least since the late palæolithic period. For social ills there are social remedies—and one must presume that white groups are educable. But we are informed that "It may well be that in many cases the discouragement of 'racial crossing' may be the correct policy". It rather seems as if Dr. Huxley suddenly remembered the manifesto of the Eugenics Society and his position on its council, but it comes too late to be really effective; and a single lapse from the "appeal to fact" is surely excusable in a book otherwise so attractively radical.

CEDRIC DOVER.

Scientific Study of Place-Names

The Place-Names of Essex

By P. H. Reaney. (English Place-Name Society, Vol. 12.) Pp. lxii+698. (Cambridge: At the University Press, 1935.) 25*s*. net.

ESSEX is generally reputed to be the one county of England which has best preserved among its peasantry the traditional outlook of an earlier day, just as its buildings are richer in characteristic examples of early styles of domestic architecture. The impression of a certain remoteness which compels attention outside the urban areas is intensified by a flavour, an archaic quality, in the names of its smaller towns and villages, which seem to recall more insistently than elsewhere a countryside which was part of a social order based on church and manor very different from that of the twentieth century.

Even when every tangible evidence of antiquity has vanished before the advance of suburban London, the names remain. Stratford—not the "Stratford-atte-Bowe", which lies across the river in Middlesex—still marks where the Roman street crosses the river, although its neighbour Leyton is no longer, at the request of its mid-nineteenth century inhabitants, the "Low'tun on the Lea"; and it comes as something of a surprise that names so familiar to the suburban as Chingford and Billericay have an antiquity which has left no trace of their derivation.

It is one of the functions of inquiry pursued in the scientific spirit to confirm or destroy impressions. The volume of the Place-Name Society which deals with the county of Essex brings together an imposing array of current names—to say nothing of those no longer in use—of a more than respectable antiquity. They point to a general continuity of long tradition throughout the county area which here and there, in names that defy etymological analysis, may stretch beyond the bounds of recorded history.

Of the Celts, notwithstanding the seat of the great British kingdom at Colchester, there are few traces—names such as Camulodunum itself, Colne, Lea, Pant, Stour and a few others of Celtic origin, as well as names imposed from outside, such as Walton or Walden, "the wood of the serfs", or more probably, "the Britons". Early political or geographical conditions may be responsible. It does not necessarily follow that the earlier inhabitants were completely evicted by the East Saxons, whose kingdom, with its capital in London, embraced the modern county and Middlesex as well. From these East Saxon settlers and their descendants the majority of Essex place-names are derived, memories of the Roman occupation appearing in Colchester, Chesterton and others now no longer in use. On these Saxon names is superimposed a stratification of racial and social history in names of Scandinavian, Norman-French, French and English origins, in which descriptive, locative or functional elements are embodied, as well as derivatives from personal and family names.

Exposed as the county was to entry from the sea by way of its many creeks and estuaries, as the Saxon settlement had shown, it was inevitably raided by Scandinavians; but they do not seem to have been disposed to settle as they had farther north. Scandinavian derivations are not common, though they are seen in such names as Audley End, Kirby, Skighaugh and, more doubtfully, in Clacton, Thorpe-le-Soken and Frowick. No county, however, shows more strongly the effect of the Norman invasion. Many names derive from feudal and manorial custom, or are survivals of the personal and family names of barons of the county, such as Grays from Henry de Grey, its baron in 1194, Helion Bumpstead, Hadfield Peverell or Woodham Ferrers. Names that are of purely French derivation, such as Pleshey and Beaumont, are relatively not infrequent.

However great the interest to the historian of the later evidences of the growth and organisation of society which have been collected by students of Essex place-names, the archæologist will return again and again to the indications of great age and of early settlement to be found in county nomenclature. In evidence of both these Essex is especially rich. As the distribution of the earliest forms, those ending in *ge* and *ingas*, would show, the earliest Saxon settlements were along the estuaries and river-valleys, Thames, Lea, Blackwater, Crouch and Colne, as well as along the coast, now marshy, but then more attractive, with a tidal level thirteen feet lower than it is to-day. To this group belong such settlements as Firminghoe at the mouth of the Colne and Dengee on the coast between the Blackwater and the Crouch. Later, from these isolated settlements they spread along the Roman roads and to the less easily worked lands, and to woodland clearings which they at first had avoided, until settlement was general throughout the county. It is significant that it is in the wooded areas, and especially towards the heavy soils of the north-west, that the Saxon names are latest in form and that traces of the survival of a Celtic element are found.

Of paganism there is evidence in the worship of Thunor and Woden which appears in Thundersley and the lost Thunderlow and Wodnesfeld in Widdington. High Ongar and Little Wakering were probably once places of worship, while in Broxted and Hertisheued in Lindsell there is suggestion of heathen sacrifice. The familiar Teutonic water-sprite is responsible for Nickerlands in Stanford Rivers and Nickersmadwe in Greenstead by Colchester. The general distribution of these and similar names points to a widespread settlement of the county area while paganism still flourished.

The attention given to the names of fields in recent volumes of this series has been carried further in the study of Essex. In the long list given here much information may be gleaned bearing on social and economic conditions. Of such, for example, are names which point to the dedication of certain fields to specific services of the church, or the presentation of land to the bride on the morning after the wedding.

The publications of the Place-Name Society go from strength to strength, and the Essex volume is an advance on a standard already high. It is recognised how much of the excellence of the volume is indebted to the labours of such great scholars as the late J. H. Round and R. C. Fowler. It affords a technical equipment, including an excellent series of distribution maps, which will be of the greatest assistance to further research.

Parasitism and Disease

By Theobald Smith. (Published on the Louis Clark Vanuxem Foundation.) Pp. xiii + 196. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1934.) 9*s*. net.

In these lectures the late Prof. Theobald Smith reviewed the knowledge and experience of nearly fifty years of fruitful devotion to research on infective disease in man and animals. The book contains an analysis of the complex interactions of host and parasite and a commentary on the very varied aspects of the subject. Starting with the maxim that the most effective factor in the evolution of parasitism is the continued life of the host, the writer maintains the thesis that parasitic diseases have begun by the straying of the invader into a new tissue or animal, where it may be at once destroyed or may set up an unwonted cycle with serious consequences for the host; after this phase and perhaps after many such attempts, a new recurring disease may be started, and finally a mutual tolerance established with little inconvenience to host or parasite, and so the continuance of both attained. The four essential stages of parasitism are laid down as entrance of the parasite, multiplication in the new environment, exit and transit to fresh hosts. The modifying influence of host on parasite and the converse, and the origin of races of parasites peculiar to special hosts are discussed.

The author derives the need for active public health measures from the axiom that Nature abhors a crowd and reduces superabundance by disease, but he points out that freedom from disease exacts the price of constant vigilance and readiness to use new tactics to avert renewed attacks in the constantly changing ecology.

The book is full of interest to all biologists as well as to medical men and veterinarians, for the matters discussed have been passed through the mind of a master who had no small share in the original observations and in their elaboration.

Faraday's Diary:
being the various Philosophical Notes of Experimental Investigation made by Michael Faraday, D.C.L., F.R.S., during the Years 1820–1862 and bequeathed by him to the Royal Institution of Great Britain, Now, by order of the Managers, printed and published for the first time, under the editorial supervision of Thomas Martin. Vol. 6: Nov. 11, 1851–Nov. 5, 1855. Pp. xiv+495+8 plates. (London: G. Bell and Sons, Ltd., 1935.) 7 vols., £12 12*s*. net.

THIS, the penultimate volume of Faraday's Diary, covers the period from November 1851 to November 1855. In the main, the topics treated are lines of magnetic force, the construction of a magnetic torsion balance and the measurements made therewith, electrodynamic induction in liquids and magnecrystallic action. The MS. of this section of the Diary is noteworthy as containing a number of "the actual specimens prepared by Faraday in 1851 to illustrate the delineation of lines of magnetic force by iron filings. The filings were fixed on cartridge paper by means of gum water, sometimes mixed with a solution of 'the red ferro-prussiate of potassa' (apparently potassium *ferric*yanide), which was found to leave a blue impression of the pattern after the filings had been removed or worn off". A number of the specimens have survived the changes of more than eighty years, and this volume contains collotype reproductions of some of the more suitable specimens. The frontispiece is a reproduction of the famous painting which represents Faraday giving the Christmas lectures of 1855–56 before the Prince Consort, the Prince of Wales and Prince Alfred.

The volume maintains the interest of its predecessors. Detailed consideration of its contents is deferred until the appearance of the concluding volume, when opportunity will be taken to discuss the whole work. A. F.

Die Blutsverwandschaft im Volk und in der Familie: ein Beitrag zur menschlichen Lebenskunde (Anthropologie). Von Dr. Walther Jankowsky. Pp. viii+166+12 plates. (Stuttgart: E. Schweizerbart'sche Verlagsbuchhandlung (Erwin Nägele) G.m.b.H., 1934.) 6 gold marks.

DR. JANKOWSKY here enters upon an investigation of no little general interest, as well as of importance in the present standing of racial studies and the question of human inheritance. His central problem is that of resemblances in appearance, both as between members of a family and as between individuals who are not known to be personally related. He also brings into consideration the biological character and significance of such phenomena of resemblance. He discusses successively the concepts of blood relationship, resemblance factors, individual heredity and pseudo-resemblances. Further, he examines and sets out the methods of investigation applicable to the investigation of the specific problem. One of the most important aspects of the question, on which his views will be found of no little interest to the ethnologist and the student of human heredity, is that of the degree to which significance is to be attached to resemblances without personal relationship in the light of the theory of chance and with special reference to the conditions of descent within a given population.

Dr. Jankowsky's cautious conclusions and well-marshalled arguments, in what is admittedly an obscure field, will serve as a useful corrective of over-hasty generalisations which too frequently go beyond what a scientific interpretation of the evidence would admit.

Anorganisch Chemisches Praktikum:
für Studierende der Chemie und anderer Naturwissenschaftlicher Fächer. Von Prof. Dr. Wilhelm Manchot. Pp. viii+103. (Dresden und Leipzig: Theodor Steinkopff, 1935.) 4.30 gold marks.

THIS course, by one who has made important contributions to inorganic chemistry, is based on the axiom that a student of chemistry should be given the opportunity of becoming acquainted with the appearance and reactions of as many materials as he can in the time available, since this opportunity may never be available in his later career. By combining a course on qualitative analysis with preparative experiments he has attempted to provide a wider basis of instruction, and since this course has been followed in his own institution at Munich, it is obviously a possible one. The order seems at first sight unusual, since experiments on potassium compounds, for example, are followed by halogens, these by silica and silicates, and hydrogen peroxide comes between oxyacids of sulphur and the oxides of nitrogen. Whilst this arrangement may have some advantages as proceeding from less to more difficult experiments, it would seem to conflict with the usual order of lecture courses and would probably not be found satisfactory in English universities.

The Socialization of the Electrical Supply Industry
By G. H. (Published for the New Fabian Research Bureau.) Pp. 104. (London: Victor Gollancz, Ltd., 1934.) 3*s*. 6*d*. net.

THIS survey of the electric supply industry is published under the auspices of the New Fabian Research Bureau, but the author alone is responsible for the views expressed. The conclusions are substantially in agreement with those in the Labour Party Policy Report No. 3. The ownership of local authority and company undertakings will be transferred to a reconstituted Central Electricity Board. The Central Electricity Board would issue new bonds secured on the revenue from the whole supply industry of the country in payment for the ownership. Difficulties in the way of doing this are clearly explained. Similar difficulties will arise in the socialisation of all industries. The present average yield on electric lighting shares is about 4 per cent; this would be replaced by redeemable bonds giving 3½ per cent and so the capital charges would be reduced by about 12 per cent. The advantages of mutual co-operation between gas and electricity supply are pointed out. One advantage of railway electrification would be to cheapen the cost of supply from the grid. The book is well written and free from dogmatism.

The Psychological Approach to the Problem of Road Accidents*

By Dr. Charles S. Myers, C.B.E., F.R.S.,
Principal of the National Institute of Industrial Psychology

IT is well recognised that the problem of road accidents may be approached from various aspects, for example, the statistical and the engineering aspects. In this paper I consider the approach made by the psychologist—whose special training should render him expert in considering and advising on the part played by 'the human factor' which, it has been estimated, enters into eighty to ninety per cent of road accidents.

The psychologist cannot, of course, neglect the value of statistical data; indeed he is bound frequently to use them. Nor is he by any means unconcerned with engineering and other similar mechanical factors. But all these must be his servants rather than his masters; he has to regard them in their subservient relation to his psychological and physiological knowledge—his knowledge of the living mind and body.

Many statistical data, for example, appear to the psychologist as vitiated, if not valueless, because they have been collected and treated without the foresight of pitfalls, and without the care in framing questions, which would have been employed by one trained in psychological experiment and in psycho-physical methods.

So, too, the merely mechanical perfection, say, of car signals and of car controls (levers and pedals) does not content the psychologist. He would institute an inquiry into which of their manifold forms and positions best and least satisfy the human requirements of the driver or pedestrian; no such investigation has yet been made, at all events in Great Britain.

Or again, while recognising the proved value of traffic signals, the psychologist would ascertain their best mode, form, height, etc., again in relation to the human factor in their percipients. For example, it would be easy for him to overcome the dangers of defective colour-vision among road users by instituting differences in shape of the red and green traffic signals, and it appears to him worth while to investigate the problem whether the present system of unwarned changes from one colour signal to another is not deserving of improvement.

In regard to the lights of roads and cars, the psychologist is not content with the desirability of merely increasing their intensity: his familiarity with the physiology of vision compels him also to take into expert consideration the dangers of contrast, shadows, glare and the like, and individual differences in speed of adaptation to sudden gross changes in illumination.

The various traffic regulations—in respect of direction, speed and signals—are each, doubtless, individually justifiable, when based on scientific experimental evidence. The psychologist would, however, also investigate the combined, total effect of these various regulations on the driver. Is there no danger of their becoming so numerous as to impose excessive strain on his attention by increasing his distraction, and thus to enhance his liability to accident? May they not also so seriously affect his peace of mind that, when he escapes from their zone into less crowded thoroughfares, he tends immediately, in his irritation, to reckless driving and again to enhanced liability to accident?

The psychologist fully recognises the value of incentives and deterrents—rewards and punishments—in promoting good behaviour, but experiment and experience have taught him much concerning the value of their various forms; and it is becoming increasingly recognised that his help should be invoked to determine whether or not an offender deserves to be wholly or partly excused from punishment or to receive other forms of treatment. This help is rendered by the psychologist not merely by inquiries into the conscious and unconscious mental and bodily make-up of the offender; he must also investigate the remote, as well as the direct, causes of the accident—the effects of predisposing previous strain, fatigue, worry and irritation, and of such drugs as alcohol. He would also ask to be allowed to extend his inquiries into dangerous behaviour on the part of road users which might have resulted, although it did not actually result, in accident; and he must be in a position to recognise the mental and physical abilities and the temperamental qualities required for a safe driver, to assess those abilities and qualities, and to assert whether a driver possesses them in adequate measure for him to follow with fair safety his unquestionably dangerous occupation or amusement. Finally, he should be allowed to advise the prospective or the inefficient driver as to those of his defects, revealed by psychological tests, which might be improved by special training.

*A paper at a joint discussion in Sections G (Engineering) and J (Psychology) of the British Association read at Norwich on September 10, 1935.

At present, motor drivers are selected merely on the basis (*a*) of freedom from gross physical disabilities, (*b*) of their knowledge of traffic regulations and signals, and (*c*) of their ability properly to start, stop, turn and reverse their vehicle, and to overtake, meet or cross the path of other vehicles. At present about eleven per cent of the applicants for car licences fail in this examination. But it will be at once recognised that, like most other examinations, this is one that can be passed by unsatisfactory people after sufficient 'cramming' and repeated entry, and that it is not an adequate test of the qualifications required for a really safe driver.

There can be no doubt that certain people are more liable to accidents than others. Some psychologists have assumed that there exists in various degrees among mankind one and the same *general* liability to accidents, whatever be the employment or activity in which accidents may occur. Acting on this hypothesis, the Industrial Health Research Board has devised a series of tests which have been uniformly applied to fitters, plumbers, carpenters, engineers, as well as to the drivers of certain public vehicles, with the ultimate object of eliminating those who are most liable to accidents in these various occupations. These tests are, generally and broadly, tests of the accuracy and speed of hand-and-eye co-ordination; and, as might be expected, the scores obtained from them prove to be closely related to manual and mechanical efficiency. Undoubtedly the ablest workers sustain the fewest accidents; but it seems also that there really exists in every individual in a certain degree a general susceptibility to the very different kinds of accidents that may occur in widely different occupations.

Nevertheless, those who have had the most experience in vocational selection have come to place greater reliance on tests which have been devised after a special study of the conditions and requirements of the particular occupation to which they will be applied. It is therefore also a possible, and it may well be a more promising, line of research to study the special qualities required for the successful avoidance of accidents in any one particular occupation and then to devise methods for the assessment of those qualities in that occupation. This has been the method adopted by the National Institute of Industrial Psychology in regard to the selection of car drivers.

In any event, before applying them to new applicants, the psychologist will test his tests by applying them to drivers good, bad and indifferent, in order to ascertain the correlation between the scores made by them at the tests and the known frequency of their accidents on the road. This correlation reaches a satisfactory degree in the case of the Institute's methods.

The motor-driving tests which have been devised and installed at the National Institute of Industrial Psychology assess separately—speed of appropriate reaction to a given signal, resistance to distraction, the ability to 'attend to several things at once', vision, judgment of size and speed, and also self-confidence, road behaviour and manipulative ability. Although no single mental test, whatever its nature, can ever be absolutely infallible, together these tests appear to afford a sufficiently reliable criterion of driving ability. They assess certain important, innate qualities, of which some will doubtless appreciably improve with practice, but others of which are not susceptible of such obvious improvement. They do not pretend to determine that a driver who passes them satisfactorily will never be prone to reckless conduct; but they do claim to select those drivers who possess the necessary abilities to extricate themselves from a dangerous situation when it confronts them; in other words, such tests when applied to the selection of drivers do reduce their liability to accident. Similar tests applied to drivers in the Paris omnibus service have, according to the most recent data published, reduced the accidents to these vehicles by 66 per cent between the years 1929 and 1933, although the number of omnibuses had meanwhile increased by 77 per cent and their speed limit by 44·5 per cent. During the same period, the total number of motor-vehicles in Paris increased by only 35 per cent, but their accident rate *increased* by 5 per cent. This difference has been attributed to the use of selection tests. No comparable data are available in Great Britain. But it is noteworthy that in the Metropolitan Police District of London, between April and the first half of August of this year, the total number of persons killed and injured from all road accidents was reduced only by about 9 per cent, as compared with the same period during the previous year; while the number of licensed motor vehicles throughout Great Britain increased by about 7 per cent.

If the application of such selective tests results occasionally in the exclusion of good drivers, whether public or private, some hardship must be incurred individually. But surely from the point of view of the community, it is far better to inflict occasional hardships on the individual than to admit by our present far less efficient methods of selection, those who will afterwards reveal their unsuitability as drivers by injuring or killing their fellow-citizens. Even if public opinion is not ready to concede this, these tests will still undoubtedly prove helpful in the case of 'border-line' entrants to the Ministry of Transport's examination, in

confirming the unfitness to drive of those whose conduct has resulted in threatened or actual accidents, or in indicating what is amiss in them and what may be amenable to correction. They will also prove useful in selecting the best applicants for driving public vehicles and vehicles owned by commercial or industrial companies.

If stringent selection is impossible, and if proper mechanical safeguards have been introduced, training is the next most important prevention against accidents. Clearly, the pedestrian and the bicyclist cannot be selected; it is therefore essential that they, above all others, should receive instruction how to avoid accidents from motor traffic. There is one truth which the experienced industrial psychologist never tires of asserting, that no one should be permitted to pick up his methods as best he can—not even the road user! Systematic training is essential for all road users, including the car driver. Yet at present no systematic training is required even from the latter.

A still wider problem of psychological importance relates to the most effective forms of propaganda and of appeal to the public for the improvement of road behaviour. The methods devised by the industrial psychologist in market research would prove of great value here. These methods have hitherto been employed to save the waste of time, effort and expense which is so often incurred when the psychologically untrained industrialist places an advertisement or a new design or package of goods in the market in the mere *belief* that it will be commercially successful. Market research consists in ascertaining systematically and directly what the general public desires and prefers, and in ascertaining the differences in desire and preference due to sex, age, social level, etc. Experience in such market research has enabled the industrial psychologist to avoid various pitfalls which await the inexpert, untrained person. If his methods were applied to the discovery from all angles of the most attractive, least resented forms of propaganda and appeal to the general public in regard to the avoidance of dangers on the road, this would prove to be yet another psychological approach to the problem of road accidents.

Thus there are many ways in which the special abilities and training of the applied psychologist can be utilised—in the design of traffic and car signals and car controls, in the nature and multiplicity of traffic regulations, in the illumination of roads and vehicles, in incentives, propaganda and instruction of road users, in inquiries into accidents and defective road conduct, and in the selection and rejection of drivers.

Progress in the Gas Industry

PEOPLE are so accustomed to having gas on tap, requiring only the aid of a match to give them heat or light, that they are prone to forget the gas industry is a progressive one, continually improving on the production side, in quality of product and in the efficiency and adaptability of the apparatus used to burn it. It is a proud boast of the industry that gas excels all other public services in reliability.

In this Jubilee year it is appropriate to summarise the developments throughout the industry during a quarter of a century: this has been happily done in the summer number of *West's Gas Journal*, which contains articles by several leading experts in the various sections of gas engineering. A brief epitome of the developments should be of interest to a wider public, since coal and its carbonisation form one of the major problems of Great Britain. The use of raw coal in the domestic grate and many other appliances, including the factory boiler and furnace, has been condemned for years, and a prior treatment advocated to recover the volatile constituents leaving the smokeless fuel—coke—for burning. The old customs die but slowly though there now appears to be an acceleration in the disuse of raw coal, judging particularly from the statistics of railway traffic.

Gas is made by carbonising coal in horizontal or vertical retorts or in large chambers. In 1910 vertical retorts were newly introduced; they have since made great strides. The methods of charging the coal and discharging the coke have been greatly improved, as also the manner and economy of heating the retort settings. As a consequence, the number of gaseous therms per ton of coal carbonised has considerably increased.

Since the Gas Regulation Act of 1920, gas has been sold on a declared calorific value and charged for by the therm instead of by volume, though it is this which is actually measured by the meters. The London undertakings have tended to keep a higher calorific value (of 500 B.T.U.) than the provinces, in part owing to the necessity of getting a higher duty out of their distribution mains. It is desirable to emphasise that the great gas companies send out a gas of constant heating value, at a constant pressure, of a constant density and low in sulphur, so that it burns in suitable apparatus

without any regulation. Coke at one time was regarded as a by-product and its quality varied accordingly; to-day it is standardised as carefully as is gas and distributed graded as to size, ash content and burning capacity, so that it requires a minimum of supervision when burnt in closed stoves. A great amount of scientific work has been applied to realise these high standards of quality of gas and coke, and the achievement is no mean one. The penetration of the chemist into the gas industry largely coincides with the Jubilee period: he is being regarded more and more as one of the key men in the industry and there are not wanting those who regard its future as largely on the chemical side.

The gas engineer continues to develop improvements in detail and to organise gas matters on a larger scale, including carbonising, purification and distribution. Condensing practice has changed in favour of the horizontal tube form of welded steel construction, electric precipitation removes the last traces of tar. Centrifugal and static type washers are in use, and it has become customary to remove naphthalene and benzole by washing. Unfortunately, the ammonia recovery has received a setback owing to the fall in price due to the competition of the synthetic product. Purifying is almost exclusively done with oxide of iron, which enables the sulphur to be recovered in a marketable form; in some cases the sulphur is almost completely removed by a catalytic process, though generally this problem is still left for the future. For storage purposes, the waterless holder now competes with the old-fashioned gasometer: in Great Britain it is still in the experimental stage in regard particularly to economy of maintenance and the extra supervision required, though both on the Continent and in America it has become widely adopted.

High pressure distribution of gas has brought new problems, largely solved by the use of welded steel tubes. The introduction of spun cast iron pipes has increased their length and given a more homogeneous material than ordinary cast iron.

For a long time the output of the industry increased each year. Latterly, there has come a great change in the domestic habits of the people, and gas also has to face intense competition from other sources of light and heat. In consequence, there is an awakening to salesmanship with the provision of show-rooms. In particular, a great stimulus has been given to the improvement of gas-cookers and fires which, since 1910, have been bettered in all respects almost beyond recognition. The same applies to water heating and to the use of gas for industrial heating, a field in which there is great development taking place. Lastly, gas holds its own for street lighting, as an evening in the streets round Whitehall or in South London will testify. Here the physicist has been called into co-operation so that the maximum light can be directed along the length of the road.

This brief sketch indicates the virility of what is now an old industry, largely due to the more scientific outlook which it is showing towards its problems. There is a tendency to concentrate the industry in larger units, either by regional absorption or amalgamation of the smaller companies by the larger, or by the purchase of isolated companies by holding groups. The former plan obviously makes for greater efficiency and benefit to the consumer; the latter move is regarded with some unrest by many.

Chemotherapy of Malaria*

By Colonel S. P. James, F.R.S.

WITH the distressing effects of the malaria epidemic and famine in Ceylon still fresh in our minds, the subject of the chemotherapy of malaria may very appropriately be discussed at the present time. The area affected was not so large as Yorkshire, but the cost of relief measures was about £350,000, and during the six months from November until April, 14½ tons of quinine, costing £50,700, was used. About £20,000 was also spent on the new antimalarial remedy called atebrin. The epidemic reminded the world once again that no royal road or short cut to the prevention of malaria has yet been found. During recent years similar reminders have come from British India, Malaya, East and South Africa, Nigeria, the Sudan, Mauritius, Trinidad, Barbados and other British territories overseas. A few years ago an epidemic in British India prostrated the whole population of an area twice as big as England. The ordinary business of large cities was interrupted, no labour could be obtained, transport was disorganised, and even sellers of food ceased to carry on their trade. In one group of towns and villages the deaths during the month

* Opening of a discussion in Sections B (Chemistry) and E (Geography) of the British Association at Norwich on September 9, 1935.

of October, instead of being as in a normal year about 6,840, were 76,250.

The financial losses due to such an epidemic, or to the recent epidemic in Ceylon, are quite incalculable, but some idea of the cost of malaria is indicated by the amount of money spent in ineffectual attempts to combat it. For example, the island of Mauritius has spent more than 3½ million rupees on antimalarial measures since 1909, but the prevalence of the disease has not appreciably decreased, and local experts have recently suggested that the whole question should be studied anew with the object of discovering some less costly method of checking the scourge. Lagos, the capital of Nigeria, has spent even more money with less success, for the present position is that every native inhabitant of the town above one year of age has the disease.

Perhaps the most striking examples of failure to prevent malaria by applying the teachings of existing knowledge occurred during the War. One example must suffice. In June, 1916 a British division moved forward from Salonika to occupy the valley of the Struma river in Greek Macedonia. About a fortnight after entering the valley the troops of the division began to go down with malaria at the rate of more than 100 a day. During July and August there were 5,000 cases; in the whole year there were 30,000 and the next year 70,000. A French army corps under General Sarrail held the line next to our troops. That army entered the valley 115,000 strong, but within the next few months 60,000 were down with malaria, and by the end of the year only 20,000 were left in the line. General Sarrail reported to the French Government that his army was immobilised in hospital. The German army on the same front suffered equally, but it is not difficult to picture what would have happened if either of the opposing forces in that war region had been able to keep its soldiers free from the disease.

In view of these and other examples it has to be admitted that, despite some remarkable discoveries, existing knowledge on the prevention of malaria is not sufficient. Direct war on the malaria-carrying mosquito is too difficult and too costly for general use, and quinine has failed to maintain its old reputation as the sovereign remedy which meets all needs. More knowledge is needed in many different directions, one of them being chemotherapy, in which subject British chemistry has as yet played only a very small part. This seems surprising when we reflect that, of the 3½ million deaths from malaria recorded in the world every year, the great majority occur in the British Empire, and that the British Empire alone spends every year about £450,000 on quinine.

Quinine has been in general use for nearly a hundred years, but no one knows, and scarcely anyone is trying to discover, how this remarkable natural remedy acts. Even yet its merits and defects as an antimalarial agent are very imperfectly understood, and it has been said that there are almost as many methods of treating malaria with it as there are physicians who use it. To a considerable extent it satisfies the practising physician because it promptly stops most clinical malarial attacks, but it has grave defects from the point of view of preventive medicine for it does not prevent infection of either the human host or the mosquito, and it does not prevent relapses. These defects became strikingly evident during the War, and in consequence it was realised how advantageous it would be to have antimalarial remedies which would be effective for particular purposes for which quinine is known to fail.

To discover and prepare such drugs is the chief aim and object of antimalarial chemotherapy. What is aimed at is not to supplant quinine, but to supplement it with additional weapons for use in particular circumstances and for particular purposes. In Germany, two synthetic antimalarials, plasmoquine and atebrin, which to a considerable extent fulfil that requirement, have already been discovered, and now it is hoped that Great Britain will make adequate arrangements to pursue the subject in the same intensive way and with the same objects in view. Up to the present the chemical industries of this country have not concerned themselves with the matter, and the grants which have been allotted by Government during the last few years to assist antimalarial chemotherapeutic research have amounted to less than a two hundredth part of the Empire's annual bill for quinine.

If and when adequate arrangements for antimalarial chemotherapeutic research are made in Great Britain it will, of course, be one of the tasks of the biologist to tell the chemist all that he knows of the life-history and biological properties of the various species of malaria parasite, and for what particular purposes he is desirous of being supplied with drugs that are superior to quinine. As Sir David Prain said a few years ago: "When medicine is in a position to tell chemistry exactly what medicine requires, the chemist will in due course deliver the goods". Prof. Robinson has said much the same thing in other words, so I shall now give some indications on that subject by pointing out the chief defects of quinine as an antimalarial agent, and some of the merits of atebrin and plasmoquine as additional antimalarial weapons.

The first and by far the most important defect of quinine is that it does not prevent infection:

it is not a true causal prophylactic. What we want is a drug which, taken in non-toxic doses, will entirely destroy the organisms injected by infected mosquitoes before these organisms begin to continue their developmental life-cycle in the human host. Until a few years ago quinine was thought to be effective for this purpose. It was thought that if persons in malarious places would take a dose of quinine at sunset and another at sunrise, all the germs injected by a mosquito which had bitten them during the night would be killed and they would not suffer from malaria. Clinical observations give no support to that belief. For example, the temperature chart of a person who took ten grains of quinine shortly before being bitten by mosquitoes, the same dose shortly after being bitten, and the same dose daily thereafter for ten days showed that these prophylactic doses had no effect in preventing or delaying the malarial attack. Another trial with larger doses of quinine showed the same failure. The attack occurs, even when prophylactic doses of 45 grains (3 grams) of quinine are used.

It is interesting and important that the same trials with either of the new synthetic preparations plasmoquine or atebrin give a quite different result. In a comparative trial with quinine and atebrin and plasmoquine against infections of malignant tertian malaria, all the controls who took no prophylactic drug and all those who took quinine as a prophylactic had their attack of malignant tertian malaria within the usual incubation period, but none of those who took atebrin or plasmoquine had any malarial attack.

Atebrin and plasmoquine do not work so well as true causal prophylactics against benign tertian malaria as they do against malignant tertian, but lack of time prevents my giving details on that subject. The point I wish to make is that these drugs are not simply substitutes for quinine: they are new weapons with a specific action on a phase of the parasite against which quinine has no effect.

A second defect of quinine is that it is not equally effective against all species and strains of the human malaria parasite. This defect is common to all known antimalarial remedies, and is the chief reason why it is desirable to have several drugs at disposal for treatment in order that, when one fails, another may be tried. For example, some strains of malignant tertian malaria are not at all susceptible to quinine, but are very susceptible to atebrin. On the other hand, some strains of benign tertian malaria react quicker to quinine than to atebrin, and for this reason many clinicians prefer to 'break the fever' (as they say) with quinine, and to continue later with atebrin.

A third defect of quinine is that it is not very effective in preventing the relapses which are such a troublesome feature of some cases of malaria. Here again a chief difficulty arises from the fact that different species and strains of the malaria parasite react differently to the various anti-malarial remedies at present known. In malignant tertian malaria, relapses may often be entirely prevented by treatment with atebrin instead of with quinine. On the other hand, the relapses of benign tertian malaria are much more difficult to prevent. The most important type is that which occurs about eight months after recovery from the primary attack. It is the type which causes what is called 'the spring rise of malaria' in northern Europe and other countries. It was the type responsible for the second wave of the recent malaria epidemic in Ceylon. No drug treatment yet known will prevent this type of relapse.

Lastly there is the problem of preventing the spread of malaria by what is called gametocyte therapy. Gametocytes are the forms of the malaria parasite which infect mosquitoes, and it has long been known that in malignant tertian malaria quinine is quite ineffective in preventing the infection of mosquitoes which feed upon persons suffering from this disease. Plasmoquine, on the other hand, is so effective against the gametocytes of malignant tertian malaria that doses even as small as two centigrams are sufficient to prevent mosquito infection. For this purpose, therefore, plasmoquine is a new antimalarial weapon of proved efficacy. But a further requirement in this category is a drug that will prevent the production of gametocytes in the human host and their appearance in the peripheral blood from which they are sucked into the stomach of the mosquito when it feeds on infected persons. Plasmoquine kills gametocytes *after they have been produced and have appeared in the peripheral blood*, but it does not arrest their birth and development.

From these few examples it will be evident that the epoch-making discoveries made by Prof. Schulemann and his colleagues at Elberfeld have placed in our hands new antimalarial weapons of great power and precision, but that there is still ample scope for further research in Great Britain and other countries. It is not expected, of course, that in England funds available for chemotherapy research will ever be provided on the same scale as in Germany, but the British Empire with its vast malarious territories in Africa, India and the Far East is more concerned with the provision of effective antimalarial agents than is any other group of nations in the world and, having regard to the humanitarian, economic and imperial interests at stake, it is greatly to be hoped that something will be done about it.

Obituary

General A. W. Greely

ADOLPHUS WASHINGTON GREELY, whose death was recently announced, was born in Massachusetts in 1844, and in 1867 joined the Signal Corps of the regular army. In 1881 he was placed in command of the United States expedition to Lady Franklin Bay, Smith Sound, which was one of the two American circumpolar stations in connexion with the first International Polar Year. Greely and twenty-five officers and non-commissioned officers of the United States Army, with two Eskimos, were landed at Lady Franklin Bay on August 18, 1881, and a station, named Fort Conger, was erected. The ship then departed, her commander intending to return the following summer and not expecting any difficulty in again reaching the station. Admiral Nares had taken the *Alert* farther north, off the same coast, in 1875; but these ice-infested channels are seldom navigable, as the British expedition organised by Shackleton's younger son found only last year. Scientific observations were begun, and much game, especially musk-oxen, was seen. Some of these cattle were shot, and eaten during the winter.

In 1882 Lieut. Lockwood made a sledge journey along the north of Greenland, on which he discovered and charted about 125 miles of new coastline, beyond the farthest point reached by Beaumont of the Nares Expedition. Lockwood reached the record latitude of 83° 24′ N. in long. 40° 46′ W. Greely himself made even more interesting discoveries in the interior of Ellesmere Land, including Lake Hazen, more than fifty miles long, mountains, rivers and a number of Eskimo bone instruments. The relief ship failed to arrive and a second winter had to be spent at Fort Conger, as other parties, less well supplied, have done. There were caribou as well as musk-oxen, and salmon in the Lake Hazen district.

In April 1883, Lockwood followed Greely westwards, but completely crossed Ellesmere Land to Greely Ford, where he discovered a weird and wonderful cañon country. As the ship again failed to arrive, the outlook was serious and a retreat southwards was begun on August 18. News was found that the ship had been lost. Greely's party reached Cape Sabine on October 12 with very little food, and in this district game was scarce. In November the rations were reduced to 14 oz. a man a day, and in January 1884 the first man died. Lockwood kept his meteorological record until April 7 and died two days later. On May 24 all the food was finished, except for seaweed and shrimps, though the men became too weak to procure them. One man had to be shot for stealing on June 6. The seven survivors, including Greely, were rescued on June 22.

Greely gave the results of the expedition in his "Three Years of Arctic Service" (2 vols., 1886), which is worthy of comparison with the greatest works of other explorers. Work in the Signal Corps then claimed Greely, who eventually became Major-General and Chief Signal Officer. In 1909 he published a "Handbook of Polar Discoveries", in 1912, "True Tales of Arctic Heroes", in 1927, "Reminiscences of Adventure", and the following year, "The Polar Regions in the Twentieth Century". In 1923–24 D. B. MacMillan placed a tablet on Cape Sabine in memory of the disaster; and in 1934 Greely was awarded the Congressional Medal of Honour. The Royal Geographical Society recognised his services by the award of the Founders' Medal in 1886. He was one of the founders of the American Geographical Society, to which he bequeathed his Arctic collections. Greely did excellent work in his day and set an example, not always followed, of careful and accurate detail. He was an explorer of whom the United States may well be proud. J. G. H.

Dr. F. E. Rowett

TECHNICAL education in London has suffered a great loss by the death of Dr. F. E. Rowett, principal of the North Western Polytechnic. His career is an excellent example of the use of the facilities offered by our modern educational system, for a youth having ability and perseverance, to climb the academic ladder.

Dr. Rowett was the son of Capt. J. Rowett of the Board of Trade. His early life was spent at Portsmouth, after which the family moved to Gillingham, where he attended the Wesleyan Elementary School until he entered H.M. Dockyard, Chatham, at fourteen years of age, as an engine-fitter apprentice. Besides attending the Dockyard School, he went to Gillingham Technical Institute in the evenings and eventually obtained a Whitworth exhibition. After spending one year at East London College under Prof. D. A. Low, he obtained a Whitworth scholarship, the first year of which he spent at the Royal College of Science under Prof. Perry and the remaining two years at St. John's College, Cambridge, where he took his degree in 1914 on the research side, working under Prof. Bertram Hopkinson. In 1915 he joined the research staff of the engineering laboratory of the Royal Naval College, Greenwich, under Sir James Henderson, where he did good work on war problems for the Navy and Air services until 1918, when he was appointed principal of the Medway Technical Institute, Gillingham.

In this new post, Rowett left his mark as an organiser and teacher by re-equipping the laboratories and raising the standard to the requirements of the Board of Education, and when the new North Western Polytechnic was erected in London, he was selected to be its first principal. He planned the equipment, he gained the confidence of the Governors, the loyal co-operation of his staff and the affectionate regard of the students.

While at the Medway Institute, Rowett had taken the B.Sc. degree, London, in 1919, with first class

honours, and his D.Sc. degree in 1921 for a thesis on "Accurate Viscosity Determination of Fluids". His published papers deal with elastic hysteresis in steel, elastic properties of steel at moderately high temperatures, and viscosity of liquids; but his research work at the Royal Naval College has not been published.

Dr. Rowett was of a very retiring and modest nature, a skilful engineer and an ingenious research worker of great ability, very thorough in all he did. His work was his hobby, and forms a lasting memorial to him. Ill-health overtook him in his prime and he died at the early age of forty-six years. J. B. H.

WE regret to announce the following deaths:

Prof. A. V. Fomine, director of the Botanical Museum of the Ukrainian Academy of Sciences, and professor of botany in the University of Kiev, an authority on the Cryptogams and plant geography, on October 16, aged sixty-six years.

Prof. J. G. Goodman, emeritus professor of civil and mechanical engineering in the University of Leeds, on October 28, aged seventy-three years.

Prof. Frederick L. Ransome, professor of economic geology in the California Institute of Technology, on October 6, aged sixty-seven years.

News and Views

Sir Charles Sherrington, O.M., G.B.E., F.R.S.

THE official announcement of Sir Charles Sherrington's retirement from the Waynflete professorship of physiology at Oxford recalls the simple but moving ceremony which took place at the Oxford meeting of the Physiological Society in July. Sir Charles was then presented with an address recording his long association with the Society, and expressing the esteem and affection of his fellow members. These feelings are world-wide. Sir Charles's studies of the nervous system will command the admiration of neurologists for years to come, but those who have been privileged to know him personally have far more to admire. During his tenure of the chair at Oxford, the conception of the nervous system which he originated has become part of the classical doctrine of physiology. At the same time, his more recent studies have made Oxford the chief centre in Great Britain for research on the central nervous system. He has been president of the Royal Society, has served on countless scientific committees, and recently has done much for the improvement of scientific bibliography. Though we may regret the loss from active work of such a leader, we cannot grudge a rest and change of scene to one whose example has so enriched the scientific life of our time.

Progress in Medical Science

IN his Sir Halley Stewart Trust Lecture on October 31 in the Memorial Hall, Farringdon Street, London, E.C.4, Prof. Edward Mellanby, secretary of the Medical Research Council, discussed recent developments in medical science. He said that it is only in the past hundred years that medicine has made substantial advance. This relatively dormant state of knowledge lasting over a period of thousands of years was due partly to the idea that disease was caused by the invasion of the body by evil spirits—a view held by the Egyptians, Babylonians and Assyrians—and partly to the belief that man's body was of no account as compared with his soul—a view held throughout the Middle Ages. Landmarks of medical advancement were introduced on the anatomical side by the Italian school as represented by Vesalius and on the physiological side by Harvey, who gave the first classical demonstration of the possibilities of acquiring knowledge by the experimental method. By the time of Pasteur, the field was set for development and intensive study. Pasteur's work on enzyme action immediately opened up a new chapter of knowledge and led to the work of Lister on antiseptics and of Koch on bacterial disease in general. In the present century, medical research has become more and more intense. In Great Britain, the Medical Research Council was initiated in 1913 and, besides using its own public funds, it has the privilege of working in close association with the efforts of private benefactors such as the Lister Institute of Preventive Medicine, founded by Lord Iveagh, the Rockefeller Foundation, and the trusts formed by Sir Otto Beit and Sir Halley Stewart. On the administrative side, the greatly increased activities of the Ministry of Health and local health authorities have resulted in the application of new knowledge acquired by research to the practical problems of health.

PROF. MELLANBY gave some results showing the effect of advancement in medical science on mortality rates. The infant mortality rate in the period 1896–1900 was 156 per 1,000 births registered; in 1934 it was 59. The mortality rate of men between 45 and 55 years of age was 20·3 per 1,000 males in the period 1870 to 1875; in the period 1926–30 it was 11·7. Progress in medical science has tended in recent years to centre round three types of knowledge affecting: (1) Problems of infection—protozoal, bacterial and virus—and their control by raising the immunity. In this way such diseases as smallpox, measles, diphtheria, meningitis and scarlet fever have been influenced. In a group of 399 London children recently treated by immune serum, not one had died of measles, whereas in a control group the death rate

was 5 per cent. (2) Diseases due to abnormality of internal secretion, such as diabetes, pernicious anæmia, Addison's disease, myxœdema, cretinism and simple goitre, tetany and osteitis fibrosa cystica. As an example, reference was made to the latest results obtained in the treatment of pernicious anæmia by the pure or nearly pure anti-anæmic principle of liver as recently isolated by Dakin and West. So little as 0·2 gm. injected once weekly has a remarkable curative effect on this otherwise deadly disease. (3) Nutritional disease: Dr. Mellanby illustrated this subject by showing how discoveries leading to the cause, prevention and cure of rickets had been obtained. He also dealt with the problem of defective teeth and said that dental decay will remain a scourge in Great Britain unless methods are adopted of feeding infants and children on diets which would produce perfectly formed instead of the present imperfectly formed teeth. He described the beneficial effect of such substances as abundant milk, egg-yolk, fish and animal fats on dental structure, as compared with the harmful effect of cereals such as oatmeal, flour and other similar substances unless balanced by sufficient milk.

The Case Against Vaccination

In his Chadwick Public Lecture delivered at the Royal Society of Tropical Medicine and Hygiene, on November 1, Dr. C. Killick Millard discussed the vaccination question. In the past, one either had to believe in vaccination or to disbelieve in it. Dr. Millard said that his faith in vaccination, as a means for protecting the individual against smallpox, is just as strong and unassailable as ever it was, but he recognises that, as a State institution for protecting the community, infant vaccination has been largely a failure. Until recently, it was taught that the neglect of infant vaccination entailed serious and imminent risk of a return of smallpox mortality. The experience of the City of Leicester, which abandoned infant vaccination fifty years ago, and yet where, during the last thirty years, there have been only two deaths from smallpox, makes such a belief difficult. Since the War, an ultra-mild form of smallpox has appeared in Great Britain and considerable spread has taken place. It has now been officially recognised as a distinct variety, which breeds true, and it has been accorded a separate name, 'variola minor', to distinguish it from the severe form of smallpox, 'variola major'. As a matter of fact, although not officially recognised as such, variola minor existed in Great Britain long before the War, and in certain countries, under the name of 'alastrim', it has existed from time immemorial. Variola minor presents quite a different administrative problem from variola major. Compared with the latter it is non-fatal, non-disfiguring, non-loathsome. In some ways it is no more serious than vaccination, so that no case can be made out for retaining compulsory vaccination merely on account of variola minor. Dr. Millard concluded by expressing the opinion that the repeal of the vaccination Acts is now over-due.

Liberation of the Electron

For his Friday evening discourse at the Royal Institution on November 1, Mr. C. C. Paterson took as his subject "The Liberation of the Electron". He described how the whole art of electrical engineering had been born again when the electricity, which the older engineers had confined to wires and cables, was liberated from them by the physicist and handed back to the engineer to be exploited in the wireless valve, the photo-electric cell, the cathode ray tube, and other devices which use 'free electrons'. He demonstrated the essential causes which enabled these devices to establish broadcasting, long-distance telephony, television, and similar social services. The secret of the revolution is that a stream of free electrons, whether in a vacuum or a gas, can be manipulated with such facility that the electricity can be increased or decreased at the rate of millions of times per second, or alternatively as slowly as desired, and no limit is set to the amount of energy which can be so controlled. So much of what we see and hear consists, if analysed, of extremely rapid happenings. The eye and the ear are unconscious of these high-speed fluctuations and vibrations, although sensitive to them. In order that we may faithfully reproduce and transmit these very rapid oscillations and variations, it is necessary to make exact electrical copies of them. This is done by suitably controlling a stream of free electrons. Mr. Paterson went on to point out how the free electron is also being used in astounding ways in the art of electric lighting. The many coloured luminous discharge tubes used for display purposes in the streets are due to the action of 'free electrons'. They have led the way to more brilliant and more efficient industrial light sources. Some of them give much more light for the electricity consumed than existing filament lamps. The effects are the result of high-speed (up to six million miles an hour) encounters between free electrons and the gas atoms in the tubes.

Science and Unemployment

In his presidential address to the Institution of Electrical Engineers delivered on October 24, Mr. J. M. Kennedy dealt mainly with the subject of the distribution of electricity. It is obvious that hand labour is gradually being replaced by mechanical power, and that a large fraction of the labour so displaced is unable to find further employment. There are certain depressed areas in which unemployment is particularly rife owing to the dying out of industries or their transfer to more suitable areas. It is now generally recognised that lack of forethought and absence of planning for the future during the recent rapid industrial development has been one of the main factors that has allowed these industrial troubles to develop. Absence of initiative and the policy of letting things drift often prevent real progress from being made. Mr. Kennedy discussed the relation between advancing applications of science and unemployment. He does not agree with those who fear that any steps taken to plan industry so as to re-absorb the present number of unemployed

will cause difficulty in the event of a great revival of trade. So far as the electrical industry is concerned, those employed in manufacturing, contracting and supply have grown in number from 200,000 to 330,000 in the last ten years. Scientific and technical development soon find a remedy for any potential shortage of work by increasing the rate at which power is developed and utilised. He reminded his hearers that electricity is a commodity in everyday use, and that it is unnecessary to fill up complex forms before it can be supplied. If the present rate of progress is to be maintained, more intensive effort and in many cases an appreciable reduction of tariffs is required.

School Dietaries

THROUGH the laxity of their parents in nutritional matters, nearly all children go to boarding schools as 'damaged goods'. This accusation, which is broadly true, is made by Prof. H. E. Armstrong in No. 7 of the gastronomical quarterly *Wine and Food*, in which he reviews Dr. Friend's book "The Schoolboy. A Study of his Nutrition, Physical Development and Health". Schools may not be able to repair the injury inflicted by parental carelessness, but at least they should not add to it, as they commonly do, by providing ill-planned dietaries during the crucial period of adolescence. For more than twenty years resident medical officer at Christ's Hospital, Dr. Friend has striven to better the physical condition of the boys passing under his care by improving the biological quality of the school diet. These experiments have been watched and encouraged by Prof. Armstrong in his capacity as a governor of the school. Prof. Armstrong is constantly directing his stinging wit and pungent criticisms at first one and then another public nuisance. The problem with which he is exercised at the moment is:

"How should the little busy boy
His belly daily fill?"

Prof. Armstrong urges the introduction of wholemeal bread; far more vegetables, particularly in a raw state; a comprehensive sausage including some of every kind of 'innards'; milk and milk products, of course. For the better provision of bone-forming minerals and vitamins, the milk should be from herds on lime-treated pastures, and in winter-time the cows should be fed on hay made from rapidly dried young grass.

THE large boarding school of the future will call for the exercise of special activities and of special intelligence on the part of the staff. The training of the child's character will be through that most wonderful House of Assembly, the 'tummy', and not through the pursuit of cricket and foot balls and dead languages. The school farm will be as carefully watched as the school classroom. Precious hours of sunlight will not be wasted indoors or the health-giving power of light be annulled by over-clothing. Dr. Friend initiated a great work, and Prof. Armstrong has been his staunch supporter, but how many boys' or girls' schools have such enthusiastic medical officers or governors? Though it is an improvement on customary school diets, the Christ's Hospital diet is still far from ideal: sugar is too plentiful; fresh fruit and vegetables too scarce; not all the bread is wholemeal, and more milk and potatoes might with advantage be included. The progress of experiments with improved diets is hampered in schools, and may be invalidated by the unintelligent opposition of the school teaching and domestic staff, and by lack of co-operation from the boys and girls, who resent food changes, and protest if their expenditure on the 'tuck shop' is curtailed. In spite of these obstacles, we hope the time is near when schools will ensure health not by fighting disease with an array of clinical thermometers and antiseptics, but, by means of proper food and sunlight, building sound bodies resistant to infection.

An Experiment in Political Education

THE 'educated electorate' dreamed of by the liberal statesmen of two generations ago is still to seek; the great mass of voters to-day are probably no better qualified than their ancestors of Gladstone's day to form independent judgments of the merits of rival candidates for election to Parliament. A similar deficiency stultifies democratic government on the other side of the Atlantic. The problem how to help the masses to achieve that critical thinking postulated by democratic theory was discussed in a stirring address delivered on July 26 at the University of Minnesota by Dr. J. W. Studebaker, United States Commissioner of Education. Attention was directed in the address to a remarkable experiment now in operation in Des Moines, Iowa, where the local education authority has inaugurated a public forum for adults. Its objectives are, (1) exchange of information and points of view, (2) development of tolerance and open-mindedness and (3) development of critical intelligence. It is recognised that the leader of such a forum must be a man of eminence in the academic world, with both the theoretical and practical knowledge of current affairs which would command respect and, above all, "that serene detachment which alone can guarantee clarity of judgment". The basic conception of the forum is educational with emphasis upon critical thinking as opposed to the emotional appeal and obscurantism of the demagogue. Such forums, Mr. Studebaker thinks, ought to be found in every city and village throughout America; and he forecasts support by the Federal Government for schemes for establishing them. University extension discussion classes in Great Britain were started with similar aims, but failed to attract as participants more than a minute proportion of the electorate. It will be interesting to see whether Mr. Studebaker's suggestions fructify.

Origins of Some Mechanical Inventions

FOR his presidential address to the Newcomen Society delivered on October 16, Mr. C. F. Dendy Marshall took the subject of "The Germs and

Development of Some Mechanical Inventions". His address, he said, followed a well-beaten track, but as many uncritical accounts and inaccurate illustrations have been published regarding the early history of pumps and engines, he thought it would be of interest to consider some of the earliest printed records. Recent research has shown that much less is known of such men as Ctesibius and Heron than our fathers thought they knew; and even in the case of Heron, the earliest manuscripts are posthumous to the extent of more than a thousand years. The first printed edition of his "Spiritalia" was in Latin and was published at Urbino in 1573. In this is described the first known application of heat to produce motion in fluids, a device for opening temple doors by the agency of heat, and the famous æolipyle. The word 'æolipyle' has been used by writers in three senses, namely, (1) for a vessel shaped like a retort for producing a jet of steam, (2) for Heron's engine and (3) for a wheel impelled by steam as invented by Branca. The word means the doorway of Æolus, that is, that of the cave in which the winds were kept. After touching upon some of the inventions described by Agricola, Porta, de Caus, Branca, D'Acres, von Guericke, Boyle and the Marquis of Worcester, Mr. Dendy Marshall made some interesting remarks on Papin and his invention of the safety valve. To the plug valve, Papin added the lever and moveable weight, but he did not propose it as a safety valve or hint that it might be useful to prevent explosions. From Papin, Mr. Dendy Marshall turned to the work of Savery and Newcomen on the steam engine, and concluded with some remarks on the early history of tramways, railroads and mechanically propelled vehicles.

Road Traffic in the United States

In a recent radio talk given over the Columbia Broadcasting System, Prof. S. S. Steinberg, of Maryland University, discussed the highways of the United States. With more than 25 million motor vehicles, the business of highway transportation is one of the largest in the country. Last year, holiday motorists in the United States spent almost 600 million pounds. Highway facilities are still far from complete; only five per cent of the three million miles of rural roads are hard-surfaced, while only thirty per cent have received any kind of improvement. In many places, need for reconstruction is urgent, and the mileage of secondary light traffic roads required is very great. The loss of life due to accidents is high, as almost a hundred persons are killed every twenty-four hours, and last year one out of every hundred of the population was injured in a road accident, one of the gravest risks being the 'railroad grade' crossings, of which there are 240,000. About 1,500 persons are killed annually at these crossings; at least 30,000 such crossings are dangerous, and it will take many years before they can be made safe. Congress has provided sixty million pounds of emergency relief funds for this purpose, and the development of 'farm to market' roads will be a great boon to the country. The work will provide employment for many at present unemployed as the cost of constructing roads is mainly for labour. Mr. Robinson points out that the highways affect everyone vitally as they are the arteries which carry the life-blood of agriculture, commerce and industry, as well as bringing many social and educational amenities.

London and Home Counties Joint Electricity Authority

Under the Electricity Acts of 1919 and 1922, joint electricity authorities were set up, which were to be representative in these districts of the authorised undertakers, the local authorities, the county councils, the large consumers and other interests. In a pamphlet describing the opening of new electricity showrooms in Sutton, a list of those composing the Joint Electricity Authorities for London and the home counties is given, and a record of the progress that has been made since the Authority took over the undertaking. The list of the members is thoroughly representative, and wonderful progress has been made in developing the industry. By instituting two-part tariffs, assisted wiring and hire and hire-purchase schemes, the electric supply has been made available to the poorest people in the district served, which is mainly residential. The supply area covers 190 square miles and is divided into an inner and outer zone, consumers in the latter having to pay slightly more. The work was taken over in July 1932, and in July 1935 the number of consumers had increased by 89 per cent, the load having more than trebled. The Authority has done much useful work in standardising the apparatus and systems it has inherited. The whole of Surbiton has been changed from direct current to alternating current, and in Sutton the supply is being converted from 200 volts to the standard 230 volts. Practically the whole of the supply is being received in bulk from the Central Electricity Board. The bulk supply from the Grid is taken at 33 kilovolts, transformed at the Grid substations to 11 kilovolts and then transmitted to the Authority.

Climate and Health

At the Harrogate Congress of the Royal Institute of Public Health, Mr. L. C. W. Bonacina delivered an address on "The Study of Weather and Climate in Relation to Public Welfare", which has been published in the *Journal of State Medicine* (**43**, No. 10). He points out that the effect of climate on general well-being is so complex that it is not possible to discriminate between the different elements, but that in Great Britain the general effect is distinctly favourable. Hence it follows that the effect of a marked change of climate, even if superficially an improvement, as for example a doubling of the amount of bright sunshine, might not really be to our advantage. The great importance laid on sunshine is "probably only an exaggerated response to the evil consequence of smoke-vitiated light and air in the great industrial centres, and the curative results in proper doses of natural or artificial sunlight". The wind and the rain, by cleansing the air, are also of great value,

and Mr. Bonacina is in full agreement with the trend of modern ideas in emphasising the importance for health of frequent contrasts of weather, and especially of temperature and wind. He ends on a practical note by insisting that the open-air study of weather and especially clouds also makes for health by training the powers of observation and inference. Forecasts 'on tap' by wireless are a very good thing, but there are occasions, for example in mountaineering, when much discomfort or even risk might be avoided by the ability to foresee a storm an hour or two ahead.

Meteorology of Southern Rhodesia

THE annual report of the Meteorological Department of the Department of Agriculture of Southern Rhodesia for the year ended June 30, 1934, follows the general lines of previous reports (Salisbury: Department of Agriculture, 1934). In the rainy season of 1933–34, as in that of the preceding season, there was substantially less rain than usual, although the formula used for predicting the season's fall had indicated an excess of rain. During the five years for which this computation has been made, this was the first occasion on which the sign of the departure from the normal was not correctly given by the formula. An Aircraft Weather Service that had been organised for Imperial Airways operated satisfactorily during this year, and it was decided to extend the service to all aircraft. Arrangements were made to transfer the observatories at Salisbury and Bulawayo to the aerodromes, where they will be maintained by a staff of two, who will prepare regular weather reports and forecasts, and make observations of the upper winds. According to the report, the provision of an adequate weather service for aircraft is now regarded as the most important function of the Meteorological Department. The number of tables in the report has been reduced owing to financial stringency; but among those included is an interesting one showing the average Rhodesian rainfall for thirty-six years. In the first season, 1898–99, the fall was based on the records of seven rain-gauges, and in the most recent (1933–34), on three hundred and forty-four.

A Totalising Anemometer

IN the *Hydrographic Review*, 12, No. 1, Dr. J. N. Carruthers describes a suggested totalising anemometer for oceanographers, the records of which he considers likely to be of value in climatology. Although the ordinary Robinson anemometer is a totalising instrument in so far as it registers the number of miles and fractions of a mile of air that have flowed past the anemometer in a given time, it does not distinguish between the different wind directions, and its records can only be used for obtaining the total run in particular directions in the case of the more complicated self-registering form of this instrument that records automatically both the run and the direction, and then only after laborious calculations. In the instrument described by Dr. Carruthers, a wind vane is used which rotates a vertical rod bearing at its lower end a circular tank divided radially into eight equal compartments, each of which has a draw-off tap. A separate mast carries a 4-cup anemometer which makes and breaks an electric circuit after a certain run of wind past the cups. When the circuit is made, it energises a solenoid and the latter rocks a small pipe which is pivoted on the rim of a tank in which water is maintained at a constant level by means of an ordinary ball valve. This pipe carries a dipper which delivers a definite quantity of water through it into whichever of the eight compartments of the circular tank is beneath at the time. At the end of a period of observation, the total run of air in each of the eight directions is readily obtained by drawing off and measuring the quantity of water in each compartment.

Co-ordination of Scientific Surveys

AT the recent meeting at Norwich of the British Association, Mr. E. Wyllie Fenton made an interesting plea, in a paper read before Section K (Botany), for the extension and co-ordination of the existing Ordnance and Geological Surveys into a wide body to carry out periodic surveys not only of topography, rocks and soils but also of vegetation, agriculture and animal life. Mr. Wyllie Fenton's illustrations of the wider need were mainly botanical, as for example, the invasion of valuable land in Scotland by bracken moving downhill to the better land "like a series of plant glaciers", and the association of this fact with changes in land settlement and agricultural practice. A plea was advanced for a prompter recognition of these significant changes in vegetation and in the results of changes in population, distribution, etc., with the argument that a more scientific utilisation of the land, in housing development, in agriculture and in forestry, etc., would be possible if such a general scientific survey service provided the data. Mr. Fenton recognises, however, the ambitious nature of such a proposal, and suggests that a start might be made by the attachment of a few botanists to the Geological Survey.

Metals in the Chemical Industry

IN his Jubilee Memorial Lecture of the Society of Chemical Industry delivered before the Yorkshire Section at Leeds on November 6, Dr. C. H. Desch took as his subject "Metals in the Chemical Industry". The range of both ferrous and non-ferrous metals available for the purposes of chemical industry has been immensely widened in recent years. Resistance to chemical attack is one of the first considerations, and as no one material is resistant to all chemical agents, a choice must be made in each instance, for which ample data now exist. Corrosion fatigue, caused by the simultaneous action of fluctuating stress and of a chemical agent, is quite different from the sum of the actions of fatigue and corrosion, and is responsible for many unexpected failures. Special conditions arise where high temperatures and pressures are involved. Resistance to 'creep' is required as well as chemical resistance, and internal changes may cause progressive weakening. Not only chemical

composition, but also texture, determine the degree of resistance to all these factors. The qualities of metals required for chemical purposes may be improved by (*a*) the elimination of impurities, (*b*) adding other metals in such quantities as to produce substantially new alloys, or (*c*) adding very small quantities of foreign elements which produce an effect great in proportion to their amount.

Neolithic Camp in Sussex

DISCOVERIES which will have a bearing of no little importance on the future study of the neolithic age in Britain are reported from Whitehawk Camp, near Brighton. Mr. E. Cecil Curwen, acting on behalf of the Sussex Archæological Society, with the assistance of Miss Leslie Scott, who has worked at Maiden Castle, Dorchester, has held an archæological watching brief while the Corporation of Brighton has been engaged in constructing a road across the camp. Whitehawk Camp, which is scheduled under the Ancient Monuments Acts, is one of the largest and best surviving specimens of the neolithic camp of concentric interrupted ditches. In places, the original ramparts still stand seven feet high. The line of the road cuts the line of all four ditches on both sides of the camp, and these are now being cleared down to the bottom and the original chalk. According to a report in *The Times* of November 4, up to the present, the inner ditch has proved rich in neolithic pottery, also yielding great quantities of animal bones, flint flakes, saws, scrapers and a flint axe. Two small pits full of neolithic pottery and animal bones appear to be unconnected with the ditches. Another interesting discovery is a piece of chalk scored with a chess board pattern, similar to a device found on the wall of a pit shaft on Harrow Hill, near Cissbury. Several post-holes on the ramparts appear to have supported palisades, and a similar structure is indicated as forming a side wall to the entrance passage through the outer rampart. These are unique in British neolithic camps. The pottery, which is of modified Windmill Hill type and a type with whipped cord impressions, suggesting Peterborough ware (Neolithic *B*), should prove an important addition to existing material.

Etruscan Forgery in the British Museum

MEMORIES of an ancient controversy are revived by the action of the Trustees of the British Museum in withdrawing from exhibition in the Department of Greek and Roman Antiquities at Bloomsbury the widely known "Cervetri Sarcophagus". The revived and extended interest in Etruscan antiquity, marked especially by the recent publication of Dr. D. Randall-MacIver's researches in the history and affinities of Etruscan culture, is, no doubt, largely responsible for the removal of a piece of which the antiquity and authenticity can no longer be held to be a matter of question, in view of the more critical examination to which details of design, structure and style can now be submitted in the light of greatly extended knowledge. Doubt as to the genuine character of the sarcophagus, indeed, was raised very soon after its acquisition by the British Museum as part of the Castellani collection in 1873; and it was pointed out in March of the following year that the inscription on its lid was derived in part from a gold brooch in the Louvre, while another inscription, which had been misread, was indicated later as another possible source. The spurious character of the inscription has been admitted even by some who were prepared to argue for the sarcophagus as a genuine ancient example of Etruscan art. Now, however, the recognition of anachronistic and incongruous details in form and design stamp it as a forgery beyond dispute. There can be little doubt that the story to which reference is made in *The Times* of November 2 embodies the truth which came out in the quarrel between the brothers Pennelli, of whom Enrico, employed at the Louvre, boasted that he had made the sarcophagus, while Pietro had sold it to Castellani, stating that he had excavated it at Cervetri. It is unfortunate that the inquiry demanded by Sir Charles Newton, keeper of the Department at the time, was not pressed home.

The Realm of the Stars

The Realm of the Stars, or *Říše Hvězd*, is the title of a monthly journal edited by Dr. Hubert Slouka and published by the Czechoslovak Astronomical Society, which now has more than a thousand members. One of the objects of the Society and its journal is to encourage a wider appreciation of astronomy among educated Slav peoples, and from the journal it is evident that Czechoslovak astronomers are familiar with modern progress and with the latest instruments in use elsewhere. In the last few issues of the journal there are recent photographs showing the appearance of the moon's surface, some spectrographs taken in Czech observatories and a number of illustrated semi-popular contributions and reports. One issue is mainly devoted to the proceedings of the international astronomical meeting held in Paris during July. Czechoslovak astronomers have interested themselves in such subjects as sunspots, the atmospheres of planets, and celestial bombardment. In the annual report for last year it is stated that 11,797 people and 130 school groups visited the Štefánik Observatory, near Prague. The Society also has observatories and branches in several provincial centres, and noteworthy observations from these groups are reported in *Říše Hvězd*, but being in the Czech language they can appeal only to their own members and, in a limited degree, to colleagues in other Slav countries.

Nature Protection in Poland

A CENSUS of the wild creatures in the famous Polish National Park of Bialowicza gives the present numbers as 4 wolves, 9 lynx, 3 otters, 5 martens, 4 foxes, 5 badgers, 82 wild boars, 29 stags, 72 roebucks and many hares (*Quarterly Information Bulletin concerning the Protection of Nature in Poland*, **5**, II; 1935). In the Park, there now exist 17 European bison, including half-bred individuals, and in Poland as a whole there are 21 of pure breed, out of the 70 known to exist in the world. The State Council for the Protection of Nature in Poland has issued three

small albums, each containing 12 picture postcards of the natural features and the animal and plant life of the parks and reservations, which should help to spread the knowledge of these magnificent natural areas. It is curious to look upon these activities in Poland and the interest of the State and people in them, and to consider that in our more highly populated land, where the need for protection is greater than in Poland, there is no national park at all, and no State attempt to protect the disappearing land mammals, which were once as varied in kind as those of Poland now are.

Campaign against Noise in New York

THE New York campaign against noise officially started on October 1, when the Mayor instructed the police to warn offenders and to educate the public without making arrests. The sounding of motor horns between 11 p.m. and 7 a.m. is prohibited, and citizens have been instructed to keep their wireless apparatus at a moderate level. During the first three days, 4,071 warnings were given and 9 summonses were issued. The League for Less Noise has established an office for investigation of complaints, among which motor horns and barking dogs are most frequently mentioned.

Early Frost in 1835 and 1935

THE note entitled "The Horticultural Society" which appeared in NATURE of October 19, p. 654, refers to the occurrence of a severe frost (27° F.) on October 20, 1835. Miss E. Armitage, writing from Dadnor, Ross, Herefordshire, remarks that the first frost this season took place on October 20, 1935, with 6° F. of frost. All tender autumn flowers were killed, and, in particular, some spikes of *Kniphofia maxima globosa*.

Canadian Earthquake of November 1

FROM the brief account of it that has so far been received, the earthquake that disturbed eastern Canada and New England shortly after 1 a.m. on November 1 seems to be one of great interest. The epicentre is placed by Canadian seismologists at a point about 250 miles north of Ottawa. The shock was severe throughout the whole northern Abitibi region, and at one place railway lines were torn up and twisted. The earthquake is remarkable, however, not so much for its intensity in the central district, which does not seem to have been unusual, as for its large disturbed area. To the south, it was felt at Chicago, Washington, New York and Boston. The northern limit of the disturbed area may be difficult to trace, as it traverses a sparsely inhabited country, but the total area probably exceeds three-quarters of a million square miles, an amount not often surpassed in North American earthquakes.

Announcements

THE Mackinnon research studentship of the Royal Society has been awarded to Dr. G. W. Brindley, assistant lecturer in physics in the University of Leeds, for his research on X-ray reflections from metals in relation to atomic vibrations.

MR. P. L. O. GUY has been appointed Director of the British School of Archæology in Jerusalem for the year ending September 30, 1936, on the retirement of Mr. J. W. Crowfoot. Mr. Guy was formerly chief inspector of antiquities for the Government of Palestine, and has had many years experience of field work and excavation. He has already taken up residence in Jerusalem.

DR. S. I. LEVY will deliver the Brauner Memorial Lecture of the Chemical Society on November 14, at 8, in the rooms of the Society at Burlington House, Piccadilly, London, W.1.

A DISCUSSION on "Some Aspects of the Interaction between Gases and Solids" will be held at the Chemical Society on November 21 at 8 p.m. The discussion will be opened by Prof. E. K. Rideal, who will be followed by contributions from Dr. J. K. Roberts and Dr. R. M. Barrer.

A COMMITTEE has been formed under the presidency of J. A. van Heuven in connexion with the celebration of the three hundredth anniversary of the foundation of the University of Utrecht in 1636.

ERRATUM.—In the last line of the letter by Prof. A. I. Alichanow, A. I. Alichanian and M. S. Kosodaew entitled "Emission of Positrons from a Thorium-Active Deposit" published in NATURE of September 21 (p. 475), the words "per cent" should have been inserted after "0·02–0·03".

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A lecturer in chemistry in the Sir John Cass Technical Institute, Jewry Street, Aldgate, London, E.C.3—The Principal (Nov. 20).

A civilian technical officer in the Admiralty Technical Pool (engineering or physics)—The Secretary of the Admiralty (C.E. Branch), Whitehall, London, S.W.1 (Nov. 22).

A principal of the Municipal College, Southend-on-Sea—The Director of Education (Nov. 25).

A deputy director of agriculture in East Sussex, who will also act as vice-principal of the School of Agriculture, Plumpton—The Director of Agriculture, County Hall, Lewes (Nov. 25).

A lecturer and research assistant in the Department of Higher Degrees and Research in the Institute of Education, Southampton Row, W.C.1—The Secretary (Nov. 25).

A head of the Physiology Department of the Rowett Research Institute, Bucksburn, Aberdeenshire—The Secretary (Nov. 30).

A director of the Laboratory of Bacteriology and Pathology in Adelaide Hospital, who will also act as Director of Medical Research in the University of Adelaide—The Agent General for South Australia, British Industries House, Marble Arch, London, W.1 (Dec. 12).

A University professor of statistics in the London School of Economics—The Academic Registrar, University of London, S.W.7 (Jan. 31).

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 761.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS

Radioactive Indicators in the Study of Phosphorus Metabolism in Rats

RECENT progress in the production of radioactive isotopes by neutron bombardment makes the radioactive isotope of phosphorus $_{15}P^{32}$ easily accessible. This isotope, which has a half-life value of 17 days, can be utilised as an indicator of inactive phosphorus in the same way that the radioactive isotopes of lead, bismuth and so on were formerly used as indicators of these elements. If, for example, we add active $_{15}P^{32}$ to 1 mgm. of inactive phosphorus in such quantity that the Geiger counter registers 1,000 impulses per minute, carry out with the phosphorus activated in this way any sort of chemical or biological reaction and then find that the product obtained gives 1 impulse per minute, we may conclude that 1/1,000 mgm. of the phosphorus originally introduced is present in the product investigated.

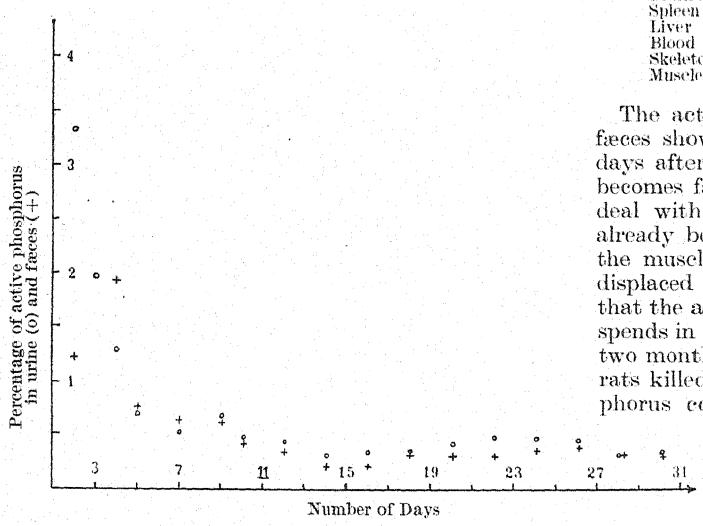

FIG. 1.

(On the first day, 7·4 per cent of phosphorus was found in the fæces and 5 per cent in the urine)

Rats were fed with a few milligrams of sodium phosphate containing $_{15}P^{32}$ as indicator. The radioactive phosphorus present in the urine and fæces was then investigated for a period of a month. The result is shown in Fig. 1, which shows the percentage of the 2 mgm. of phosphorus taken, found daily in the excrements. The rat was killed, and, after ignition, the phosphorus content of the different organs was investigated. The result of an experiment in which the rat was killed 22 days after being fed on active phosphorus is seen in the first column in Table 1. The largest part of the phosphorus taken is present in the bones, and the smallest in the kidneys. When, however, we take into account the very different weights of the different organs and calculate the phosphorus content of the latter per gram after drying, we obtain a very different picture, as seen from the second column in Table 1. The spleen, kidneys, and the brain are found to contain per gram most of the active phosphorus. During one of the experiments, the rat produced six offspring on the seventh day, of which five were eaten by the mother; this caused a large increase in the active phosphorus content of the excreta in the following three days. The presence of 2 per cent of the 2 mgm. active phosphorus taken by the mother was revealed by the analysis of the remaining offspring.

TABLE 1.

Distribution of the active phosphorus in the rat

	Per cent	Per cent per gm.
Urine	26·3	
Fæces	31·8	
Brain and Medulla	0·5	14·7
Spleen and Kidneys	0·2	18·2
Liver	1·7	13·9
Blood	0·4	1·8
Skeleton	24·8	2·8
Muscles and fat	17·4	7·4

The active phosphorus content of the urine and fæces shows great fluctuations during the first few days after the intake of the preparation. Later, it becomes fairly constant; and we have obviously to deal with the excretion of phosphorus which has already been deposited for a while in the skeleton, the muscles, or other organs, and which has been displaced again. From our experiments, it follows that the average time which a phosphorus atom thus spends in the organism of a normally fed rat is about two months. This is also supported by the fact that rats killed about a month after the intake of phosphorus contain only about half the active phosphorus found in those killed after a week's time. This result strongly supports the view that the formation of the bones is a dynamic process, the bone continuously taking up phosphorus atoms which are partly or wholly lost again, and are replaced by other phosphorus atoms. In the case of an adult rat, about 30 per cent of the phosphorus atoms deposited in the skeleton were removed in the course of twenty days.

In another set of experiments we investigated the different parts of the skeleton. No conspicuous differences in the active phosphorus content could be found, with the exception of the teeth. The front teeth, which grow rapidly in rats, contained a larger part of the 2 mgm. phosphorus taken than the average of the whole skeleton, the ratio being about 10 : 1 in the case of adult and 6 : 1 in that of half-adult rats, whereas the molar teeth took up less than the average per gram of the skeleton, the ratio being 1 : 2 in the most extreme case. A detailed account of these and further results will be published elsewhere.

We wish to express our thanks to Prof. Niels Bohr for the kind interest he has taken in this work. For the preparation of the radioactive sources, and helpful assistance in making the measurements, we would also like to thank Mr. J. Ambrosen and Mr. S. Høffer-Jensen.

Induced Radioactivity by Bombarding Magnesium with α-Particles

THE publication of the full details of the following experiments will be somewhat delayed owing to the departure of one of us to Canada. We wish, therefore, to state briefly our main results.

We have examined in detail the induced radioactivity produced by bombarding magnesium with α-particles. The main effect is due to the well-known body Al^{28}, which emits β-rays and has a period of 137 sec.

$$_{12}Mg^{25} + {}_2He^4 \rightarrow {}_{13}Al^{28} + {}_1H^1$$
$$_{13}Al^{28} \rightarrow {}_{14}Si^{28} + \varepsilon^-.$$

In agreement, however, with Curie and Joliot[1], and with Eckardt[2], we have found the induced radioactivity to be complex, and by analysing the emission with a magnetic field, we have been able to identify two other bodies, present in only small quantities, one emitting β-rays with a period of about 11 minutes, and the other emitting positrons with a period of 5–7 minutes. We suggest these bodies are respectively Al^{29} and Si^{27}, formed as follows:

$$_{12}Mg^{26} + {}_2He^4 \rightarrow {}_{13}Al^{29} + {}_1H^1$$
$$_{13}Al^{29} \rightarrow {}_{14}Si^{29} + \varepsilon^-$$
$$_{12}Mg^{24} + {}_2He^4 \rightarrow {}_{14}Si^{27} + {}_0n^1$$
$$_{14}Si^{27} \rightarrow {}_{13}Al^{27} + \varepsilon^+.$$

By investigating the relative yield of these three bodies when produced by α-particles of different energies, we are led to believe that Mg^{25} has a strong resonance level for α-particles of energy less than $5{\cdot}4 \times 10^6$ volts, and that either Mg^{24} or Mg^{26}, or both, have a resonance level for α-particles of energy between $5{\cdot}4$ and $6{\cdot}1 \times 10^6$ volts.

Using α-particles of energies up to $6{\cdot}6 \times 10^6$ volts to bombard a thick layer of magnesium, we find that the cross-section (integrated over all energies) for proton emission from Mg^{25} is about thirty times that for proton emission from Mg^{26}, and about three hundred times the cross-section for neutron emission from Mg^{24}.

While Al^{29} has a period of 11 minutes and Al^{28} only $2{\cdot}3$ minutes, yet we find that the β-rays from Al^{29} are more penetrating than those from Al^{28}. This suggests that Al^{28} undergoes a 'permitted' transition (no change of spin) while for Al^{29} the transition is 'non-permitted' (change of spin). The strong γ-ray emission from Al^{28} shows that the Si^{28} nucleus is usually formed in an excited state, whereas our experiments suggest that Si^{29} is usually formed in the ground state.

The discussion of these results will be deferred until the publication of the full details of the experiments.

$_{19}K^{43}$ and the Radioactivity of Potassium

IT has recently been suggested by Newman and Walke[1] and Klemperer[2] that the natural β-radioactivity of potassium is due to an isotope $_{19}K^{40}$ present in very small abundance. Sitte[3], however, has come to the conclusion that another relatively rare isotope of potassium exists which is the source of the β-particles, and this, he states, can only be $_{19}K^{43}$.

It is to be noted in this connexion that β-ray emission occurs from isotopes in which too many neutrons are present, so that we should anticipate, in general, that when two or more β-radioactive isotopes of a single element exist, that those with the higher number of neutrons would have the shorter lives. This is clearly indicated by the unstable isotopes of thallium:

$_{81}Tl^{210}$ (RaC″)	1·32 min.
$_{81}Tl^{208}$ (ThC″)	3·20 min.
$_{81}Tl^{207}$ (AcC″)	4·76 min.

Hence it appears probable that $_{19}K^{43}$ would have a shorter period than $_{19}K^{42}$, since it has a higher number of nuclear neutrons. As the period of $_{19}K^{42}$ is 16 hours, it is apparent that $_{19}K^{43}$ could not be the source of the natural radioactivity of potassium.

The period of this isotope could probably be tested by preparing it artificially. Rutherford and Chadwick have observed the emission of protons from argon when bombarded with α-particles. Since $_{18}A^{40}$ is 160 times as abundant as $_{18}A^{36}$, it is almost certain that the protons are produced by the reaction:

$$_{18}A^{40} + {}_2He^4 \rightarrow {}_{19}K^{43} + {}_1H^1.$$

Thus by bombarding argon with strong sources of α-particles it should be possible to detect the β-radioactivity of $_{19}K^{43}$.

Finally, it is to be noted that Nier[4], using a special type of mass-spectrograph, has detected $_{19}K^{40}$ present in normal potassium to the extent of about one part in 8,600, whereas he found no trace of either $_{19}K^{42}$ or $_{19}K^{43}$ and concluded that these isotopes, if they exist at all, were present in abundance less than one part in 150,000.

It is apparent, therefore, that the hypothesis of Newman and Walke[1] and Klemperer[2] is confirmed by mass-spectrographic evidence, whereas that of Sitte[3] is not.

Note added in proof. The existence of $_{19}K^{40}$ has been confirmed by Brewer (*Phys. Rev.*, 48, 640; 1935), who estimates the ratio K^{39}/K^{40} as $8{,}300 \pm 100$.

A Molecular Map of Resorcinol

ALL those organic compounds which have until now yielded to quantitative X-ray analysis display some element of molecular symmetry in the crystal. The structure of the complete chemical molecule can then be built up from a fraction by symmetry operations, thus greatly simplifying the analysis. But some of the most interesting structures have a lower symmetry, and in these cases the molecule must be treated as a whole. This applies to resorcinol, space

group C_{2v}^9 (P_{na}), $a=10{\cdot}53$, $b=9{\cdot}53$, $c=5{\cdot}66$ A., where the asymmetric unit consists of one chemical molecule. A quantitative analysis of this compound has now been carried out, and the preliminary results have been refined by a double Fourier synthesis which is shown in Fig. 1.

Although the benzene ring is inclined at a high angle to the plane of this projection, it can be seen to answer the tests of a regular plane hexagon. Now if we assume the usual C-C interatomic distance of 1·41 A., the complete orientation of the molecule in the crystal can be calculated from this diagram. The centres of the OH groups are then found to be situated at 1·35 A. from the benzene nucleus. The line joining the OH groups, lying in the plane of the ring, makes angles of 134°, 46° and 101° with the a, b and c crystal axes, and the line perpendicular to this, also in the plane of the ring, lies at 63°, 77° and 149° to these axes.

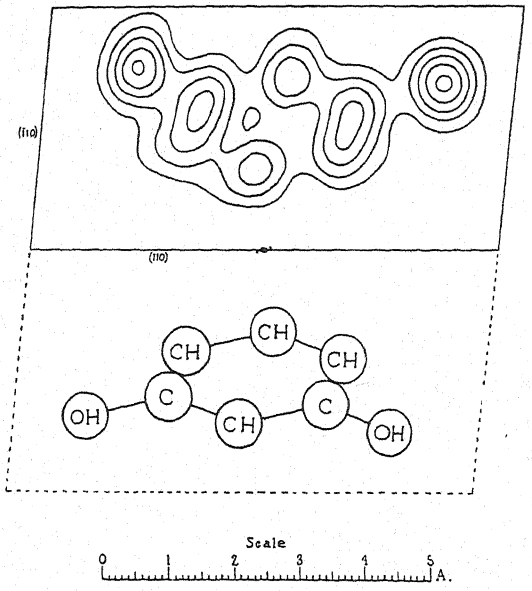

FIG. 1. Resorcinol. c axis projection. Each contour line represents a density increment of two electrons per square A.

Perhaps the most interesting aspect of the structure is the close approach of the hydroxyl groups on adjoining molecules (not shown in Fig. 1). These groups are arranged in spiral formation about the dyad screw axes, and the distances between successive groups belonging to neighbouring molecules are 2·66 A. and 2·76 A. Now these distances are much less than the observed approach distances for molecules of hydrocarbons (3·4–3·8 A.), where only residual or van der Waals' forces are acting. In benzoquinone, the minimum distance between oxygen atoms on neighbouring molecules is 3·62 A. It is evident that some type of secondary valence force must be assumed between the hydroxyl groups of adjacent resorcinol molecules. From the order of the distances this would appear to be either a strong 'hydroxyl bond', or something intermediate between the Huggins and Pauling hydrogen bond and the hydroxyl bond recently discussed by Bernal and Megaw[1].

Lecithin as a Dispersing Agent for Dibenzanthracene

DURING the course of experimental work in connexion with his study of cancer at this Institute, Dr. M. J. A. des Ligneris expressed a desire to study the effect of dibenzanthracene on tissue cultures *in vitro*, and invited the co-operation of the Biochemical Department in devising a suitable means of introducing this substance into tissue culture media.

Since dibenzanthracene is insoluble in aqueous media, the preparation of a colloidal solution was considered. Orthodox methods of dispersion from alcoholic solution were unsatisfactory because the low solubility of dibenzanthracene in even boiling alcohol necessitated the addition of so much of the alcoholic solution that toxic concentrations of alcohol were attained. Moreover, in physiological salines no dispersion occurred unless protective colloids such as serum proteins were present.

Familiarity with the properties of lecithin suggested the possibility of using it as a protecting agent. As a preliminary experiment, 100 mgm. lecithin (crude acetone-insoluble lipoid from egg-yolk) and 50 mgm. dibenzanthracene were ground together in an agate mortar for half an hour, moistening occasionally with distilled water. By means of 50 ml. of Ringer's solution the mixture was then transferred to a bottle and shaken for two hours. The resultant fluid was yellower than a solution of 100 mgm. of lecithin alone in 50 ml. of Ringer and remained so on standing a few days despite the settlement of a yellow deposit.

Although aseptic precautions had not been observed, the fluid proved to be sterile on bacteriological control, and was passed on to Dr. des Ligneris for use. His results will be published shortly.

A similar result has since been obtained by dissolving lecithin in a 0·5 per cent solution of dibenzanthracene in benzene, removing the solvent by causing a jet of air to play on the surface and taking up the mixture in Ringer's solution.

No attempts have been made to determine optimum proportions of lecithin and dibenzanthracene, since the above solution appeared to be sufficiently stable for the purpose intended and the examination of colloidal solutions is not regularly undertaken in this laboratory.

Chemical Nature of the Amino Acids excreted by Leguminous Root Nodules

SOME years ago we showed conclusive evidence that considerable amounts of nitrogenous compounds appear in the medium in inoculated, but otherwise sterile, cultures of leguminous plants. Since then we have tried to isolate these nitrogenous compounds and to determine their chemical nature. The nitrogen compounds were extracted from the quartz sand with water and found to consist chiefly of amino acids. Amino nitrogen determinations according to van Slyke—the reaction mixture being shaken for 30 minutes—showed that 87–98 per cent of the total nitrogen was amino nitrogen. The amino nitrogen values varied to some extent in different extracts.

Further analysis of the amino acid mixture has now led to the following results. About 50 per cent of the total nitrogen consists of amino nitrogen of aspartic acid. This amino acid has been estimated

quantitatively by the aspartase enzyme, and identified qualitatively in the form of the copper salt. Approximately the other half of the nitrogen (40–50 per cent) is precipitable by phosphotungstic acid. Since cystine, arginine, histidine and aromatic amino acids are absent, it is probable that this fraction consists of lycine. Further work is in progress to determine the nature of the compounds precipitated by phosphotungstic acid.

In an earlier paper[1], it was mentioned that aspartic acid is not present in the amino acid mixture. This erroneous conclusion is ascribable to the fact that, owing to the small amount of material available, the determination was made from the solution from which ammonia had first been distilled off according to van Slyke, in which process aspartic acid seems to be precipitated as a calcium salt.

The composition of the excreted amino acid mixture is very interesting in several respects. In the first place, it confirms our earlier view that the excretion is not ascribable to decomposition of the nodules or the roots. According to our recent investigations the nodule protein contains a variety of different amino acids (tryptophane, tyrosine, arginine, etc.). Hence it follows that, should the excretion be due to decomposition of this protein, the amino acid mixture in the medium would also contain several different amino acids. In view of the fact that the rate of excretion is highest at an early stage of growth, it seems very likely that the excreted compounds represent the primary amino acids formed in the fixation of nitrogen. Since aspartic acid is formed from fumaric acid through a well-known enzymatic reaction, the excretion of large amounts of aspartic acid is a most interesting phenomenon. On the other hand, it is also interesting to note that, in sterile cultures, aspartic acid forms an excellent source of nitrogen for uninoculated leguminous plants, as we have earlier found.

Quantitative Determination of Ascorbic Acid

AT the sixth Caucasus Congress of Physiologists, Pharmacologists and Biochemists, held in Erivan, Armenian S.S.R., on October 11–17, 1934, a communication was made by A. G. Jonnissian under the title of "Uber den Chemismus des Vitamin 'C' ".[1]

Amongst other conclusions of the author occurs the statement "Fruktose und Arabinose geben mit dem Reagens nach Tillman [*sic*] ein positives Resultat".

Tillmans recommended the use of 2 : 6 dichlorophenolindophenol, which has been found by many workers to be a quantitative reagent for ascorbic acid. It is known not to be strictly specific, but the number of naturally occurring substances that have so far been found to interfere with the determination of ascorbic acid by this dyestuff is not great, and methods have been evolved for eliminating their interference. If it were true that widely occurring sugars also interfered, the value of the reagent would be severely limited, and doubt might be cast on much published work.

Using the ordinary technique, we have examined specimens of purified *l*-fructose and *l*-arabinose, and in neither event have we been able to detect the slightest reducing action on Tillmans's reagent. We have no explanation to offer of Jonnissian's results, but we thought it might be of interest to publish the above facts, in case that author's statements should lead other workers to under-value what has come to be recognised as an extremely useful reagent.

Colloid Osmotic Pressure of the Body Fluids of Marine Animals

EXCHANGES of water between blood and tissues are generally believed, since Starling's work, to be regulated by the equilibrium of two forces, namely, hydrostatic capillary pressure which drives water out into the tissues, and blood colloid osmotic pressure which draws it into the vessels. Based on clinical and experimental investigations, I pointed out several years ago that this assumption leaves out of consideration the role of the tissues, which are, from a physico-chemical point of view, a much more complicated system than blood. In my opinion, the hydration of tissues determines the colloid osmotic pressure of blood, this pressure being but an intermediary between the different tissues[1].

Comparative physiology has furnished a strong argument in favour of this view. According to Krogh[2], "when the body is immersed in water the hydrostatic pressure is everywhere counterbalanced and all the capillary systems can be considered as being at the level of the heart. This is probably of some importance for large aquatic animals such as whales which should therefore, in spite of their enormous size, require only a low colloid osmotic pressure in the blood to prevent filtration". This presumption should, *a fortiori*, be valid also for animals of smaller size. I have therefore measured the colloid osmotic pressure of the body fluids of marine animals (serum of fishes, hæmolymph of Crustaceans, Molluscs and Tunicates, cœlomic fluid of *Sipunculus*). The following average values have been given by 140 measurements:

	Colloid osmotic pressure	(cm.H_2O)
Sipunculus nudus	0·95	(0·7–1·2)
Lamellibranch Molluscs	1·0	(0·8–1·2)
Gasteropod Molluscs	1·5	(1·2–1·9)
Cephalopod Molluscs	3·3	(2·8–3·8)
Decapod Crustaceans	3·6	(2·1–4·4)
Tunicates	1·7	(1·2–2·3)
Elasmobranchs	4·6	(3·1–6·4)
Teleosteans	19·1	(14·6–25·0)

These results show conclusively that neither the postulate of Krogh's theory, nor consequently its reasoning, can be correct: the blood of Teleosteans has a colloid osmotic pressure only a little inferior to that of the blood of the large terrestrial mammals (horse: 22·5–29·0 cm. H_2O).

What is the explanation of the difference of colloid osmotic pressure of the different animals? An answer to this question is suggested by the striking differences between Elasmobranchs and

Teleosteans. It is well known that not only the skeleton, but also the circulation, respiratory and excretory systems of these two classes of fishes are very different. I incline to the conclusion that the colloid osmotic pressure of the body fluids of an animal is but an expression of its general organisation. With one exception, all the values recorded above can be arranged in the order of phylogenetic development. The only exception to this rule not only does not weaken this argument, but even strengthens it: adult Tunicates are animals degenerated by fixation; their organisation is comparable to that of the gasteropod Molluscs; the colloid osmotic pressure of their hæmolymph has indeed the same value as that of this class of animals.

Function of the Labral Glands in *Chirocephalus*

MISS NICHOLSON and Prof. Yonge, in their letter in NATURE of October 12, claim to have obtained experimentally the same results that I described[1] from the study of sections of fixed material of the Fairy shrimp, *Chirocephalus diaphanus*. They maintain that they have demonstrated that what I described as the coagulated labral gland secretion is, in fact, the contents of the gut regurgitated as a result of the action of the fixative. But what are the facts? They fed an animal on carmine and then fixed, or rather, killed it, by placing it in a solution of Bouin, and observed that during this process its gut showed a periodic antiperistalsis by which the gut was emptied through the mouth. Now while Bouin is an excellent fixative for isolated pieces of tissue, it is a very bad fixative for an active animal of the size of *Chirocephalus* as it takes far too long to act. I tested it last week and found that one specimen was wriggling violently after a minute, and even after two minutes was still jerking its half-dead limbs. Is it surprising therefore if, during its death struggle, it vomits?

The killing agent in which my animals were fixed was a boiling saturated solution of corrosive sublimate, and it is, without doubt, the high temperature rather than the chemical which produces the coagulation of the tissues. Now in this solution fixation is instantaneous. Even if this word is objected to, it must be admitted that the first parts of the animal to be fixed will be the outer parts, which would include any secretion around the mouth, the mouth parts and the œsophagus. Hence even if, during the 'split' second while fixation is taking place, the animal desired to regurgitate, it would find the way blocked by a fixed œsophagus. On the grounds, therefore, of the totally different technique employed, it is difficult to see why any similarity should be expected between the results obtained in the two cases.

Miss Nicholson and Prof. Yonge go further and maintain that sections of their animal "revealed no essential difference between the distribution" of the regurgitated food and the mass of material that I described as the secretion of the labral glands. Prof. Yonge very kindly lent me his sections, and I was able to see at once that, on the contrary, they show no real similarity.

I described the arrangement of the coagulated mass as extending backwards from a mass underneath the head region and mouth parts beyond the tip of the labrum where it is sucked against the inner surface of the first two pairs of trunk limbs. *In this latter region "it forms a blanket over the anteriorly directed food current converting the anterior part of the food groove into a functional tube"*. The tube so formed makes its exit around the sides of the labrum through the coagulum. Further, in the *atrium oris*, that is, in the region where the labral glands open, I described the coagulum as a diffuse scattered mass extending to the actual mouth. Now is it likely that a *Chirocephalus* could regurgitate the contents of its gut and arrange them in this complicated manner? Apart from this, however, the sections which Prof. Yonge sent me showed merely a very large mass of material, *completely* filling the *atrium oris* and the food groove as far back as the sixth trunk limb, and even entering the inter-limb spaces, so that it appeared on the wrong side of the filter setæ. There was no trace of the functional tube which I described in detail and illustrated by photomicrographs. The sections showed, in fact, just what one might expect from the crude technique employed. I have photographed the critical sections and can supply copies to anyone interested for comparison with the photographs published in my own paper.

The *a priori* reasons given by Miss Nicholson and Prof. Yonge for opposing my views appear to be based on an erroneous idea of the anatomy of the labral glands and even of the function in forms where this has been established. They state that "All the unicellular glands of the 'Entomostraca', including the labral glands, have essentially the same structure" and suggest that they all produce "a substance of low surface tension which sets as a *hard cement* on contact with water". But Ostracods are included among the 'Entomostraca' and in this group there is one genus, *Conchoecia*, which is classified on the differences between its unicellular glands, while there are many Ostracods the labral glands of which produce a luminous secretion, and this can scarcely be described as a cement. More important, however, is the fact that the labral glands of *Chirocephalus* are *not* unicellular. Sections of well-fixed material show at once that they are complex structures (Cannon, 1922)[2] quite different from the other glands occurring on the trunk limbs and food groove. In fact, it is doubtful if the labral gland of any Branchiopod is unicellular.

Persistence of Sperms to a Later Mating in *Gammarus*

MRS. SEXTON'S recent criticism[1] of my views on the above subject gives me an opportunity of citing further evidence in their favour. So far as I can see, only three explanations of the appearance of the anomalous black-eyed individual (for particulars see my previous note[2]) are possible: that a reverse mutation had occurred, that the individual had been accidentally introduced owing to careless technique, and the one advanced at the time (fertilisation of a single egg by sperm persisting from a previous mating).

No certain data exist on the frequency of mutation in *Gammarus*, but white-eye, the most mutable locus in *Drosophila*, only changes once in about 300,000 individuals, and no mutation has ever been seen in the laboratory in *Gammarus*. Yet a number of curious cases of the type given in my previous note[2] have been observed by different workers. It therefore seems unlikely that they are due to reverse mutations.

With regard to the second possibility. It is the rule in Oxford, as in Plymouth, to give the female in a cross mating a fresh bowl, etc., after her moult. Pipettes are always well washed out and examined, and where possible dried, before being used for another stock. In these circumstances, I consider it very unlikely that the results are due to contamination from other pots.

Fortunately there is in this case definite positive evidence for the third explanation, for the anomalous individual appeared a whole day before the rest of the brood, strongly suggesting that the egg from which it arose had been fertilised before the rest. I do not know how much, if any, of the lining of the oviduct is shed at the moult, but I think that the possibility of sperm persisting in the mesodermal region, and fertilising one egg on its way to the brood-pouch cannot be excluded, and is much the most reasonable explanation of the results observed.

Mrs. Sexton suggests that if this explanation were true, all the genetic work so far done on the species would be valueless. An added precaution is always taken in this laboratory to ensure the authenticity of the offspring. It is clearly necessary to discard the first family, which may have been in the pouch before the female was mated up, but here either the *next* brood is also discounted or some other precaution to the same effect is taken, and little doubt can be cast on results on this score.

With regard to the statement that Mrs. Sexton had never met a comparable case, it may be mentioned that only in a proportion of instances could the persistence of sperm in this manner be detected.

Overlapping of Speech Sounds

THE piece of sound film reproduced in Fig. 1 shows the last part of the vowel and the first part of the consonant in a registration of *ash*. The vibratory bits that characterise the vowel can be traced in ever-diminishing strength to the third line in the reproduction. The mixture of regular and irregular vibrations that characterise the consonant can be traced back to the middle of the first line. The end of the vowel and the beginning of the consonant are seen to be overlapped.

Fig. 2 reproduces macrophonic registrations of the pressure of the breath at the mouth during *a*, *sh*, *e*, *s* and *ashes* spoken on one occasion. Comparison shows that the word *ashes* was spoken with the sounds *sh* and *s* slightly overlapped, and the two vowels mounted on top of them. The overlapping is indicated by the heavy horizontal lines at the bottom of Fig. 2.

As it is not possible to produce two sounds in succession and then by a reversal of time push the later one forward, the overlapping must occur before the sounds are spoken. This indicates that the central—or inner—activity that originates what is spoken has not only dimensions of time and pro-

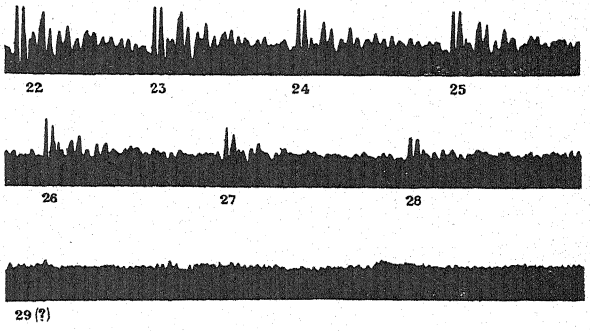

FIG. 1.

minence but also a dimension of breadth that provides for simultaneous events.

The overlapping clears up a mystery. It is well known that the character of a speech sound may depend on a sound that appears later in the printed word. How a sound could work backward against

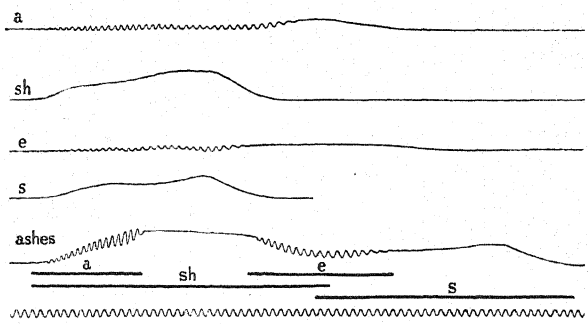

FIG. 2.

time was unexplainable. The difficulty disappears if sounds can be overlapped in the word to be spoken. This principle may well prove fertile in explaining the phenomena of sound change.

Origin of the Wing accompanying the Rayleigh Line in Liquids

IT has been recently reported by Gross and Vuks[1] that, in the light scattered by some organic crystals, there are a few lines or bands very close to the Rayleigh line. The origin of these lines has been attributed to lattice oscillations in the crystals. It has been further pointed out by these authors that these lattice oscillations persist even in the liquid state, but, owing to the looseness of the oscillations in the liquid state, these lines spread out so as to form a continuous wing on both sides of the Rayleigh line. According to these authors, the major portion of the wing is thus due to the persistence of these lattice oscillations in the quasi-crystalline groups present in the liquid, and only the portion very close to the Rayleigh line which increases in intensity with

the rise of temperature may be connected with the rotation of the molecules in the liquid. If this hypothesis be correct, the intensity of the portion of the wing very close to the Rayleigh lines should increase and that of the other portions should diminish on dissolving a liquid in a solvent which itself gives a very feeble wing, because the quasi-crystalline groups of the solute should disappear or at least their number should diminish considerably in the solution.

The wing due to cyclohexane is very feeble in comparison with that due to benzene. In order to test the above hypothesis, the distribution of intensity in the wing due to benzene on the Stokes side of the Rayleigh line 4046 A. has been compared with that due to a 40 per cent solution of benzene in cyclohexane. The exposures in the two cases were so adjusted that the Raman line 990 cm.$^{-1}$ of benzene was of the same intensity in the two spectrograms, and also the cyclohexane lines were so feeble that the wing due to cyclohexane was totally absent. A Fuess spectrograph producing absolutely no coma on the Stokes side was used. The microphotometric records of the spectrograms due to pure benzene and the mixture are reproduced as Figs. 1 (*a*) and 1 (*b*) respectively.

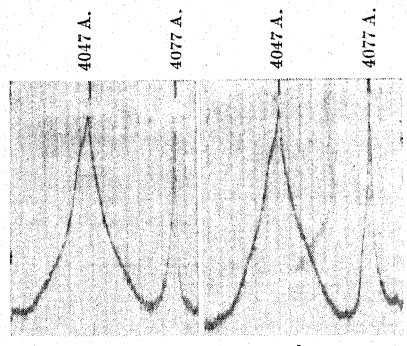

FIG. 1.

It will be seen from these figures that on dissolving benzene in cyclohexane, the intensity of the portion of the wing very close to the Rayleigh line *diminishes*, while that over a short region from about 50 cm.$^{-1}$ from the centre of the Rayleigh line *slightly increases*, and also the total *width of the wing remains practically unchanged*. These facts are contradictory to the hypothesis of Gross and Vuks mentioned above. In fact, the intensity of the portion of the wing very close to the Rayleigh line diminishes also with the rise of temperature in the case of benzene[2].

It may be briefly mentioned here that the Raman spectra of diphenyl ether and naphthalene in the solid and liquid states and also dissolved in cyclohexane have been studied by me, and it has been observed that the width of the Raman lines or bands lying very close to the Rayleigh line in the case of the solid state increases only slightly in the case of solution. The intensity of the strongest of these lines diminishes *only slightly* in the case of diphenyl ether and *considerably* in the case of naphthalene on dissolving these substances in cyclohexane. These facts suggest that these lines are not due to lattice oscillations but may be due to oscillations of very small groups of molecules which are more stable in the case of polar than in the case of non-polar molecules. These points will be discussed in more detail in a paper which will be published shortly in the *Indian Journal of Physics*.

My thanks are due to Prof. D. M. Bose for his kind interest in the work.

Back to Minkowski

A REVIEW of my recent work on "Relativity" appeared in NATURE of October 19 under the above title. There is just one reference which might give a wrong impression, namely, where the reviewer says that the author of the work considers "that the apparent regression of the nebulæ may be interpreted as a progressive diminution in the velocity of light". This evidently refers to an article which I contributed to *Engineering* in 1933 and which I had reprinted as Appendix IX of the book in question.

I wish to point out that the implication of the article in question was not to suggest the explanation given but to make it clear that no experiment that could be devised would distinguish between an expansion of the universe and a progressive diminution in the velocity of light. I advanced no argument or theory in favour of one or the other. Philosophically the question is one involving the relativity of magnitude.

F. W. LANCHESTER.

Dyott End,
Oxford Road,
Moseley,
Birmingham.
Oct. 25.

THE reference which Dr. Lanchester thinks may give a wrong impression was founded on his Appendix IX, interpreted by the aid of p. x of the preface —"the later discussion (Chapter xiii), in which the doctrines of general curvature and expansion are discredited"—and of pp. 13 and 124—"it is clearly without meaning to talk of the expansion of the Universe unless some part of the Universe be excluded from the general expansion with which to make comparison, and then it is no longer an expansion of the Universe". If my interpretation was wrong, I must express my regrets.

H. T. H. P.

South and East African Stone Age Typology

IN my letter in NATURE of September 21, p. 475, in the fifth paragraph, I said that the oscillation which marks Bed III at Oldoway and the Intrapluvial in Pluvial II, in Uganda, "may be equated with that between the Kamasian and Gamblian" of Kenya. That was wrong, for it has recently become clear that following the Uganda Pluvial II oscillation, and separated from it by a considerable thickness of sediments, there were two less marked breaks. Study of the implements from these two non-pluvial beds reveals the fact that the last actually represents the break equivalent to that between the Kenya Kamasian and Gamblian pluvials, since in it were

some tools (Late Acheulean) comparable to the Nanyukian. The latter stage was found by Dr. J. D. Solomon on the slopes of Mount Kenya in a rubble which was regarded as marking the Kamasian-Gamblian Interpluvial.

Therefore, the first climatic break in Pluvial II, Uganda, and as recorded in Bed III Oldoway, was a much earlier affair than I suggested.

Kelvin and the Age of the Sun

WHEN the age of the sun is discussed, it is often assumed that Kelvin asserted quite dogmatically that the age of the sun could not exceed 20,000,000 years. It is well, however, to turn to his own words on "The Age of the Sun's Heat" in a lecture printed in *Macmillan's Magazine* in 1862 and reprinted in his "Popular Lectures and Addresses" (vol. 1), published by Messrs. Macmillan and Co. On p. 368, he wrote that it seemed most probable that the sun had not illuminated the earth for 100,000,000 years and almost certain for not exceeding 500,000,000 years. "As for the future, we may say, with equal certainty, that inhabitants of the earth cannot continue to enjoy the light and heat essential to their life, for many million years longer, unless sources now unknown to us are prepared in the great storehouse of creation." The concluding words display the prescience of this great man of science, much of whose work has now become so familiar that we have forgotten that it had ever to be brought into being.

C. TURNBULL.

21 Percy Park,
Tynemouth.
Sept. 21.

Points from Foregoing Letters

THE average time that an atom of phosphorus spends in the body of a rat which has been fed with sodium phosphate is about two months. This is the conclusion to which O. Chiewitz and Prof. G. Hevesy have come by feeding rats with small quantities of sodium phosphate containing radioactive phosphorus as indicator, and analysing the excreta of the animals and their organs after death. The authors further believe that the formation of the bones is a dynamic process, involving continuous loss and replacement.

By the bombardment of magnesium with α-particles, Dr. C. D. Ellis and W. J. Henderson have obtained, in addition to aluminium of mass 28, already known, two other radioactive products. One of these emits electrons of 11 min. period and the other positrons of 5–7 min. period; the authors suggest that these two radioactive products are, respectively, aluminium of mass 29 and silicon of mass 27.

H. J. Walke suggests that potassium of mass 43 should have a radioactivity of less than 16 hours, which is the radioactive period of potassium of mass 42; it could not, therefore, account for the long-period radioactivity of ordinary potassium. This has been attributed by Newman and Walke and by Klemperer to radioactive potassium of mass 40, and H. J. Walke now directs attention to recent publications supporting this latter hypothesis.

An electron density map of a molecule of resorcinol is given by Dr. J. Monteath Robertson. This is the first example of an organic molecule which has yielded to quantitative X-ray analysis without the aid of symmetry components in the molecule itself. The complete structure is determined, and it is shown that the hydroxyl groups belonging to adjoining molecules approach to within 2·66 A., indicating the presence of hydrogen or 'hydroxyl' bonds between the molecules.

A suitable method for preparing colloidal dispersions of a cancer-producing substance, dibenzanthracene, for injection into experimental animals and for tissue cultures, has long been desired. H. D. Barnes describes such a method, in which he employs lecithin, a constituent of egg-yolk, as dispersing agent.

Further analysis of the amino acids which, according to Prof. A. I. Virtanen and T. Laine, are excreted in the soil by nodules of leguminous roots, have convinced these investigators that aspartic acid, which they failed to find on a previous occasion, is a constituent of the amino acid mixture. The remainder apparently consists of lysine. The authors believe that these compounds are the primary amino acids formed in the fixation of nitrogen by leguminous plants.

According to experiments by Dr. Paul Meyer, the colloid osmotic pressure of the body fluid of marine animals shows a close relationship to their general organisation. The values obtained with serum of Teleosteans are nearly as high as those of large terrestrial mammals. The assumption of Krogh that aquatic animals should require only a low colloid osmotic pressure in the blood to prevent filtration is not confirmed by the author.

Miss Nicholson and Prof. Yonge, disagreeing with Prof. H. Graham Cannon's views as to the function of the labral glands of the fairy shrimp, *Chirocephalus*, have stated that the material described by Graham Cannon as coagulated gland secretion was in fact the regurgitated contents of the gut. Graham Cannon now answers that there are essential differences between the coagulated mass described by him and that observed under different conditions by Nicholson and Yonge.

Sound-film tracks and breath-pressure records of speech-sounds, submitted by Prof. Scripture, indicate that successive speech-sounds may overlap one another in the spoken word. This may explain how the character of a speech sound can depend upon a sound that appears later in the printed word.

The outer portions of the 'wings' accompanying the Rayleigh line in the Raman spectrum of the light scattered by certain organic liquids such as benzene have been ascribed by Gross and Vuks to the persistence of quasi-crystalline lattice oscillations, rather than to the rotation of the molecules. Dr. S. C. Sirkar points out that one may then expect the intensity of the outer portions of the wings to diminish when benzene is mixed with a liquid like cyclohexane, which has feeble 'wings'. This, however, he finds does not occur.

Research Items

Neolithic Civilisation of Manchukuo

As part of the work of the Japanese first scientific expedition to Manchukuo, archæological investigations, not however of an intensive character, were carried out in the province of Jehol. Some twenty-four sites in southern Jehol produced results, mainly pottery, but associated with implements of chipped or polished stone. In a report on the results of this reconnaissance by Ichiro Yawata (Rep. of the First Scientific Expedition to Manchukuo, June to October, 1933, Sect. 6, Pt. 1, Waseda University, Tokyo. In Japanese with summary in English) the pottery is classified into four main groups: (i) yellowish-brown and dark brown of rather coarse fabric, some plain, but a large proportion with cord-marked or banded ornament; (ii) grey, brown or black ware of fine paste, wheel-made, with slip, and polished and in some instances with painted designs; (iii) grey, bluish or black, wheel-made, and baked to a fine texture, commonly known as Han type pottery; (iv) reddish-brown, of fine texture, containing a large proportion of talc powder. The distribution of the groups varied, but on most of the sites examined two or three of the groups were present and sometimes all four. So also polished as well as chipped stone implements were found sometimes on the same site. At Ho-Tung, Chen-teh, on a hillock on which relics were found from foot to summit, quantities of groups i and iii with small quantities of ii and iv were associated with spindle-whorls, chipped and polished stone axes and stone knives; and on a hill to the north-west of Lwang-ping, with groups i, iii and iv, stone knives, a grattoir, and some pieces of iron were found. The axes collected included one perforated specimen. Near Pei Piao a fragment of a bronze vessel was discovered. This appears to have had a high ringed foot. The bottom was divided into three panels, each with a double dragon design. An analysis gives a composition of copper, 66·98; tin, 8·62; lead, 21·64; nickel, 0·05; arsenic, trace. The results of chemical and metallurgical examination point to a pre-Han origin.

Methods of Psychodiagnosis

Character and Personality (3, No. 3) contains an article entitled "The Development Test as Applied to Infants in the Service of Psychodiagnosis" by Hildegarde Hetzer and Anneliese Braun, Educational Academy, Elbing. It gives a short report of the Vienna developmental tests carried out by Ch. Bühler, H. Hetzer and others. With these tests, consisting of seventeen series each containing ten tasks, they claim to "provide one means for the psychodiagnosis of infants useful for pediatricians, psychologists, educationalists and practitioners of healing methods for children". They check the performances of one to six years' old children in six chief lines of human behaviour: sensory perception, body control, sociability (language), learning capacity (memory and imitation), capacity to deal with a given material, intellectual productivity. The quantitative degree of development in each of these at a certain age is noted. Thus they find the developmental quotient in the same way as one finds the intelligence quotient. This quotient indicates "a general habit" and not inborn efficiency in a limited field of behaviour alone. An analysis of three practical cases illustrates the method. The results are checked by a doctor's opinion and general observation. They throw light on character traits and factors influencing character and personality, reveal errors of everyday judgment and give hints for therapy.

American Ground Squirrels and Pneumonic Plague

THE most extensive outbreak of plague among ground squirrels since the peak of the animal epidemic in California between 1907 and 1919 is being experienced on the west coast of the United States. Dr. W. H. Kellogg states that not only is ground squirrel infection not decreasing after thirty years, but rather it is increasing and spreading over a wider territory, so that from the Coast Range it has penetrated to the interior valleys of California and even to the Sierras (*J. Amer. Med. Ass.*, Sept. 1935). Thus a permanent endemic rodent focus has clearly become established. Equally disturbing is the fact that the plague shows renewed virulence and an increasing pulmonary tendency in the prevailing strain of the plague bacillus, and pneumonic plague, more deadly to man than bubonic, is thought to be directly related to the plague in ground squirrels and ground hogs. Once pneumonic plague has obtained hold in highly populated human areas, its spread becomes independent of ground squirrel or the flea which acts as carrier, because the bacilli are in the sputum and transfer may take place by droplet infection.

A Remarkable Dipterous Insect

THE discovery of a remarkable type of fly in Japan by Mr. M. Tokunaga was announced by him in 1932, when he gave it the name of *Nymphomyia alba*. Since this insect did not come within the limits of any known family of Diptera, the new family Nymphomyiidæ was established for its reception. Mr. Tokunaga's preliminary paper appeared in *Annotationes Zoologicae Japonenses* of 1932 and a brief account of this communication appeared in our columns (NATURE, **132**, 68; 1933). In the *Philippine Journal of Science*, February 1935 (pp. 127–210), the same writer contributes a long and detailed study of this insect's morphological features. Although *Nymphomyia* possesses brachycerous antennæ, it is regarded as belonging to the series Nematocera on the basis of the wing venation and other general characters. Its specialisation isolates it from any known families of Diptera, and on the whole, its primitive features mark it as being among the lower assemblage of the order. A study of its larval structure is greatly needed and, until this is available, definite conclusions as to its nearest affinities lack an important possible link in the evidence. A very peculiar feature of the insect is that the wings are deciduous, being easily broken off along a definite line, as in termites and ants. Whether or not this is a normal occurrence in life is as yet undetermined.

Sense-Organs of Spiders

Two almost simultaneous papers make a noteworthy contribution to our understanding of the sense-organs on the legs of spiders. B. J. Kaston (*J. Morphol.*, 58, 1, 189–207; 1935) describes the histological structure of the lyriform or slit organs, and concludes that they probably function as chemoreceptors, stimulated by odorous vapours. They closely resemble the sensilla on the antennæ of insects. In an exceptionally interesting paper, H. Blumenthal (*Z. Morphol. Okol. Tiere*, 29, 5, 667–719; 1935) has made a full histological and experimental study of the tarsal organ first noticed by Dahl in 1883. This organ, which lies dorsally on the tarsi of legs and palpi in both sexes of all but a few families, appears, like the slit-organs, to react to vapours. Spiders were found to respond to the arrival of a drop of water by approaching and drinking it, but this did not happen if the tarsal organ was excised. The organ may also function as a detector of taste, for spiders were apparently able to distinguish between pure water, sugar solution and brine. It is suggested that its chief biological value is in the search for drinking-water, in the finding of a mate and in the tasting of captured prey. The organ is comparable in structure to the Haller's organ of the ticks and the chemoreceptors described by Minnich on the legs of insects.

Growth and Moulting of Lobsters

KNOWLEDGE of the development of lobsters is a matter of great importance, for legislation fixing size limits and close seasons ought to be founded upon the natural history of the species. Some observations upon the growth of young lobsters have been made by W. C. Smith at Port Erin Marine Biological Station (*Trans. Liverpool Biol. Soc.*, 48, 51; 1935), though the fact that the conditions were artificial warns against acceptance of the results as of general significance. It was found that moulting and mortality in lobsters from about a year to 2½ years old were almost confined to the summer months, with temperatures above 10° C., and that death rate reached a maximum with temperature. Moulting occurred from two to five times during the second year, generally three times; and two or three times in the third year. After the fifth to the eleventh year there is only one moult annually. Sizes were, at end of first growth period, 26–32 mm., at end of second year 42–57 mm., in autumn of third year 70 mm., but the numbers measured were very small. One female lobster was ten years old before reaching the legal fishery size of 9 inches, although a male of five years may reach the legal size for catching after next moult.

Pruning of Mature Apple Trees

MANY apple growers continue to prune mature trees as a matter of routine. It has been assumed that pruning is an indispensable foundation for fruitfulness in trees of all ages, but the conclusions expressed in a recent publication by Joseph Oskamp (Bull. 624, Cornell Univ. Agr. Exp. Sta., Ithaca, N.Y., March, 1935) do not support this view. The bulletin handles a formidable collection of detailed records, extending over a period of twelve years, which refer to trees about twenty-five years old. No significant effect of pruning on yield of fruit, or on its size, colour and freedom from blemish has been found. It is suggested that mature trees should merely be kept within bounds, so that the fruit is not difficult to gather, and that sufficient attention be given to the mechanical ability of branches to bear heavy loads of apples. The need for light at the centre of the tree also makes it necessary to remove whole branches as they tend to fill up the space within the crown of the tree too tightly.

Methods of Orientation in Ancient Babylonia

DR. ECKHARD UNGER appends to an account of ancient Babylonian maps and plans which have survived on clay tablets certain indications of the methods of orientation emerging from their examination (*Antiquity*, September). A world map, for example, shows, especially by the 'dark' fifth region in the north, that the north-west was at the top of the map. It has been shown that the Sumerians originally based their system on the direction of the prevailing winds in Mesopotamia, these being approximately north-west, north-east, south-east, south-west. They determined the individual character of these winds, and interpreted them as manifestations of gods of a like nature. The manifestation of the gods through the winds played an important part in the orientation of the temples set up to them, but owing to wind variation, the direction was the arc of a quadrant. The rising of the sun in the north-west quadrant at the summer solstice was the time for determining orientation in Babylon, the run of the streets, etc., affording an astronomical time-gauge, occurring once a year and providing a basis for the adjustment of the calendar by an intercalary month. The moon and stars also afforded systems of orientation; but in all the system was inclined, and did not follow the cardinal points as we understand them. This shows that the tradition of a deity associated with the wind survived. In practice, owing to wind variation, orientation was checked by the position of certain stars. 'Sunrise' and 'sunset' imply a similar orientation by quadrant, indicating not the direct easterly or westerly points, but the complete quadrant within which the sun rose or set.

Seismology in New Zealand

SOME interesting reports on earthquakes in New Zealand have recently been published. Dr. C. E. Adams and Dr. J. Henderson describe the earthquakes of the year 1934 (Dominion Obs. Bull. No. 102; 1935), twenty-four in number, one of which, on March 5, was of destructive intensity. Its epicentre lay in lat. 40·95° S., long. 176·8° E., about thirty miles off the east coast of the North Island. The earthquake caused considerable damage in the south-east portion of the North Island, and slightly disturbed the face of the country in the districts round Pahiatua and to the east. Dr. L. Bastings (Bull. No. 103) gives a list of the destructive earthquakes in New Zealand during the century 1835–1934. They are sixty-nine in number, six of intensity 10, fourteen of intensity 9 and forty-nine of intensity 8 (Rossi-Forel scale). Taking account of earthquakes of all three intensities, the author claims for New Zealand a seismicity twice as great as that of Japan. Mr. R. C. Hayes (Bull. No. 104) considers the annual and diurnal frequency of earthquakes in New Zealand. For all earthquakes (1848–1934), the maximum number occurs in June, and for strong earthquakes (intensities 7–10) during the hours 0–3 a.m.

Oxidation of Metals

G. D. PRESTON and L. L. Bircumshaw (*Phil. Mag.*, Oct.), working at the National Physical Laboratory, have investigated the oxide films found on metals and alloys at low temperatures up to 400° C., using electron diffraction patterns to identify the thin films produced. The oxide film on copper, formed at room temperature, at 100°, and at 183°, showed the structure of Cu_2O, the thinner films showed a marked tendency to orientation with a (111) plane parallel to the polished surface of the metal, but orientation disappeared with the thicker films. A brass (30 zinc : 70 copper) formed a Cu_2O film at 183° C. and ZnO at 400° C., an aluminium brass gave a film of Cu_2O, the absence of any record of Al_2O_3 being ascribed to the amorphous nature of the substance. Magnesium and its alloys gave cubic films of MgO. It is suggested that the orientation observed with Cu_2O (and less markedly with MgO) is such that the plane in the oxide having the higher density of metal atoms tends to lie on the polished surface.

Absorption of Short Wave-Lengths

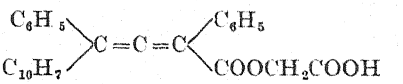
IN a paper published by the Bangalore Press on the transparency of the atmosphere in the ultra-violet and a possible means of extending the solar spectrum in the region 2200–2000 A., K. R. Ramanathan and L. A. Ramdas, of the Meteorological Office, Poona, have collected together many of the results obtained by different workers on the absorption of short wave-lengths by various agencies, particularly by oxygen and ozone. In the light of these results, they discuss the possibility of extending the solar spectrum beyond the limit attained up to now in the ultra-violet, which limit is stated to be 2863 A., reached by Paul Götz in Switzerland. Measurements of the absorption coefficients for ozone suggest that if the sun radiates as a black body at about 6,000° Abs. there should be a revival of the solar spectrum beyond the Hartley absorption band at about 2200 A. if ozone is the only absorbing agent. Herzberg, one of the investigators of the absorption of very short wave-lengths by oxygen, has suggested that the failure to detect any such revival is due to absorption by oxygen. This paper analyses some of the measurements of transparency of long horizontal columns of the atmosphere of the order of 1,000 metres that have been made by various workers, and a table is given which shows the absorption coefficient between 2893 A. and 1855 A. after the effects of haze, molecular scattering and ozone have been allowed for approximately, based on measurements by Jausseran and Rouard. In another table are shown the values of the intensity of solar radiation at 2900, 2200, 2063 and 2000 A. at the surface, at 16 km. and at 20 km., assuming that the sun radiates as a black body at 6,000° Abs., that the quantity of ozone in the atmosphere is 0·2 cm. at normal temperature and pressure, that the absorption coefficients for ozone below 2300 A. found by Meyer in 1903 are correct, and that the coefficients for atmospheric air are those found by Buisson, Jausseran and Rouard. The figures suggest that at 16 km. the solar spectrum might be photographed beyond 2200 A., if spectrographs of the same power as those used at the surface could be employed, but that it is very doubtful whether we could go beyond 1950 A. It is pointed out that a height of 16 km. is attainable by sounding balloons and even by manned stratosphere balloons.

New Kinetic Theory of Gases

IN the "Physics Forum" of the September issue of the *Review of Scientific Instruments*, Dr. I. I. Rabi of Columbia University directs attention to the new experimental facts with respect to gases which have been discovered by the use of molecular beams, and to the revision of the kinetic theory of gases which these facts have rendered necessary. While the hard sphere picture of the collision of two molecules is retained, wave mechanics requires the addition to it of a de Broglie plane wave of wave-length equal to Planck's constant h divided by mv, where m is the reduced mass $m_1m_2/(m_1+m_2)$ and v is the relative velocity of the two molecules. The effective area of the collision cross-section is changed from the πa^2 of the older theory to $4\pi a^2$ for small relative velocities and to $2\pi a^2$ for high velocities. The mean free path thus becomes a function of the temperature of the gas as well as the pressure, and there is no necessity to assume an attractive force between the molecules, which formerly meant the introduction of an assumed constant into the theory. The author concludes that the molecular radii and laws of force between molecules deduced from the older theory "have no real basis in fact".

Resolution of an Allenic Compound

IT is now known that allenic compounds in which at least one of the hydrogen atoms on each of the terminal carbon atoms of allene has been replaced by a substituent, can be obtained in optically active forms (Mills and Maitland, NATURE, **135**, 994 ; 1935). Another example is furnished by the resolution of an allenic acid :



by E. P. Kohler, J. T. Walker and M. Tishler (*J. Amer. Chem. Soc.*, **57**, 1743 ; 1935). The acid was first prepared by Lapworth and Wechsler in 1910, in one of the earliest of the many attempts to prepare an allenic compound suitable for resolution. The acid chloride has now been prepared, and also the glycolic acid derivative, which was resolved by means of the brucine salt. The acid, which melts at 195°, is a racemate or racemic mixture of two optical opposites which melt at 145°–146° and in ethyl acetate have the rotation $[\alpha]_D = 29{\cdot}5°$.

Late Type Variable Stars

IN the October *Observatory* (**58**, 285), Mr. A. D. Thackeray contributes an article on the observational facts which are known about the late type variable stars. We have here a field of astronomical work in which an enormous wealth of observational material is at hand with which theory has been unable to deal adequately. The complexity of the variations in magnitude, radial velocity and in spectral phenomena is very great, and there are many features which present grave difficulties to any attempts at a theoretical explanation. In particular, the presence of bright lines in the spectra is very difficult to account for in view of the very low temperatures of these stars, and the most hopeful line of attack must be an explanation in terms of chemical luminescence. This article should prove very useful, as it gives a summary of the known facts, with extensive references to the original works.

Theories of Vision

By Dr. F. W. Edridge-Green, C.B.E.

THOUGH the subject of theories of vision has been under discussion for many years, it has been suggested to me that a useful purpose would be served by a statement of the case for the visual purple theory in comparison with the duplicity theory. The visual purple view is that the cones are the sole percipient elements of the retina, being stimulated by the photochemical decomposition of the liquid surrounding them, the rods not being percipient elements but nerve elements regulating the supply of visual purple to the liquid surrounding the cones. Direct stimulation of the colourless transparent cones is against all photochemical laws, and these colourless transparent cones are surrounded by a highly absorbent photochemical substance, the visual purple, which when decomposed must produce an effect.

Visual purple was found in liquid form in the retina surrounding, but not in the cones, by Devereux Marshall and me with monkeys' retinæ examined immediately after removal of the eyes. This experiment is supported by the fact that Kuhne found visual purple in a fluid form in the retina and poured it out on a plate.

There are numerous physiological facts, as, for example, the control of vision by the nervous system, the removal of waste products and the resensitisation of the cones, which are inexplicable on a direct stimulation hypothesis[1]. If the rods and cones were distinct percipient elements there should be a distinct qualitative difference between the portion of the retina containing only cones and that containing rods, but von Tschermak, Hering, Hess, Garten and others have found only gradual quantitative differences in the sight between the foveal and the extra foveal area. The Purkinje phenomenon, the alteration of optical white equations by the state of dark adaptation, the colourless interval for spectral lights of increasing intensity, the different phases of the after-image, all exist, not only in the extra foveal, but also, only gradually diminished, in the foveal region. In certain conditions the colour of the positive after-image of any colour or white is purple[2].

Helmholtz pointed out that the evidence only proved that the cones were percipient elements and that there was no evidence that the rods were percipient elements. At a later date this view was reaffirmed by Nagel.

The eye resembles a photographic apparatus, and actual photographs have been taken on the retina and fixed by Kuhne. It will be noted that on the duplicity theory there is a very unsatisfactory correspondence with the film of a photographic apparatus. Photographers know that the sensitiveness of this film must be under control and a different sensitiveness is required for different intensities of light, but on the duplicity hypothesis there is only a mechanical arrangement. Bauer has shown that the visual purple is regenerated more rapidly under the stimulus of light than it is in absolute darkness, so that it must have a function in the daytime. If, however, we suppose that the function of the rods is to regulate the sensitiveness of the photographic film, that is to say, they are the nerve elements which liberate the visual purple into the liquid surrounding the cones, making this film more or less sensitive in accordance with the requirements of vision, we have an explanation of every known fact of vision.

The decomposition of the visual purple surrounding the cones causes stimulation of the cones and a visual impulse is set up. It is difficult to see how from the stimulation within the cone hypothesis the waste products can escape and a cone return to a condition in which it is able to receive further stimulation. It is probable that even in the early forms of vision, stimulation of the nerve ends took place not through the direct stimulation of the nerve end by light but indirectly through some light-absorbing substance which when acted upon by light gave off products which stimulated the nerve end. This appears to be the case even with the vision of insects.

The following are given as facts supporting the duplicity theory :—(1) that certain animals have only cones and others have only rods ; (2) that the periphery of the retina is colour-blind ; (3) that the eye is totally colour-blind in dark adaptation ; (4) that the Purkinje phenomenon and the recurrent image are not found with the fovea ; (5) that Porter-graphs consist of two branches, one the branch corresponding to light above 0·25 metre-candle, corresponding to the cones, and the branch for light below 0·25, corresponding to the rods. With regard to these, I make the following comments :—

Though I have examined numerous collections, I have never been able to find any animal with only rods or only cones, neither have I met anyone who has seen such a retina. The tortoise is the most quoted ; it is stated to have only cones. The rods and cones in the retina of the tortoise are as clearly defined and distinct as in the human retina. The periphery of the retina is not colour-blind when colours of sufficient intensity are used. This can readily be tested with a doctor's red lamp, which, it will be found, can be seen as red to the extreme periphery. In dark adaptation the eye is not totally colour-blind. Further, there is no scotoma or blind area corresponding to the rod-free portion of the macula which is equal to a visual angle of about three degrees. The Purkinje phenomenon and recurrent image are found with the fovea.

Frank Allen states that in his experiments all branches of the Porter-graphs were obtained on the same central area of the retina where rods are fewest in number or are altogether absent, the flickering at the point of fixation being specially noted. The presence of *B* branches in the graphs obtained under these conditions is therefore quite adverse to the duplicity theory. The larger number of branches of the Porter-graphs and their identification with enhancing and depressing reflex actions seem to remove the graphs completely from their support of the duplicity theory.

Secondly, facts which are explained in some measure by the duplicity theory can be explained in a far better manner by the visual purple theory. For example, the Purkinje phenomenon is found with other photochemical substances so that it is only a photochemical phenomenon. The visual purple gives a curve which is very similar to that of many other photochemical substances. We know that with photochemical substances the chemical effect is not proportional to the intensity of the light: a different curve is obtained with weak light from that which is formed with light of greater intensity. It is reasonable, therefore, to suppose that the visual purple which is formed by the pigment cells under the influence of a bright light would be somewhat different in character from that which is formed in darkness. Again, from the chemical analogy just given, even if the visual purple were of the same character we should not expect similar curves with different intensities of light. It is probable that both factors are in operation.

On the duplicity theory, the decomposition of the visual purple is supposed to stimulate the rods directly, but what other organ in the body produces a secretion which stimulates itself?

The fact that a small star is seen more clearly on the para-foveal region than with the foveal region has been given as a strong fact supporting the duplicity theory, but the yellow pigment of the yellow spot has been entirely overlooked. This absorbs light, particularly blue, and would account for the phenomenon. Pertz has shown that the dark adapted fovea is more sensitive to red light than the periphery, and yet red light bleaches the visual purple. Again, the most sensitive portion of the dark adapted retina forms an oval with its long axis horizontal, the oval being ten degrees in its vertical axis and fifteen to twenty degrees in its horizontal axis. This is just at the edge of the yellow spot where there are few rods. If this were a rod phenomenon, the light should appear much brighter farther out where the rods are much more numerous. The phenomenon is also found with the light adapted eye. If two discs of white paper each of a diameter of a sixteenth of an inch be pasted on black cardboard an inch apart and viewed from a distance of twelve to eighteen inches it will be found that the one that is directly looked at (with one eye) appears much darker and yellower than the other.

Congenital night blindness has been supposed to be due to absence of rods, but a better explanation is that the cones are not so sensitive as normal to a feeble stimulation, especially as this condition can be produced by continuous exposure by day to a bright light, as, for example, that reflected from snow. Congenital day blindness has been supposed to be due to absence of the cones, but a better explanation is that the mechanism of light adaptation is defective, probably from defective development of the rod and cone apparatus. This is supported by the fact that many of these persons see red imperfectly, and the rods are not supposed to convey impulses leading to the perception of colour.

In light adaptation, more visual purple is used up, but more is formed. In dark adaptation, though less is formed, much less is used up and so accumulates in the peripheral regions. The sensitisation of the foveal region from the periphery appears to be directly under the control of the nervous system.

We now come to facts which are inexplicable by the duplicity theory: the presence of visual purple in liquid form in the retina and surrounding but not in the cones; the fact that vision is plainly under the control of the nervous system is not explained.

At one moment the fovea appears the least sensitive portion of the retina and at the next moment may be the most sensitive portion of the retina. Helmholtz, whilst recording the fact, confessed that he was quite unable to suggest an explanation. The following simple experiment illustrates this:—On opening an eye on awaking in the morning and looking at the ceiling the central portion is seen as an irregular, circular, rhomboidal or star-shaped black spot. On closing the eye again a bluish violet circle appears at the periphery or middle of the field of vision, contracts and then after breaking up into a star-shaped figure and becoming brighter disappears, to be followed by another contracting circle. If the eye be opened when the star figure has formed in the centre it will appear as a bright, rose-coloured star, much brighter than any other part of the field of vision. If, however, we wait until the star has broken up and disappeared before opening the eye, it will be found that only a black spot is seen in the centre. This is explained on the theory that when there is visual purple in the fovea this is the most sensitive portion of the retina; when there is none there it is blind. It also shows that the fovea is sensitised from the periphery.

There are numerous methods by which currents in the field of vision which are not due to the circulation can be seen. The currents carry the visual quality, colour and brightness of the region from whence they come into an after-image. They also tend to move an after-image towards the centre; if we have two similar after-images, one situated in the centre and the other a short distance from the centre, the one external to the centre may be carried into the centre and combine with the one already there. These currents are formed by the flow of sensitised liquid.

The following simple experiment shows the influence of the para-foveal regions on the foveal region of the retina. Let a piece of black cardboard eight inches square be taken and place this on a wallpaper with a coloured pattern. The light in the room should not be too bright. The black cardboard should be viewed with one eye at a distance of six feet, the eye being kept as immovable as possible. It will then be noticed that portions of the colours of the wallpaper will appear to detach themselves from the wallpaper and move with a slow spiral motion into the black area. This will go on until the whole black area has completely disappeared, the surface being covered with a mixture of colours similar to those on the wallpaper.

There are numerous variations of the experiment. If a piece of yellow paper be placed on a blue ground and viewed as above, it will be noticed that the blue will invade the yellow until the latter appears quite white and then gradually becomes blue.

The bending of the re-current image at the fovea discovered by Hess is not explained by the duplicity theory. The duplicity theory fails to explain the change in position in the field of vision of after-images on movement of the eye.

The cones, therefore, are the sole percipient elements, and on being stimulated start impulses which are conveyed along the optic nerve to the brain and stimulate certain cells of the visual centre causing a sensation of light, and other cells causing a sensation of colour.

Molecular Structure of Carbohydrates

THE British Association discussion at Norwich on September 5, in Section B (Chemistry), on the molecular structure of carbohydrates, following the presidential address to the section, revealed both the variety of the important problems which still await solution, and the diversity of methods now employed in the attack on these problems. The discussion was opened by Prof. W. N. Haworth, president of Section B, whose presidential address constituted a survey of the present position of polysaccharide chemistry. It was shown that the recognition of the pyranose structure of ordinary glucose —a discovery barely ten years old—led the way in the elucidation of the ring structures of the disaccharides and afterwards of the polysaccharides.

Cellobiose (4–β–glucopyranosido-glucopyranose) and maltose (4–α–glucopyranosido-glucopyranose) are of special importance respectively in the chemistry of cellulose and of starch. Both these polysaccharides consist essentially of chains of glucopyranose units linked through positions 1 and 4, the glucosidic link being α– in starch and β– in cellulose. Chains of glucopyranose units appear also in glycogen and in lichenin. In xylan there occur chains of β–xylopyranose residues; and chains of manno-pyranose units (mutually linked through positions 1 and 6) and galactopyranose units (linked through positions 1 and 4) occur in polysaccharides synthesised *in vivo* by the action of certain moulds on glucose solutions. All the above are of the pyranose type, but the furanose structure is also found in polysaccharides, and recent work shows that its occurrence is widespread. An arabofuranose unit forms the terminal portion of the xylan molecule; chains of fructofuranose units with mutual linkages in the 1 : 2 positions constitute inulin, whereas fructofuranose units linked through positions 2 and 6 are found in levan, an important bacterial polysaccharide, and in a closely related polysaccharide which occurs in grass.

The work of the Birmingham school has, however, gone beyond the elucidation of the molecular structures of the polysaccharides and has succeeded in determining by purely chemical methods the molecular size of the giant molecules. For example, by gravimetric assay of the tetramethyl glucose formed on hydrolysis of the fully methylated polysaccharide, the chain-length of methylated cellulose has been fixed at 100–200 glucose units, and that of starches of diverse botanical origin at 26–30 units. Use of this 'end-group' method has served for the allocation of chain-lengths to glycogen, xylan, inulin, levan, and other polysaccharides. In many examples, this chemical molecular weight is in striking disagreement with the figure obtained on the basis of Staudinger's viscosity method, and the causes for this divergence were discussed with particular reference to the important case of the amylose and amylopectin constituents of starch, in which aggregation of the macro-molecules takes place. Special emphasis was laid on the need for clear differentiation between the chemical molecule and aggregates of such molecules which function as physical units.

Other methods of attack on the problem of molecular weights are also being employed, and in a subsequent paper Dr. S. R. Carter described results of osmotic pressure measurements on methylated and acetylated derivatives of inulin and lichenin. One of the principal difficulties in the use of this method lies in the choice of suitable semipermeable membranes, but by use of a disc of 'viscacelle' of adjusted porosity in specially designed apparatus, accurate measurements of osmotic pressure were obtainable. The figures for inulin were of particular interest, since they are in complete agreement with the chemically determined chain length (30 fructose units), whereas the viscosimetric measurements indicated only one-third of this value (10 units). In this case the failure of the viscosity method may be connected with the special conformation of the fructose units in the polysaccharide molecule.

Prof. Haworth's address concluded with a reference to investigations which have been commenced on the constitution of plant gums. These are of particular interest in that a derivative of gum arabic is known to possess properties resembling those of the specific polysaccharide of Type III pneumococcus anti-serum. The recent discoveries of such polysaccharides having immunological properties are of great importance, and the elucidation of the chemical structure of these substances must be of the greatest possible service to medicine.

In the paper which followed, Dr. W. T. J. Morgan discussed the function of polysaccharides in immunological specificity. He described the early discoveries concerning the specific precipitant for pneumococcus antibacterial immune serum, which led to the recognition that the capsular substance, different for each kind of bacterium, contains a complex polysaccharide which is the specific agent responsible for the serological reactions of the organism with the homologous antibody. Considerable progress is being made in inquiries into the chemical location of the specific characteristics, and it appears that the latter depend upon (*a*) the nature and stereochemical arrangement of the component sugars; (*b*) the mode of linkage of the sugar residues; and (*c*) the nature and position of substituent groups in the sugar residues. The mode of combination by which the reducing group of a glycuronic acid molecule forms a glycosidic union with the terminal primary alcoholic group of a glucose (or galactose) molecule, appears to have special significance in immunological chemistry. In addition, the specific properties of the polysaccharide-protein complex are closely governed by the presence in the polysaccharide of appropriately situated substituent groups, such as acetyl.

The two remaining papers were concerned with the intimate structure of the simple sugars. Dr. E. L. Hirst considered the possible correlation of structure with optical rotatory power in the sugar group. Although many empirical rules relating structure and rotation have been enunciated, their validity is always severely restricted to a small group of substances, and exceptions are frequent. It was shown that measurements of the rotatory power in the ultra-violet region of the spectrum sometimes give clues to the causes of departures from the rotation-rules. Three typical problems were discussed. (*a*) The abnormal rotations in the mannose series of

sugars were found to be ascribable entirely to the mutual influence of the two *cis* hydroxy groups on C_2 and C_3. (*b*) The negative rotations of tetramethyl γ-mannonolactone in organic solvents were explained by the nature of the rotatory dispersion, which requires for its representation a two-term Drude equation with terms of opposite sign, the induced term being positive both in water (where the lactone rule is obeyed) and in organic solvents. (*c*) The sign of the induced term in the rotations of amides can be correlated with the configuration of C_2 for those substances which obey the amide-rule, but exceptions occur which necessitate special explanations.

Mr. E. G. Cox gave an account of recent progress in the crystallography of carbohydrates. X-ray studies of a number of simple and methylated sugars lead to the conclusion that the six-atom ring in the pyranoses, unlike the hexamethylene ring, does not possess the Sachse form, but contains five nearly co-planar carbon atoms, the oxygen atom being displaced out of their plane. Various chemical and physical properties of carbohydrates find a satisfactory explanation in terms of this ring conformation; for example, there is much evidence that hydroxyl groups which, according to the Haworth structural formulæ, are *cis*, are actually contiguous in space. This is true for the ring form deduced from the X-ray data, but it is by no means necessarily so with a Sachse ring.

The configuration on the first carbon atom of the cyclic forms of the sugars is not established by the same rigid methods which are applied to the remainder of the molecule; the confirmation by X-ray methods of the configurations usually ascribed to the α- and β-forms of glucose is therefore a matter of considerable importance.

Educational Topics and Events

CAMBRIDGE.—At Emmanuel College, Dr. T. S. Hele, fellow of the College and University lecturer in biochemistry, has been elected into the mastership.

A. C. Bartlett, of Emmanuel College, has been approved for the degree of Sc.D.

P. H. Blair, of Emmanuel College, has been appointed an assistant lecturer in archæology and anthropology.

EDINBURGH.—The Rockefeller Foundation has made a grant of £1,500 to the Department of Medical Chemistry, to provide for the expenses of Prof. Barger's research work on vitamin B_1, for a period of three years from October 1935.

It has been agreed to offer accommodation in the University for the meeting of the International Union of Geodesy and Geophysics, which is to take place in Edinburgh on September 15–26, 1936.

SHEFFIELD.—The following appointments have recently been made: Prof. C. J. Patten, formerly professor of anatomy, and Prof. Miles H. Phillips, formerly professor of obstetrics and gynæcology, as emeritus professors; Dr. H. A. Krebs, as lecturer in pharmacology; Mr. H. E. Collins, as lecturer in mining; Dr. M. Ritchie, as assistant lecturer in chemistry; Mr. J. Harwood, as research assistant in fuel technology; Dr. J. W. Rodgers, as Ironmongers' Company research fellow (for one year).

Science News a Century Ago

Meeting of the Medico-Botanical Society

THE first general meeting of the session for 1835–36 of the Medico-Botanical Society was held on November 10, Earl Stanhope being in the chair. After the reading by Dr. Sigmond of an eulogium on the character of the late Gilbert Burnett, professor of botany to the Society, Mr. C. Johnson delivered a lecture on the importance of botany to medicine. He contrasted the present knowledge with that of the practitioner of former days, and dwelt on the necessity of giving to the vendor of drugs an education superior to what they had and of making the study of botany indispensable.

The Paris to St. Germain Railway

THE first railway to be authorised in France was that from Paris to St. Germain, and on November 14, 1835, the *Athenæum* said of this line that it "is to commence near the Church de la Madelaine on the Boulevards, and afterwards pass through a tunnel under the Commune of Les Batignolles Monceaux. This tunnel will be 907 yards in length. There are to be three stations for receiving and delivering luggage. The number of bridges or viaducts to be erected over streets and roads, between the point of departure and the Seine will be twelve. Altogether, it is considered that this railroad will be one of the best constructed, and most useful of any yet projected, not excepting those now in progress in England. It is expected, that the steam carriages on this road will be able to travel at the rate of thirty miles an hour, and according to this calculation, the distance between Paris and St. Germain will be performed in twenty-four minutes. It now occupies one hour and forty minutes."

Darwin at Tahiti

ON November 15, 1835, H.M.S. *Beagle* arrived at Tahiti, where she remained until November 26, when she sailed for New Zealand. Both Capt. FitzRoy and Darwin wrote interesting accounts of the island and its people, and Darwin said:

"I was pleased with nothing so much as with the inhabitants. There is a mildness in the expression of their countenances which at once banishes the idea of a savage; and an intelligence which shows they are advancing in civilisation. . . . On the whole, it appears to one that the morality and religion of the inhabitants are highly creditable." Of those who attacked the work of the missionaries among the islanders and its effect, he said: "They forget, or will not remember, that human sacrifices, and the power of an idolatrous priesthood—a system of profligacy unparalleled in any other part of the world—infanticide a consequence of that system—bloody wars, where the conquerors spared neither women nor children—that all these have been abolished; and that dishonesty, intemperance, and licentiousness have been greatly reduced by the introduction of Christianity. In a voyager to forget these things is base ingratitude. . . ."

On November 26, when the ship sailed, Darwin wrote: "In the evening, with a gentle land-breeze, a course was steered for New Zealand; and as the sun set, we had a farewell view of the mountains of Tahiti—the island to which every voyager has offered up his tribute of admiration."

Societies and Academies

PARIS

Academy of Sciences, October 7 (*C.R.*, 201, 573–628). LOUIS LAPICQUE: The nomenclature of chronaxies modified by the action of the nerve centres. Reasons are given for rejecting the terms static chronaxy and dynamic chronaxy. F. GANTMACHER and M. KREIN: Oscillatory matrices. RENÉ DE POSSEL: The abstract derivation of functions of ensembles. VLADIMIR BERNSTEIN: Concerning the methods of search for singular points of functions defined by Dirichlet series. ARNAUD DENJOY: Minkowskian functions. PAUL MONTEL: A theorem of Jacobi. EDOUARD CALLANDREAU: Corrective functions in the neighbourhood of the Rankine-Lévy solution of the heavy massif supported by a rectilinear wall. SERGE NIKITINE: Suction by volumetric pumps. Discussion of the relations between the yield of a pump and the number of strokes per minute. MIROSLAV NÉNADOVITCH: The influence of the inter-inclination of one of the wings on the aerodynamic characteristics of rigid biplane cells of infinite span. ANDRÉ COUDER: The cellular construction of telescope mirrors. The deformations observed in cellular mirrors are much larger than would be expected from a study of the elastic properties and are probably due to the thermal conditions existing during polishing. MAURICE DÉSIRANT and JULES DUCHESNE: A new emission spectrum of sulphur in the photographic infra-red. MLLE. YVETTE CAUCHOIS: New measurements and observations relating to the *L*-emission spectrum of platinum. V. DOLEJŠEK and M. HYLMAR: The fine structure of the L_{III} absorption discontinuity of the rare earths. GABRIEL VALENSI: The kinetics of the oxidation of metallic wires. M. BOBTELSKY and MME. BOBTELSKY-CHAJKIN: The catalytic decomposition of hydrogen peroxide in the presence of mixtures of salts of manganese and copper. MME. MARIE FREYMANN and PAUL RUMPF: The absorption spectra in the near infra-red of amines and amides. Use of the phenomenon of dissimulation in the search for amphoteric ions. The influence of neighbouring groups. The presence of an absorption band at 1·04 μ is taken as a proof of the existence in a compound of the NH group. JEAN TIMMERMANS and GUSTAVE POPPE: The mutual solubility of heavy water and organic liquids in systems possessing a curve of negative saturation. MARIUS SAUVAGEOT and EDMOND ROUSSEAU: The transformation points of nickel steels. At the beginning of the transformations produced by heating, nickel steels undergo a very marked segregation: the first portions of austenite formed are highly charged with nickel, corresponding to a metal the transformation point of which is below 0° C. Manganese may give rise to similar phenomena. VLADIMIR FROLOW: The dissolved salts in the Sandjak waters. The electrical resistance of twenty-five waters from various sources has been studied as showing the variations in the content of dissolved salts. PIERRE DANGEARD: The identity of *Laminaria Lejolisii* and *L. iberica*. PIERRE P. GRASSE and MLLE. LOUISE LESPERON: The accumulation of acid colouring matters in the silkworm by different tissues according to the mode of access. GEORGE BEADLE and BORIS EPHRUSSI: The differentiation of the colour of the *cinnabar* eye in *Drosophila melanogaster*. A. PAILLOT: A new ultra-virus disease (polyhedra disease) in the larvæ of *Vanessa urticæ*. V. A. KOSTITZIN: A relation between the sex and the number of parasites in the same host. A mathematical study of the data on this subject given by A. Vandel. MME. PAULETTE CHAIX: The kinetics of the attack of glucose and of lactic acid by small bacterial masses. The idea of minimum active mass.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, 21, 517–559, Sept. 15). CLAUDE E. ZOBELL: The assimilation of ammonium nitrogen by *Nitzschia closterium* and other marine phytoplankton. Provided small concentrations (0·2 millimol and less) of ammonium, nitrite and nitrate are compared, multiplication of the diatoms first becomes manifest with ammonium nitrogen. In cultures containing both ammonium and nitrate, the ammonium was the first to be depleted, and a trace of nitrite appeared. It is suggested that the diatoms in the sea reduce nitrate to nitrite extracellularly in the course of nitrogen assimilation and that nitrification, hitherto regarded as an essential to nitrogen assimilation, is rather a regulatory or storage process. G. A. MILLER: Groups in which the squares generate a subgroup of index less than seven. A. D. MICHAL: "Riemannian" differential geometry in abstract spaces. E. FISHER: Asymptotic representations of confluent hypergeometric functions. A. D. MICHAL and V. ELCONIN: Completely integrable differential equations in abstract spaces. CHARLES H. FAY: A refinement of the Heisenberg theory of ferromagnetism, applicable to simple cubic crystals. The micro-crystal is regarded as built up of units larger than the atom but containing sufficiently few atoms to allow calculation of their unperturbed energy levels. The method treats half the interaction rigorously, instead of none as previously, and the remainder by an average energy approximation similar to that used in the 'simple' Heisenberg theory of ferromagnetism. E. HUTCHISSON, T. H. OSGOOD and R. E. FEARON: Electrical conductance of short gaps in air. Apparatus was devised whereby two nearly flat surfaces could be brought into gradual contact, and very small potential differences, below the ionising potential of the common gases of the air, were used in order to avoid sparking. It was found that appreciable current can pass surfaces of approximately 4 cm. diameter separated by 10,000 A. in air, and that the current is proportional to the square of the applied potential difference, suggesting conduction by charged dust particles. When the plates are brought gradually closer, the current changes from an ionic to an ohmic one, the latter being probably due to metallic prominences on the opposed surfaces. SVEN PH. CARLSON: The colour changes in *Uca pugilator*. If the eye-stalks of the fiddler crab are removed, the animal becomes pale, an effect the reverse of that which occurs in most crustaceans. Extracts from the middle part of the eye-stalk of the crab cause the animal to grow dark again. The active substance seems to come from the blood-gland of Hanström and is probably the eye-stalk hormone common to crustaceans, though its effect on the fiddler crab is the reverse of that on other crustaceans. JANE M. OPPENHEIMER: Processes of localisation in developing *Fundulus*. By means of localised vital staining, it has been possible to trace the position of embryonic tissues and the movements by which their cells attain their final position. TRUMAN L. KELLEY: An unbiased correlation ratio measure.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Sunday, November 10

BRITISH MUSEUM (NATURAL HISTORY), at 3 and 4.30.—Dr. A. T. Hopwood: "Fossil Mammals".*

Monday, November 11

BRITISH MUSEUM (NATURAL HISTORY), at 11.30.—J. D. Macdonald: "Birds".*

ROYAL GEOGRAPHICAL SOCIETY, at 5.—Prof. G. Barbour: "The Evolution of the Yangtze Kiang".

Tuesday, November 12

BEDFORD COLLEGE FOR WOMEN, at 5.15.—C. A. Mace: "The Experimental Study of Incentives".*

KING'S COLLEGE, LONDON, at 5.30.—H. W. Dickenson: "The History of Mechanical Invention" (succeeding lectures on November 19 and 26).*

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN, at 8.30.—Prof. A. Smithells: "The Teaching of Chemistry" (Harrison Memorial Lecture).

Wednesday, November 13

BRITISH SCIENCE GUILD, at 4.30.—(at the Goldsmiths' Hall, Foster Lane, London, E.C.2).—Sir Josiah Stamp: "The Calculus of Plenty" (Norman Lockyer Lecture).

ROYAL SOCIETY OF ARTS, at 8.—Sir Albert Howard: "The Manufacture of Humus by the Indore Process".

Thursday, November 14

ROYAL SOCIETY, at 4.30.—G. L. Brown and Sir Henry Dale: "The Pharmacology of Ergometrine".

M. J. D. White: "The Effects of X-Rays on Mitosis in the Spermatogonial Division of *Locusta migratoria*, L."

D. E. Sladden: "Transference of Induced Food Habit from Parent to Offspring".

ROYAL ASIATIC SOCIETY, at 4.30.—Dr. M. Gaster: "Maimomides and his Works".

CHEMICAL SOCIETY, at 8.—Dr. S. I. Levy: Brauner Memorial Lecture.

Friday, November 15

ROYAL SOCIETY OF MEDICINE, at 8.15.—Discussion on "The Recent Epidemic of Malaria in Ceylon", to be opened by Sir Weldon Dalrymple-Champneys, Dr. Wigglesworth and Dr. P. H. Manson-Bahr.

ROYAL INSTITUTION, at 9.—Prof. Robert Robinson: "The Synthesis of a Natural Colouring Matter".

Food and the Nation

IN those wonder-promising days of the Victorian era, when all seemed well with the world because the *beati possidentes* alone were vocal, there appeared to be general agreement that the functions of the State should be confined to upholding justice, to protecting citizens against aggression, and to providing certain public health services, such as sanitation and preventing the spread of epidemics. As time went on, State intervention was extended to the provision of primary education, old-age pensions, health insurance and unemployment benefit; but it is only recently that the scandal of the slums has compelled Parliament to assist in providing decent housing accommodation for the poorer classes. Last of all, there is now a clear call for the State to take a hand in providing adequate food for the million.

It is strange that this most essential of all the basic needs of man should have been recognised so tardily, except for certain regulations governing chemical and bacteriological purity. It is true that there are some half-dozen Government departments dealing with certain aspects of national nutrition; but there has hitherto been no unified direction, no settled policy and no legislation either based upon, or in any way recognising, the principle that every man who does his duty by the community shall by legal right, and not by charity, be secured from hunger or from the ill-health associated with an inadequate dietary. To-day the word 'inadequate' applies to quality as well as to quantity, for scientific research has shown that man cannot live by calories alone; in addition to proteins, fats and carbohydrates, he needs certain essential vitamins and minerals that are largely to be found in fresh dairy produce, eggs, fruit and vegetables. Was it not Lavoisier who lamented the fact that the very people who needed most food and nutritious food—the labouring classes—were precisely those who were least able to afford it? What Lavoisier said towards the end of the eighteenth century applies with particular force to-day, especially in regard to nutritional quality.

Sir John Orr, in a remarkable address to the British Association at Norwich, told us that estimates show how in this year of grace 1935 there are some twenty million people—more than forty per cent of the population of Great Britain—who, largely owing to poverty, do not enjoy a diet which according to the modern science of nutrition is completely adequate for health, so that diseases due to malnutrition are still rife. In view of the glut of all kinds of food, this state of affairs is disturbing the public conscience. Although there is a great lack of authentic data, recent investigations by the staffs of the Rowett Institute and the Market Supply Commission indicate that consumption of milk, eggs, fruit and vegetables rises uniformly with income; and that physique is worse, and disease is more prevalent, in the poorer classes. The diet of the lowest income group—those earning ten shillings or less a head of the family each week—is markedly deficient from the point of view of health, and a minimum family income of about £1 a head each week is needed.

To bring the diet of the poorer sections of the community up to the standard required for health

would involve an increased food consumption of 10 per cent, representing at retail prices a hundred million pounds per annum, and to bring all diets up to the average of those of the income level of 25*s*. a head a week would require 20 per cent more food and two hundred million pounds greater expenditure at retail prices. The additional food, consisting mainly of fruit and vegetables, and animal products such as milk and eggs, could be produced at home without prejudicing our export trade or the interests of our overseas investments, and, of course, our agriculture would benefit greatly.

The measures that have recently been taken to encourage home food-production, by raising prices to a level assuring adequate returns to producers, suffer from the drawback that they maintain food at prices that retard consumption. Therefore they cannot be regarded as elements of a permanent policy. Sir John Orr would like to see the present marketing boards assume the role of public utility companies, which would control slaughter-houses, bacon factories, milk-depots, etc., buy from the farmer and sell to the distributing trades, making the staple foodstuffs available at a special low price to the poorest classes. Such an organisation would in itself lower retail prices by reducing distribution costs, and the rest of the gulf between the price paid to the farmer and the money received from the consumer would be bridged by a direct State subsidy. The ultimate effect of this subsidy would be to reduce State expenditure on public health and social services; meanwhile, it would promote internal trade, stimulate industries, and bring back money to the Treasury in the form of income-tax and other receipts.

Increased consumption, as Sir John says, is the crux of the problem, and in this connexion attention should be directed to that rare thing, a successful economic experiment, which was carried out early this year by the Potato Marketing Board in the depressed area at Bishop Auckland, Co. Durham*. This area has a population of 19,000, which in February last included 5,000 insured male workers, of whom 2,400 were unemployed. For a period of eight weeks in February and March, potatoes were sold to the unemployed and their dependants (33 per cent of the population) at 4*d*. per stone, as compared with the ruling price of 7*d*. per stone. Each buyer had to get a retailer to stamp a voucher, present it at a central warehouse, pay cash and take away his purchase in his own container. The Board paid to the retailer 1*d*. per stone of potatoes sold, as compensation for loss of trade, and 10*s*. per ton to the wholesale merchants for services rendered. About 94 per cent of the issued vouchers were used; 187 tons of potatoes were purchased by the Board at an average price of 59*s*. per ton, and deducting wastage, 182 tons were sold. The total expenditure of the Board (exclusive of overheads) was £297, comprising £111 for warehouse distribution, £121 for compensation to retailers (13*s*. 3½*d*. per ton of potatoes sold), and £65 for wholesale merchants. It was found that, although sales from retail shops fell to 60 per cent of the normal, total sales increased by 96 per cent above the normal, or 69 per cent if full allowances be made for loss of trade sustained by fish-fryers, and for a big reduction in sales during April. No change in the dietary of the unemployed was observed other than an increased consumption of potatoes.

The experiment may, therefore, be held to show that increased consumption of a cheap and valuable commodity like potatoes will follow a drastic reduction in price. The Board does not suggest that the method is of general application; nevertheless, as an emergency measure for the relief of the unemployed, or for disposing of surplus stocks, for example, of milk or meat, it might well receive the consideration of public bodies. Nor would it be maintained that all the evils associated with an unorganised distributive system, or those due to maldistribution in general, could be solved by such means.

One of the most important questions of the day is whether the existing economic system can be modified and amended in such manner that the satisfaction of primary human needs no longer remains subservient to the making of profits. Such schemes as that of Sir John Orr, which has been publicly approved by the Minister of Agriculture, may suffice to raise the general standard of living to a level commensurate with the abundance of supplies that modern industry, based upon modern science, has placed at our disposal, and in accordance with the dictates of the modern social conscience. Failing their success, the only alternative, short of pure communism, appears to be an amount of State control of trade and finance likely to provoke widespread opposition in a people still retaining a degree of liberty of action. After all, there seems to be no reason why, with abundance knocking at the door,

* An Experiment in the Distribution of Potatoes at Bishop Auckland, February–March, 1935. Potato Marketing Board, Miscellaneous Publications, No. 2. 1*s*.

every working citizen should not be guaranteed a sufficiency of the basic necessities of life, namely, food, housing, light and fuel, without prejudicing the interests of those who are more fortunately placed.

Those who look askance at the encroachments on personal liberty which such a policy would appear to entail, might consider the dictum of Huxley: "The only liberty I care about is the liberty to do right". Is there not a moral obligation on the part of the State to ensure the bare minima of the means of subsistence to all who render service to it? And what a brave new world might arise, what developments might follow if the thoughts of even a fraction of those who are now at their wit's end to meet the requirements of daily life could by such means be diverted into the cultural channels of art, science, philosophy and letters! Many no doubt will urge that it is one thing for the State to provide such means towards a fuller life, but quite another for men to use them in the way intended. The answer to that contention is that man, in the mass, has not yet been given the opportunity, and that his future progress depends primarily upon his ability to master and improve his environment, and to provide the young with the best all-round education that his wits can devise.

Original Sources in Physics

A Source Book in Physics

By Prof. W. F. Magie. (Source Books in the History of the Sciences.) Pp. xiv+620. (New York and London: McGraw-Hill Book Co., Inc., 1935.) 30*s*. net.

TWO great efforts to present to the physicist and chemist the *ipsissima verba* or translations of some of the fundamental contributions to science come to mind as one turns the pages of this latest 'source book'—Ostwald's *Klassiker* and the publications of the Alembic Club. He is fortunate who has easy access to a full set of the *Klassiker*—its hundred-odd reprints represent a remarkable attempt to collect in one group those contributions to the advancement of the physical sciences which may be regarded as classic. The publications of the Alembic Club are fewer in number and more restricted in character—they cover certain of the classics of chemical science—and it is interesting to note that a term has not yet been set to the activities of the Club, as reprints, sponsored by Dr. Leonard Dobbin, are still appearing under its name.

It is, perhaps, impossible to consider the publication in English of a series of reprints covering so wide a field as Ostwald has surveyed, and until such a venture becomes possible, we must be content with the very good second-best which Prof. Magie has provided for us. He has shown conclusively—and some of his audience were inclined to be sceptical about it—that it is possible to give something of the atmosphere of a physical paper by selections, brief enough to keep his book within moderate compass, yet chosen so as to illustrate the central thesis of a theoretical analysis or the essentials of a piece of experimental work.

The main sections of the book are headed mechanics, properties of matter, sound, heat, light, magnetism and electricity; selections from some one hundred and fifty papers are given; and the authors range, in time, from Stevinus, Galileo, Huygens and Newton, to Maxwell, J. J. Thomson, Zeeman, Röntgen and the Curies. A brief account of the life of an author precedes the selection from his papers.

The selections are far from being snippets; they convey something of the method and outlook of the author, and they provide a reference book which serves to elucidate certain obscure and doubtful passages in the ordinary texts. Once again we are privileged to hear Boyle telling how he took "a long glass-tube which, by a dexterous hand and the help of a lamp, was in such a manner crooked at the bottom that the part turned up was almost parallel to the rest of the tube"; and how, having closed the shorter end of the tube, he imprisoned air therein, and "began to pour quicksilver into the longer leg of the siphon, which . . . did . . . streighten the included air: and continuing this pouring in of quicksilver till the air in the shorter leg was by condensation reduced to take up by half the space it possessed (I say, possessed, not filled) before", how he "observed, not without delight and satisfaction, that the quicksilver in that longer part of the tube was 29 inches higher than the other".

We may read for ourselves what Grimaldi really saw in 1658; and if we want to know whether Römer did or did not enunciate a sort of Doppler principle, regarding Jupiter as a body sending

signals to the earth at regular intervals, and now moving towards, now away from the earth, so that the observed intervals varied correspondingly, the evidence is before us. We have the text of Davy's experiments on friction, and we can see for ourselves that Newton's law of cooling was established for forced convection—for bodies *cooling in a breeze*.

This last paper is specially interesting ; it is brief, it was published anonymously, and its topic is that of a "Scale of Degrees of Heat". The scale is duodecimal, the zero being the temperature of freezing water, and 12° the normal temperature of the human body. Various temperatures are recorded ; 34° is the "heat with which water boils vehemently", 96° is the "least heat with which lead melts", and the highest temperature recorded (200°–210°) is the "heat of a small fire made of wood". The scale is established with the assistance of a linseed oil thermometer and red-hot iron.

The translation in the volume under review tells us that Newton "heated a large enough block of iron until it was glowing, and taking it from the fire with a forceps while it was still glowing I placed it at once in a cold place where the wind was constantly blowing ; and placing on it little pieces of various metals and other liquifiable bodies I noted the times of cooling until all these bodies lost their fluidity and hardened, and until the heat of the iron became equal to the heat of the human body". He then proceeds to determine the "heats" under review by assuming that the "excess of the heat of the iron and of the hardening bodies above the heat of the atmosphere, found by the thermometer, were in geometrical progression, when the times were in arithmetical progression".

An interesting point arises concerning the details of part of this translation. It happens that a translation of Newton's paper was appended by Robert Smith to his edition of Cotes' "Hydrostatical and Pneumatical Lectures" (3rd edition, 1775), a useful little volume which contains as an appendix, not only Newton's paper, but also Halley on the reason for the rise and fall of the barometer with change of weather, and Jurin on capillarity. Smith's translation reads, "I heated a piece of iron . . . till it became redhot, and taking it from the fire with the tongs likewise redhot, . . . upon it I laid particles . . . and noted the several instants of time when by cooling they lost their fluidity and began to coagulate. . . ." The differences are slight but significant and, accuracy apart, the existence of an almost contemporary translation raises the point whether it is not preferable to employ such a translation whenever possible, as more likely to give the atmosphere of the original.

It is impossible to give more than the slightest indication of the generous loading of the table which Prof. Magie has spread. Faraday, Ampère, Coulomb, Hertz ; Ohm, Joule, Rowland and Hall ; Stokes, Kirchhoff, Balmer and Stefan ; these are but a few of the hundred or so authors represented, and there are remarkably few omissions. In the ranks of writers now dead, Waterston should certainly have been included ; and there are some obvious omissions of the names of workers still with us.

A. F.

A New Botanical Annual

Chronica Botanica

Edited by Dr. Fr. Verdoorn. Vol. 1, 1935. Pp. 448. (Leyden: Chronica Botanica, 1935.) 15 guilders.

THIS new periodical provides abundant matter of many-sided botanical interest. When the editor put forward his general scheme there were many who thought it impossible to carry out in a satisfactory manner, but although there is considerable unevenness of treatment there can be no doubt that the result is very satisfactory. Roughly, the idea is to give the most recent information about the four thousand or so institutions concerned with pure or applied botany and the researches of the sixty or seventy thousand botanists—and to do this annually.

The volume is divided into three parts which are readily recognised by the yellow, red and blue colouring of the page edges.

The first part (75 pages) deals with a number of heterogeneous subjects. It opens with an article by Dr. E. D. Merrill on "International Co-operation among Botanists", which is a statement of general customs and a plea for their present continuance and future development. Then follows an almanac which, among other matters, gives the birthdays of many former botanists and present ones (with some age restriction) ; and an outline programme of the Sixth International Botanical Congress held at Amsterdam on September 2–9 with photographs of the Committee and Recorders and of a dozen prominent botanists who have passed away since the last Congress in 1930. Dr. T. A. Sprague then gives a brief "Survey of Nomenclature (1930–35)" mainly concerned with

the effect of the death of Dr. J. Briquet in 1931. Dr. A. B. Rendle contributes "A Short History of the International Botanical Congresses" which goes beyond the Paris Congress of 1900 and begins with the Brussels Congrès International d'Horticulture, 1864: this is the longest article in the volume, and is a most useful and interesting account of a little-known subject. It is followed by thirty-five pages giving information about "International and Important Congresses, Committees, and Societies": those who hold there are too many congresses will surely find some arguments here in favour of their opinion.

The next 258 pages form the main part of the volume. This is a "Review of all Branches of Plant Science during 1934" arranged alphabetically by countries and further subdivided alphabetically. To get the information, a set of questions was sent out. Institutions answered in different ways and at various lengths, which accounts for a good deal of the unevenness of treatment. Research programmes, changes in staff, new buildings, investigations being carried out, explorations, extensions, publications—indeed everything that might be considered of general botanical interest, or of special interest to those working in the same field. This is supplemented by information found by the editor in periodicals; NATURE and *Science* being well combed. But there are others: for example, "*Sovjetskaja Botanica* announces that botanical lectures are regularly given to the soldiers of the Red Army, who are said to be deeply interested in this new feature". This section ought to prove of the greatest value to workers in every branch of botany, for the pages are packed with information.

The last section is again heterogeneous. It begins with "Correspondence", the sixteen letters covering a wide field: there are also half a dozen queries. Two pages are devoted to new periodicals and thirty-four pages to new and changed addresses, which is really a supplement to the "International Botanical Address Book". A touch of intentional humour is provided by "A Short Illustrated History of Botany in the Netherlands" which consists of twenty-eight sketches with legends. Forty-five pages of advertisement and two indexes complete the work.

The volume is very well produced with abundant illustrations. The type, though small, is clear.

The compilation of such a mass of detailed information has meant an enormous amount of labour, and it is to be hoped that Dr. Verdoorn, who has placed botanists under an obligation, will receive the necessary help to go on with this publication. J. R.

Practical Aspects of Illumination

(1) A Symposium on Illumination

Contributing Authors: J. F. Colquhoun, W. J. Jones, J. T. MacGregor-Morris, C. C. Paterson, A. B. Read, F. C. Smith, J. W. T. Walsh, H. C. Weston, G. H. Wilson. Edited by C. J. W. Grieveson. Pp. xv+229+20 plates. (London: Chapman and Hall, Ltd., 1935.) 13*s*. 6*d*. net.

(2) Lighting Calculations

By Prof. H. H. Higbie. Pp. xi+503. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1934.) 31*s*. net.

(3) Encyclopédie photométrique

Quatrième section: Cas extrêmes. Tome 4: Photométrie des lumières brèves ou variables. Par Madame Marguerite Moreau-Hanot. Pp. iv+126. (Paris: Éditions de la *Revue d'Optique théorique et instrumentale*, 1934.) 25 francs.

THE march of progress in illuminating engineering is aptly illustrated by the three books before us. (1) The first of these, "A Symposium on Illumination", comprises a series of lectures by experts, delivered in London under the joint auspices of the National Illumination Committee and the Illuminating Engineering Society in 1933. The book covers a wide field. Mr. C. C. Paterson's initial address on "Light in the Service of Mankind" is followed by lectures on radiation, gas and electric lamps, photometry, daylight and various applications (public lighting, etc.). The book thus represents a survey of modern knowledge, in the main simple and concise. As Lieut.-Col. Kenelm Edgcumbe suggests in his foreword, it should be of interest to the non-technical, or at least the semi-technical reader. Probably, however, the chief appeal of the book will be to students, giving them an insight into a subject on which everyone ought to know something.

(2) Prof. Higbie's treatise on "Lighting Calculations", on the other hand, is primarily a book for those who make lighting their vocation. In his ten chapters, all devoted to different types, he shows how numerous and varied are the computations that enter into the treatment of lighting problems, and succeeds in answering the question set in his first chapter, "Why bother about Lighting Calculations?" The initial chapters deal with the simpler problems. Following discussions of linear

and surface sources of light, we come to what is perhaps the most usual calculation in connexion with illumination—the predetermination of illumination by the aid of the utilisation coefficient. The apparent intricacy and elaboration of the tabular data here presented is justified by the wide use that can be made of this method, which has been shown to be applicable even to installations of a highly modern and original type.

It may come as a surprise to find from other chapters that calculations may be made on such matters as glare, shadows and the sufficiency or otherwise of the illumination provided. Problems (often containing a useful reference to some specific article or paper) are presented at the end of each chapter. More than two hundred such tests are included in the book, which is terminated by a needful but adequate index.

(3) The third volume, edited by Mme. Marguerite Moreau-Hanot, is of a still more specialised character. It forms one of a series of monographs by experts, dealing with different aspects of photometry, and is devoted exclusively to the measurement of light impulses of short duration. Such matters as the perception of transient lights, persistence of vision, the use of photoelectric cells and the measurement of variable sources are discussed. In conclusion, some reference is made to television and the optical reproduction of sound. Naturally not all the matter is of an original character—some covers ground familiar to the photometric expert—but the assembly of material makes an instructive whole.

Some of the problems handled, such as the recording of variable candlepower from fluctuating sources and lights of short duration, the measurement of variable illumination, the persistence of luminous impressions and the study of the duration of phosphorescence are of considerable interest. The book takes the reader into various by-ways of photometry not ordinarily encountered.

J. S. D.

The Hake and its Fishery

The Hake and the Hake Fishery: being the Buckland Lectures for 1934. By C. F. Hickling. Pp. 142. (London: Edward Arnold and Co., 1935.) 3*s*. 6*d*. net.

THE author's interest in the hake fishery commenced when he was an undergraduate in 1923, and ever since he has been detailed to its study as an officer of the Ministry of Agriculture and Fisheries. This means that he has gone to sea on the Milford Haven and Fleetwood trawlers for two or three months every year, with occasional cruises on research vessels.

The hake is essentially a southern fish, and the English coasts are the northern part of its range, for it extends south to Senegal and, in the Mediterranean, even as far as Palestine. It is a warm water fish, and its prevalence in British waters is largely due to the extent to which the warmer currents reach our shores. Its home is in comparatively deep water, and commercial catches have been made at 450 fathoms. It is not, however, a bottom feeder, its habit being to rest on the bottom in the daytime and to come up to the midwaters for its food at night. Spawning is at 120 fathoms and shallower depths, commencing about April in the deepest waters and then gradually at lesser depths as the summer proceeds. The male spawns when four years old and the female at ten years, then sizes about 11 in. and 30 in.; but they vary, for the fish grow faster in warmer water, even though such water has less of the ultimate food (diatoms and other plants) on which all animals depend.

The female lays upwards of two million eggs, and fertilisation is in the sea-water, the eggs floating at the mercy of the currents. To a certain degree, the abundance of hake in subsequent years can be foretold by studying their numbers. In the youngest and most vulnerable stages, the food consists largely of crustaceans, but these are gradually replaced by other fish and squids, the adults having marked cannabalistic tendencies. Few ten-year fish are now caught in British waters, the large fish having decreased in the catches by 7½ per cent per annum for the last ten years—and the author does not suggest any migratory replacement from the south. This means less and less spawn being deposited on the breeding grounds to the west of the British Isles and constitutes a real danger to the fishery, the fish being caught faster than they can make good the loss of their stock by breeding and growth.

The above story is told mainly on the author's own researches. What are his remedies? At first we always seek aid from history, and that does not help us much here. In 1890, hake were hawked all over the west country at 1*d*. per lb. under the name of "Torbay salmon"; by 1900 the price had gone to 2*d*. Morley then made his voyages of

exploration and others followed; the result was the opening up of the Spanish and other southern grounds. In 1907 the price was still low, but the quantity was large and there were also some soles in the hake catches to add to the profit. Great trawler fleets for this fishery grew up in the west, and one fleet moved from Ireland. In this year the Press began to take an interest, with the result that in the next years hake entered into the 'prime fish' category, and the trawlers, while catching less, made better profits. The absence of fishing during the War stopped any decline in this and all the fisheries of the west Atlantic, our hake trawlers being mainly located in the eastern Mediterranean for mine sweeping. However, western Europe was quite alive to the problems, and the International Council for the Exploration of the Sea came together again in 1920. Hake was a major subject for discussion and inquiry, and the statistics were greatly improved. These show a steady strong demand especially for small hake, and the price far exceeds that of the related cod and haddock.

Withal there is a disturbing loss in catch which has to be stopped, while due attention must be paid to the sufficiency of breeding fish. Any young fish brought to the deck from the trawl are dead owing to the decrease of pressure affecting their air bladders. It is impossible to close grounds in the high seas, and the trawl owner must not take a cynical line—perhaps because he is getting old and thinking of retiring—in resisting the examination of his actual method of catching. The writer remembers nearly thirty years ago a series of conferences in the greater fish ports, where the size of the mesh of the trawl was always discussed. About twenty years later, the matter was considered by the British Fisheries Association, which ought never to have been killed or allowed to die. It was contended that a larger mesh to the trawl would allow many of the smaller, less marketable and much less valuable fish (per pound weight), to escape, while the trawl would clear itself of much of its 'rubbish', move more easily over the bottom, this securing more fish, and would arrive on the deck with its catch less bruised and in better condition for market. It was confidently anticipated that the industry would make its own experiments, but its psychology was antagonistic. Its energies were largely directed to new grounds, to be discovered near British coasts by the Ministry, or to fishing in greater depths, where there cannot be food to support a rich fish fauna, or to proceeding farther afield, in this latter alone (west of Greenland) success being achieved. The industry improved its trawls, but it never, so far as the writer knows, made any scientific experiment with its trawl mesh.

Now the Ministry, acting through Messrs. Davis and Hickling, have done the industry's work, as in these lectures all may read. They have by most ingenious means proved that, with a larger mesh, the smaller hake escape from the trawl while it is actually on the bottom, its contents experiencing no change in pressure and remaining alive. At the same time it is shown that the market value of the catch is slightly increased. The remedy suggested for the hake is the application of this, for a larger mesh would allow an immensely greater proportion of the young fish to continue their growth, and this in a few years should increase the breeding stock, while meantime the fishery after readjustment should be more profitable. It is possible that on certain grounds there would be a lesser catch of soles, but usually in trawling one fish dominates the plan of each voyage, the profit of which depends upon it.

The above work of the Ministry is applicable to the haddock, cod and many fish, and its scientific staff are to be heartily congratulated upon it and many other lines of applied science. Biologists should know the Ministry's work, for it is the most important ecological work being carried on from Great Britain to-day. They should examine its results, so that their expressed ideas may be considered views which may help to form public opinion, not merely expressions against State action that scientific men often lightly express. Furthermore, it would pay the industry to reprint this little book in a cheap form and place it in the hands of every trawler man, for there is no doubt that education makes for efficiency in this as in all other trades. The fishing industry, it must never be forgotten, is a basal industry, essential to Great Britain as a maritime power.

J. S. G.

Plato's Theory of Knowledge:
the *Theaetetus* and the *Sophist* of Plato translated with a Running Commentary. By Prof. Francis Macdonald Cornford. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xiv+336. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., 1935.) 15*s*. net.

IT would have been a real treat for philosophers to have a genuine study of Plato's "Theory of Knowledge" by Prof. Cornford. As it stands, however, the title of the book is misleading as it offers no more than an excellent translation of the "Theaetetus" and the "Sophist" with a running commentary. The latter will be found most useful and inspiring by all students of Plato's philosophy, for it aims at discovering what Plato really means and how the arguments of these two dialogues are related to the rest of his work.

Catalogue of the Fossil Cephalopoda in the British Museum (Natural History)

Part 4: The Ammonoidea of the Trias. By Dr. L. F. Spath. Pp. xvi+521+18 plates. (London: British Museum (Natural History), 1934.) n.p.

PARTS 1 to 3 of this Catalogue by Foord and Crick, dealing with the Nautiloids and Palæozoic Ammonoids, were published in 1887, 1891 and 1897 respectively. The new part, although of larger size, includes only about half of the Triassic Ammonoids, namely, the Pronoritida, Xenodiscida, Meekoceratida, and part of the Ceratitida, nearly all occurring in the Lower and Middle Trias. The remaining groups, of Middle and Upper Triassic age, will be dealt with in the succeeding volume. Since the last part was published, our knowledge of Palæozoic Ammonoids has increased considerably, so that the author can now affirm that true Ammonites were already prolific in the Upper Palæozoic, and that the Permian System, contrary to the views of some British geologists, has fully justified its existence.

In the introduction the author gives a critical review of the classifications of Goniatites proposed by previous writers, and expresses in tabular form his own view of the interrelations of the Palæozoic Ammonoids and their connexion with the Lower Triassic Ammonites. In a section on "Chronology and Stratigraphy" he gives a very valuable account of the zonal divisions and correlation of the Triassic deposits, and concludes from his study of the successive faunas that the Triassic period was considerably longer than the whole of the Jurassic. The author maintains that faunas found in different regions which, although showing some differences, have been regarded as contemporary, are really heterochronous. At the same time he admits the existence of life-provinces in the Trias, but gives no criteria by which the differences dependent on age can be distinguished from those due to geographical distribution.

The main part of the Catalogue is devoted to a systematic account of the groups mentioned above, with a discussion of the mutual relationships of the various families and genera. Unlike most writers on the phylogeny of Ammonoids, the author does not accept the evidence of ontogeny, but bases his views on the morphological characters and the stratigraphical succession of forms. His conclusions will be more easily followed if shown in tabular form in the succeeding volume.

An Introduction to Inorganic Chemistry:

for B.Sc. Students of the Indian Universities. By Dr. Satya Prakash. Pp. vii+478. (Allahabad: Kala Press, 1934.) 6 rupees; 10*s*.

DR. PRAKASH'S book has some unusual features. It deals with the elements in the order of the Periodic System, the inert gases coming first, followed by the metals, and the non-metals come last. This has advantages for a student who has completed an elementary course, since his knowledge of the non-metals is refreshed again after he has dealt with the new material. A special feature of the book is the stress laid on Indian conditions and interests, a good deal of statistical data being incorporated and the native processes and names being given. This part will be quite valuable to readers wishing to know something of chemical technology in India. Extensive use is made of tables summarising information given in the text.

The text itself is rather condensed, so that a good deal of ground is covered, and the more elementary parts of the subject are briefly treated. Whilst full equations are given in the text, the summary tables contain unbalanced equations with arrows, such as $NaHSC_3 + Zn + SO_2 \rightarrow Na_2S_2O_4$, which are liable to lead to neglect of the correct equations by weaker students. Dr. Prakash's book is an interesting one of good standard. The English is not always very good, and should be revised in future editions.

Dynamo-Electric Machine in its Historical Development:

Documents and Materials. Collected by D. V. Efremov and M. I. Radovskij. Edited by V. Th. Mitkevitch. (Academy of Sciences of the U.S.S.R.: Transactions of the Institute for the History of Science and Technology, Series 3, Issue 1.) Pp. xviii+560. (Leningrad: Academy of Sciences Press, 1934.) 15 roubles.

THIS volume gives the leading papers and extracts from books, etc., from which we can see the gradual historical development of the modern dynamo. The frontispiece gives a portrait of Faraday and the book begins with his discovery of electromagnetic induction. Practically all the book is in Russian, so it will make a limited appeal to English readers. The table of contents proves that a very wide research has been made through the literature of European countries. It is the first issue of Series III in the *Transactions* of the Russian Institute for the History of Science and Technology. The printing is very clear, but some of the diagrams have not come out very well.

Hand- und Jahrbuch der chemischen Physik

Herausgegeben von A. Eucken und K. L. Wolf. Band 6, Abschnitt 1A: Elektronenstrahlen und ihre Wechselwirkung mit Materie. Von J. Hengstenberg und Karl Wolf. Pp. 236+12. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1935.) 24 gold marks.

THE discovery of electron beams is traced back to Pflücker (1859) and the recognition of their nature to Schuster's first determination of the ratio of charge to mass in 1884; but their principal interest arises from the discovery of interference effects, depending on a wave-like character of the electron. This has been demonstrated by the development of Debye-Scherrer rings by scattering (i) in thin films of a solid as in G. P. Thomson's already classical experiments with gold foil and the more recent beautiful photographs of G. I. Finch, and (ii) in vapours, as studied by Mark and Wierl in Ludwigshafen and later in England by de Laszlo. These and cognate topics are reviewed in a monograph which covers 236 pages and includes 182 figures.

Personality and Age*

By Dr. Ll. Wynn Jones

A FEW years ago the readers of many German newspapers were invited by Giese to give an account of the signs by which they noticed that they had become old, and to say at what age these signs first appeared. When these reports were analysed, it appeared that the average age of becoming subjectively old was forty-nine years, but this age of becoming old varied widely with the individual—indeed from age eighteen to eighty-two.

The bodily signs were twice as numerous as the mental. The bodily signs in decreasing order of frequency from 17·4 to 1·2 per cent may briefly be summarised thus: (1) motor (muscles, back, teeth, bones, extremities), (2) nerves (including memory and insomnia), (3) sensory (eye, ear), (4) skin (hair, wrinkles), (5) fatigue, (6) sexual, (7) circulatory (heart, arteries), (8) metabolic (sugar, gout, fat), (9) digestive, (10) kidney, (11) respiratory.

It would, of course, be expected that the layman would be more likely to refer to bodily symptoms than to mental, and it was natural that the more educated should show a higher percentage of mental signs.

The subjects who reported mental signs were divided into three classes:

(1) The negatory type. About 18 per cent of those who reported mental signs opposed the suggestion of being old and either indignantly refused to acknowledge it or perhaps referred to the health or longevity of their stock.

(2) About 38 per cent ascertained that they were old by noting the way they have been treated by the outside world in various situations and the like.

(3) About 44 per cent reported experiences from their own introspections—it might be some intellectual change in reaction such as the emergence of old recollections, or it might be an affective change such as a disinclination for amusements.

It is important that bodily and mental manifestations certainly do not go together and have widely different values for different individuals. Some lay great stress on bodily signs and scarcely any on the mental, while others do just the reverse. It is not, of course, suggested that the percentages reported above would agree with medical diagnosis, as the subjects belonged to a sample of the general population. Moreover, many of the physical symptoms reported had probably a mental origin, for, as Prof. M. Greenwood stated in a recent lecture on "The Temperamental Factor in Industry", "it is becoming realised more and more how easily emotional disturbances may result in bodily ills that can be cured only by dealing with their psychological causes".

Although psychologists have exhibited great interest in the child and the adolescent, yet there remain five or six decades of human life relatively untouched. At least four recent investigations merit our attention. They were initiated by Terman, Thorndike, Walter Miles and Charlotte Bühler respectively. It is significant that each had already made outstanding contributions in child psychology, and each research was furthered by a grant, so that a band of experts were able to collaborate and produce results which would be quite unattainable by a single investigator who had to meet the charges out of his own pocket.

In 1926 there appeared the second volume of Terman's "Genetic Studies of Genius". It is entitled "The Early Mental Traits of Three Hundred Geniuses", and the investigations were carried out by Dr. Catherine M. Cox (now Mrs. Walter R. Miles) under the direction of Terman. It was concluded that youths who achieve eminence have, in general, a heredity above the average and superior advantages in early environment: they are characterised not only by high intellectual traits, but also by persistence of motive and effort, confidence in their abilities, and great strength or force of character.

Thorndike's "Adult Learning" appeared in 1928. His purpose was to study the changes in the amount and changes in the nature of ability to learn from about age fifteen to about age forty-five, and especially from age twenty-five to age forty-five. Some of the conclusions may be briefly summarised:

(1) The differences in rate of learning between old and young are small in comparison with the differences within either group, and when factors other than age are equalised the influence of age approaches zero.

(2) Adults learn much less than they might, partly because they under-estimate their power of learning, and partly because of unpleasant attention and comment. It is disuse and lack of practice and not inner degeneration which is likely to affect learning.

* From the presidential address to Section J (Psychology) of the British Association, delivered at Norwich on September 6.

(3) Ability to learn a systematic logical language, Esperanto, rises from 8 to 16 years and probably to 20: it is then stationary to 25 or later and then drops very, very slowly to 35 and somewhat more rapidly, but still very slowly, to 45 or later.

(4) The gain made in 50 or 100 or 500 hours of study of a modern language by a group of any age from 20 to 40 will be greater than the gain made by a group aged 8 or 10 or 12. The facts are in flat contradiction to the doctrine that childhood is the period for easiest learning to read, write, or understand the hearing of a language.

(5) Learning representing an approximation to sheer modifiability unaided by past learning shows more inferiority in the case of adults than was indicated by the experiments taken as a whole. Actual learning of such things as adults commonly have to learn shows, however, considerably less.

(6) The curve of ability to learn from 22 to 42 is a very slow decline, and this decline is no greater for inferior intelligence than for superior.

Thorndike studied all sorts of learning and in each case analysed the curve of ability to learn in relation to age. Although he realises that a curve of total or average ability may be unattainable, yet he was able to conclude in general that nobody less than forty-five years of age should restrain himself from trying to learn anything because of a belief that he is too old to be able to learn it. "If he fails in learning it, inability due directly to age will very rarely, if ever, be the reason. The reason will commonly be one or more of these: He lacks and always has lacked the capacity to learn that particular thing. His desire to learn it is not strong enough to cause him to give proper attention to it. The ways and means which he adopts are inadequate, and would have been so at any age, to teach him anything. He has habits or ideas or other tendencies which interfere with the new acquisition, and which he is unable or unwilling to alter. In the last case mere age may have some influence."

Thorndike's conclusions are particularly important when we consider schemes for adult education, and it is interesting to see how well his experimental findings agree with Cicero's dicta on age: "But, you argue, the memory grows feebler. I believe it does unless you practise it, or if you are by nature rather dull. . . . What of lawyers, pontiffs, augurs, philosophers when they are old? How much *they* remember! The old retain their wits, provided their earnestness and energy lasts; and this happens not only with men who are illustrious and who have held high office, but also in a life of privacy and repose."

Having reported facts concerning the relation of adult learning to age, we may pass on to consider some of the most important human abilities in their relation to age, and noteworthy in this respect are the Stanford Later Maturity Publications, which have appeared from 1931 onwards under the direction of Prof. Walter R. Miles, and which were aided by a grant from the Carnegie Corporation. A reference to some of these abilities is now necessary.

Sensory and Motor Abilities

The importance of abilities such as reaction speed and co-ordination of movements in the various industries and sports scarcely needs mention. Motor skills are so varied that each has to be studied by itself, and although some evidence for group factors in this field has been obtained, yet in the main it is the specificity of each ability which is striking; and this is not surprising when it is considered that some demand considerable visual acuity, others visual attention, others muscular power, others neuro-muscular speed of reaction, and so forth.

Probably visual acuity is at its maximum in the 'teens. It is probably one of the first physiological functions to show a very slight deterioration with age. About the age of fifty years, on the average, this deterioration may become sufficiently serious to handicap the individual in occupations where visual requirements are exacting. In industry, of course, there are other factors which affect the issue, such as the efforts of an employer to get cheaper, that is, younger, labour, or the effort of the employee himself to acquire a more responsible position. The more striking fact, according to Miles, is the relatively small, although steady, decrement shown throughout the life-span in tests such as reaction speed or rotary motility. "Guessed on the basis of what industry has popularly said of the old and also in terms of the derogatory reports made by old people about themselves, the situation has appeared far harsher than the objective data warrant."

Intellectual Abilities

Under this heading may be considered tests of memory, manipulations of symbols and of space areas, interpretations of meaning in verbal form and all the so-called higher mental functions which figure in tests of intelligence. Here again the deterioration due to age as such is relatively small. The differences between individuals at the older ages are often quite marked, so that other factors are probably at least as weighty as age in accounting for an individual's actual score. Thus Sorenson found that the mental abilities of adults who participate in schemes of adult education are maintained at a high level over a long span of adult years.

Miles also points out that when speed is the stressed element in an intelligence test for adults, then the decrement due to age is greater than it is when power in unlimited time is stressed. The fact that intelligence tests are usually standardised for children also points to the need of further research when dealing with adults.

INTERESTS

Here we turn to one of the Stanford Later Maturity Publications—namely, "Change of Interests with Age", by Prof. Edward K. Strong. It is based on examination of more than two thousand men between the ages of twenty and sixty years representing eight occupations. The following quotation gives the author's point of view: "If 'vocational interest' is defined as 'the occupation an individual likes best now', then the conclusion must be reached that vocational interests are very unstable. There are ample data to prove that boys and girls and also older persons change their 'first choices' very frequently, and in most cases without apparent rhyme or reason. But if 'vocational interest' is defined as 'the sum total of all interests that bear in any way upon an occupational career', then we find surprising stability, certainly among adults, and, as far as we have been able to judge, also among young men of college age and presumably among still younger people."

That is to say, just as we do not probe an individual's intelligence by one test but by as many as we can afford time for, so it should be with interest.

The slight differences found between men of twenty-five and fifty-five years of age seem to indicate that interests are not particularly affected by years of activity in a given occupation, and that therefore interests are responsible for choice of occupation rather than a resultant of it.

Older men are no more catholic in their interests than younger men, but their likes and dislikes are not identical with those of younger men. Thus the older men are not so interested in situations involving physical hazards, or in anything which interferes with established habits. This factor appears to be of great significance for both employer and employee. Many an employer is unsuccessful not so much for lack of abilities, but owing to a disinclination to introduce a change, and the old employee often becomes unemployed not on account of inability, but because he has no desire to change his methods when changes are deemed essential by the management.

I now turn to the extraordinarily interesting book of Prof. Charlotte Bühler, "Der Menschliche Lebenslauf als Psychologisches Problem", which was published in 1933. The course of man's life is studied by the aid of two hundred published biographies of poets, writers, inventors, men of science, statesmen, musicians, painters, theologians, business men, financiers, actors, singers, sportsmen and philosophers. For comparison, fifty life-histories were obtained from the Old People's Homes in Vienna.

Life is regarded from several aspects: as a biological phenomenon, as a series of events and experiences, and from the point of view of work produced. Its normal structure—ascent, culmination and decline—is discussed. It is impossible to do justice to this pioneer study in a brief sketch, and I will only single out what appears to be the importance of age in athletic records. Here, then, Prof. Bühler has at hand the severe tests of the athletic field as substitutes for psychological tests in order to ascertain when various motor abilities are at their maxima in the case of the best athletes. On analysing the best lists for the year 1930 the following were the results:

Individual Sports	Age.		*Group Sports*	Age.
A. Sprint run	23·5	*A.*	Boxing	21·9
Long jump	23·5		Wrestling	22·3
Throwing the javelin	24·2		Football	23·8
B. Medium run	24·3	*B.*	Jiu-jitsu	26·0
Hurdles	24·5		Hockey	26·4
High jump	24·8		Tennis	28·5
Pole vault	25·4			
Putting the weight	25·4			
C. Long run	25·6	*C.*	Polo, Riding, Trotting	up to 50
Rowing	26·5			
Throwing the discus	26·9			
Weight lifting	30·5			
Throwing the hammer	31·0			

It is characteristic of Group *A* that the activities demand a maximum expenditure of energy per second. Economy of effort plays no part here. In Group *B* there is demanded economy of effort and a proper distribution of it. As for Group *C*, in addition to the greatest economy of effort, enormous demands are made on technique which only comes after long experience.

As two typically British sports are not included in the table—namely, cricket and golf—I have attempted to get corresponding figures for batsmen, bowlers and golfers. Taking the season of 1934, the names of eighty-three batsmen who exceeded a thousand runs in first-class cricket appear. The median age is 30 years (the quartiles being 27 and 33 and the extremes 19 and 47). Then the bowling averages were analysed. The median age is again 30 years (the quartiles being 26 and 34 and the extremes 20 and 50).

Taking the names of the forty golfers who headed the Open Championship list in 1934, the median age is about 35 years (the quartiles being 29 and 39 and the extremes 24 and 45).

Taking a still higher standard, it appears that batsmen who have exceeded three thousand runs in a season show a median age of 34·5 years (the

quartiles being 30 and 39 and the extremes 27 and 44).

In golf, the thirty-seven open champions since 1894 show a median age of 31 years (the quartiles being 28 and 37 and the extremes 23 and 44).

Theoretical Implications

A most important development in modern psychology is the search for innate, basic, unitary traits of personality. There is accumulative evidence in favour of the existence of a number of unitary traits or factors, and it has been found convenient to denote them provisionally by letters of the alphabet, analogous to a practice of physics and other sciences. This does not in the least imply that their functional interpretation is necessarily less clear than that of concepts such as introversion and the like. It is true that polysyllabic words have sometimes only to undergo a very cursory censorship, but this practice leads to abuses of the language mechanism which may retard individual cerebral evolution. Besides, the less popular use of letters to denote new concepts is not likely to proceed indefinitely, if only for the fact that the introduction of such a letter is preceded by many thousand hours of laborious work.

Closely connected with the study of traits is the difficult question of the effectiveness of past experiences. Spearman's researches show that retentivity is independent of g, and there is evidence that the old tend to deteriorate in tests of immediate memory. How far is the balance redressed when the extent and variety of all their previous experiences as well as their integration is taken into account? It is scarcely necessary to illustrate the dire effects of lack of experience. Thus the brilliant young debater is often pulverised by one who is dull but elderly. My second example is a very intelligent person who has been totally blind from birth. I found that the subject had no idea at all of the size of the sun as it appeared in the sky. The subject imagined that most stars had five points, but that some had six or even eight, and that a rainbow had the shape of a tied bow, and so forth. Manifestly all knowing, even in the case of the gifted, must start from experiencing.

Now that the method of factorial analysis is becoming increasingly effective, not only in the case of cognitive abilities, but also with regard to personality in all its aspects, it becomes necessary to study age as one of the 'primordial potencies' more systematically, not only during childhood and adolescence, but also throughout the life-span. This will determine the relative importance of the various traits at different stages of life, and in turn will lead to a fuller psychological interpretation of the unitary traits themselves.

Recent Advances in Seismology*

By Dr. F. J. W. Whipple, Kew Observatory, Richmond, Surrey

SEISMOLOGY, the science of earthquakes, is primarily concerned with such questions as where, how and why earthquakes occur, but it is also concerned with the question how the waves generated by earthquakes travel through the earth, and with the question what information as to the constitution of the earth can be deduced from the behaviour of the waves. Living in a country which is seldom troubled by earthquakes, but a country in which the waves from distant earthquakes can be studied, we have a more direct interest in questions of the latter types. This interest has been fostered by the British Association, which has facilitated the discussion and collection of the records from observatories in all parts of the world. This is an enterprise of which we may well be proud.

* Paper read before Section A of the British Association at Norwich on September 9, opening a discussion on recent advances in seismology.

John Milne, who was a great pioneer, organised the collection of observations. He used to publish lists of the readings of the seismograms at as many observatories as possible. On the death of Milne, Prof. H. H. Turner, who was already chairman of the B.A. committee, accepted responsibility for the work, which he transferred to the University Observatory, Oxford, and soon began the publication of the observations in a more convenient form, dealing with each earthquake separately. This arrangement was continued when Turner became president of the Seismological Section of the International Union for Geodesy and Geophysics. The collections of observations are now known as the International Seismological Summary. As the number and efficiency of seismological stations has increased, so the I.S.S. has grown. The Summary for 1930 is a substantial volume of 426 pages. Since Turner's death in

1930, the work has been carried on most loyally and efficiently by Mr. Hughes and Miss Bellamy. Seismologists are under a great debt of gratitude to them, and to Prof. H. H. Plaskett who has given facilities for the continuation of the work.

The I.S.S. provides a wealth of material for research. One of the objects which Turner had at heart was the preparation of more reliable tables of the travel times of earthquakes. This task was eventually undertaken by Dr. H. Jeffreys, whose revised tables for the times of *P* and *S* waves were published in 1932. Jeffreys regarded this work as a preliminary to a closer examination of the material, and with the help of Mr. K. E. Bullen he discussed the records of 61 earthquakes. For each the epicentre was redetermined and a close examination of the material of the I.S.S. was made to discover the reflected waves of different types.

The results of this heavy investigation were presented by Jeffreys at the Lisbon meeting of the I.S.A. two years ago, and have now been published. It was not to be expected that there would be anything very exciting in the results. Perhaps that is the strongest reason for admiring the enterprise of Jeffreys and Bullen. The most striking development is the confirmation of an irregularity in the run of the times of transmission of the waves of compression and distortion. This irregularity, which occurs at ranges of about 20°, had previously been studied by Miss Lehmann of Copenhagen and probably signifies that there is a discontinuity in the nature of the rocks at a depth of about 400 km.

An interesting development was the calculation by an indirect method of the time required for shearing waves to travel to the core and back. An *S* wave which reaches the core is resolved into a reflected wave, known as *ScS*, and a transmitted *K* wave. When a *K* wave reaches the boundary of the core again, some of the energy passes out as an *S* wave and some is reflected to pass out further on. Thus *SKS* and *SKKS* are produced. It is clear that the time of transmission of the *SKS* is the mean between the times for the *ScS* and *SKKS* waves. Thus the time for *ScS* waves where they are not readily observed could be calculated. It should be mentioned that Dr. Jeffreys has recently revised this *ScS* table, using records for deep focus earthquakes.

The Jeffreys and Bullen tables are now being used as the standard of reference of the I.S.S. so that they will be the starting point for the investigations of such questions as the possible departure of the earth from spherical symmetry.

The most spectacular of recent advances in seismology is in our knowledge of earthquakes with deep foci. Turner was led to the discovery of such earthquakes by finding that the ordinary tables of transmission times, which were reasonably satisfactory for ordinary earthquakes, were not applicable in certain cases. He was led to attribute the abnormality to the depth of foci, which might in some cases be so great as 9 per cent of the earth's radius, or 500 km. Similar conclusions were reached by Wadati in Japan, and the theory was confirmed by the close analysis of world-wide records by Scrase and Stechschulte.

That the great majority of the earthquakes were to be found round the Pacific was noticed by

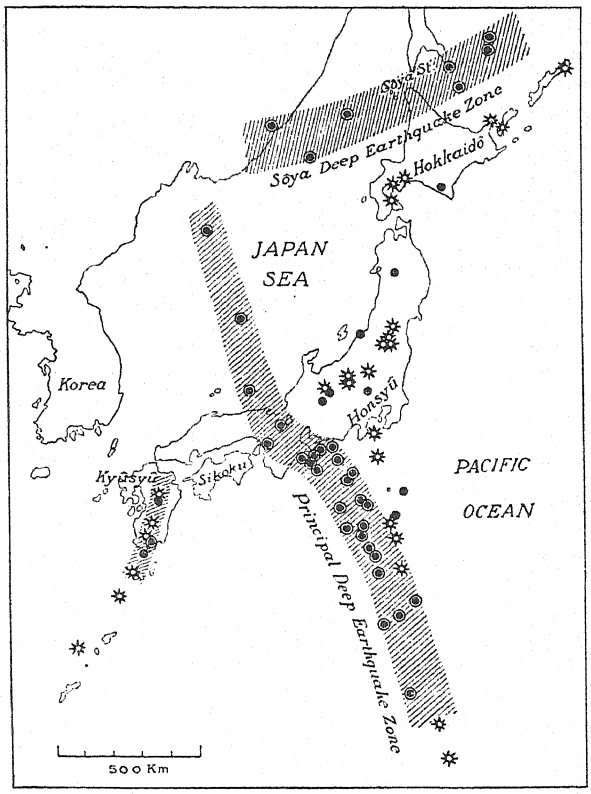

FIG. 1. Deep-focus earthquake zones and volcanoes.
● Deep earthquakes which occurred during 1927–33; * Volcanoes which have been in eruption since 1867. From *Geophysical Magazine* (Tokyo), 8, No. 2; 1934.

Turner. Japanese seismologists have mapped the foci near their own country with striking results. There is a remarkably orderly arrangement. Not only are the foci to be found on two belts meeting at right angles on the continental side of the sea of Japan, but also the depths are systematically arranged, the greatest on the outside of the angle formed by the belts.

In Fig. 1, which is due to H. Honda, the positions of the zones in which deep-focus earthquakes occur are shown, together with the positions of such volcanoes as have been in eruption since 1867. Fig. 2 is reproduced from a paper by K. Wadati. In this diagram the two principal zones

of deep focus earthquakes are joined by lines which serve to emphasise the distribution of

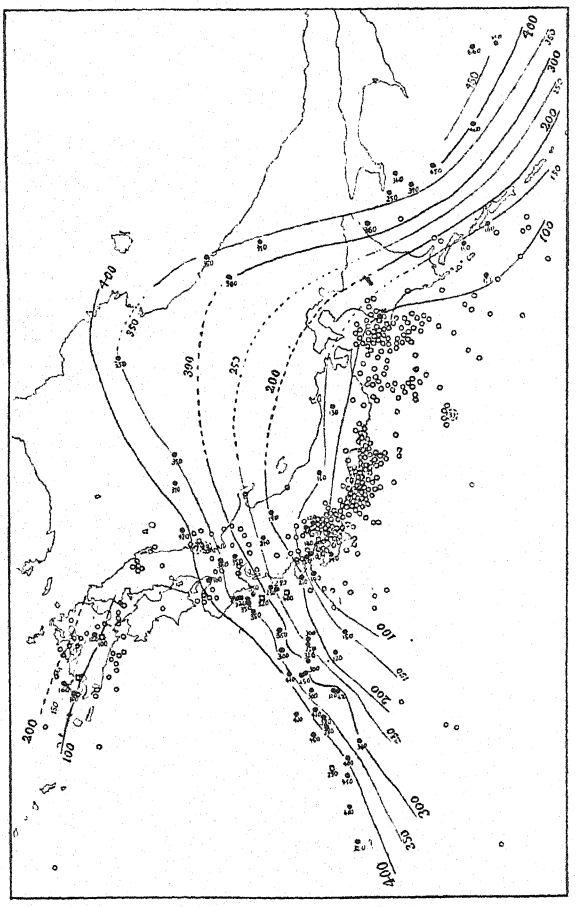

FIG. 2. Lines of equal focal depth for deep-focus earthquakes. ● Deep-focus earthquakes; ○ shallow-focus earthquakes; □, foci not accurately determined. From *Geophysical Magazine* (Tokyo), 8, Nos. 3, 4; 1935.

depth. The innermost of these lines indicates the position of foci with depths of 100 km., the outermost of the main series of lines indicates a depth of 400 km. The way in which the foci of ordinary earthquakes cluster on the east of Japan is also illustrated in this diagram.

The directions of the impulsive movements in deep-focus earthquakes with their foci near to the region where the main belt crosses Japan have been studied by Honda. He finds that at places to the north-east of the belt the ground moves downwards and towards the belt. At places to the south-west the movement is upwards and away from the belt. Thus it appears likely that huge faults extending to a depth of about 400 km. or more can exist in the earth's crust and that deep foci are on such faults. Volcanoes, live and extinct, are found above the line where the fault is at a depth of 100 km., whilst ordinary earthquakes with shallow focus occur near where the fault approaches the surface.

It has been suggested that the high frequency of earthquakes round the Pacific is due to the fact that the crust of the earth below an ocean cools more rapidly than the crust over the continents, where the radioactivity of the granite provides a source of heat.

In various studies of the times of transmission of seismic waves it has been found that the thickness of the continental granite is about 15 km. Thus the occurrence of deep-focus earthquakes implies that the strains in the crust lead to fractures at depths of the order twenty times the probable thickness of the granite. Can it be that the influence of a mere skin extends to such a depth? These foci are also far below the level at which isostatic compensation has been supposed hitherto to be operative. It is clear that they must be taken into account in all speculations as to the history of the globe.

Obituary

Prof. Henry Fairfield Osborn, For.Mem.R.S.

PROF. HENRY FAIRFIELD OSBORN, who died at his home, Castle Rock, Garrison-on-Hudson, N.Y., on November 6, 1935, was one of the foremost palæontologists of the United States, and made great contributions to our knowledge of fossil mammals and reptiles. He was born on August 8, 1857, at Fairfield, Connecticut, and began his scientific education in 1873 at Princeton College (afterwards University), where he was influenced especially by President James McCosh, the psychologist, and Prof. Arnold Guyot, the geologist. After graduating in 1877, he studied human anatomy and histology under Prof. William H. Welch, in New York; and in 1879–80 he followed brief courses in embryology under F. M. Balfour at Cambridge, and in comparative anatomy under Huxley in London. He then returned to Princeton with a biological fellowship, and in 1881 he was appointed assistant professor of natural science. In 1883 he was promoted to the professorship of comparative anatomy at Princeton, where he remained until 1891.

While Osborn was a student at Princeton, great interest was being aroused by the discoveries of numerous strange extinct mammals and reptiles by Cope and Marsh in the rocks of the western United States. At the end of his course, therefore, in 1877, he and his fellow-students, W. B. Scott and F. Speir, decided to undertake a summer trip to Wyoming in search of similar fossils, and they brought back a

small collection of early Tertiary mammalian remains, on which they published a report. In the following year they went again to Wyoming and Colorado to continue their collecting, and in subsequent years one or other of them paid repeated visits to the west for similar field work. Princeton thus began to take a share in making known the remarkable extinct vertebrates which awaited discovery in the western country then becoming more readily accessible.

These researches attracted the notice of the trustees of the American Museum of Natural History and the professors of Columbia College (afterwards University) in New York. The Museum wished to extend its scope and make a representative collection of fossil vertebrates, while Columbia decided to add biology to the subjects to be taught. In 1891, Osborn was therefore invited to become curator of the Department of Vertebrate Palæontology in the American Museum, and at the same time the first professor of biology (afterwards zoology) in Columbia University. He accepted both these appointments, and held them with brilliant success until 1910, when he had thoroughly organised them and had trained a staff to continue his work. Having ample private means, he then retired to devote himself entirely to palæontological research and to the administration of the Museum. Meanwhile, he was nominated research professor of zoology in the University, and he continued to be assistant to the president of the Museum. In 1901 he was elected a trustee and vice-president of the Museum, and eventually from 1908 until 1933 he served as president. At the same time, from 1900 onwards, Osborn was vertebrate palæontologist to the U.S. Geological Survey, and for four years (1900–4) he also held the same office in the Geological Survey of Canada. In 1906 he was nominated secretary of the Smithsonian Institution, Washington, but he decided to remain at New York.

The earlier collectors of fossils in the west had been handicapped by the frequent presence of hostile Indians, who had made detailed geological surveying impossible. When Osborn began his work at the American Museum, conditions were improving, and he took advantage of this circumstance to arrange that collectors in future should devote as much time as necessary to determining the succession of the rocks in which the various fossils occurred. Year after year he sent out his trained assistants to collect in this way, and he frequently accompanied them with help and encouragement. He and his wealthy friends provided adequate funds for the explorations, and thus was accumulated in the American Museum a unique series of fossil vertebrates of which the relative ages were definitely known. Most of these fossils were mammalian remains from the Tertiary formations, and as soon as the most important of them had been examined and described by himself and his colleagues, Osborn greatly facilitated research by publishing his "Correlation between Tertiary Mammal Horizons of Europe and America" (1900). The American Museum then began to take an active interest in the discovery of fossil vertebrates in other parts of the world. In 1898 it had already shared in the Princeton University's third expedition to Patagonia. In 1906–7, Osborn himself accompanied a party in the Fayum, Egypt. In 1922 he visited central Asia, where American Museum expeditions under Dr. Roy Chapman Andrews had already made important collections of new fossil vertebrates. In 1923 another expedition under Dr. Barnum Brown collected fossil mammals in India. Osborn had, indeed, wisely decided that our knowledge of extinct faunas could best be advanced by direct comparison of the fossils of one part of the world with those of another, and that American palæontology must not be isolated.

While occupied with the planning and direction of the collecting expeditions and the preparation of the fossils in the Museum, Osborn and his staff published a long series of valuable papers on various parts of the collection and on the rocks in which they were found. He also contemplated the publication of several exhaustive memoirs on groups which were specially well represented in America, but he was only able to complete one on the Equidæ or horses (1918) and one on the Titanotheres (1929). Others on the Elephants and the Sauropodous Dinosaurs were left in a forward state of preparation. The published memoirs are noteworthy for their beautiful illustrations and their wealth of valuable facts; but their composite authorship and their peculiar style of composition make them sometimes unsatisfactory for reference.

Osborn also found time to write several books which have contributed to the advance of vertebrate palæontology or spread an interest in the subject. His early work "From the Greeks to Darwin" (1894) has often been reprinted, and it was eventually issued in a revised edition. His "Evolution of Mammalian Molar Teeth" (1907) and "The Age of Mammals" (1910) are technical works of reference. His "Men of the Old Stone Age" (1915) and "Man rises to Parnassus" (1927) are popular works which have had a very wide circulation. His "Origin and Evolution of Life" (1916–17) is semi-popular. His volumes on "Impressions of Great Naturalists" (1924) and on "Cope: Master Naturalist" (1931) contain many interesting personal reminiscences.

Osborn's genial personality and calm sound judgement led to his being appealed to for help in many undertakings beyond his chosen sphere. He took a prominent part, for example, in the foundation of the New York Zoological Society and the planning of its Zoological Park, and he was president of the organisation from 1909 until 1923. He was also well known and much esteemed in England, where he received many tokens of appreciation. He was an honorary D.Sc. of Oxford and Sc.D. of Cambridge. He was a foreign member of the Royal Society, and of the Linnean, Geological and Zoological Societies of London; and an honorary member of the Royal Society of Edinburgh and the Royal Irish Academy. He received the Darwin Medal from the Royal Society in 1918, and the Wollaston Medal from the Geological Society of London in 1926. The death of an old friend and colleague is indeed widely mourned.

A. S. W.

News and Views

Henry Fairfield Osborn and the American Museum

PROF. H. FAIRFIELD OSBORN, an obituary of whom appears on p. 784 of this issue of NATURE, was a figure in certain respects unique in American science. In virtue of his great possessions, he belonged to a class more frequently encountered in business than in academic circles in the United States, and his personal connexions played no small part in aiding him to raise the American Museum of Natural History, of which he was honorary life president at the time of his death, to the commanding position in the scientific world which it now holds. Under his controlling influence, its scientific achievement, equally remarkable in range and variety, was no less notable than its growth and its efficiency in material equipment; while graded series of publications, ranging from popular expositions to detailed monographic studies, and from ephemeral announcements of recent discovery to the considered conclusions of prolonged research, became a regular and highly valued feature in the organisation of the Museum, placing the latest developments of its work at the disposal of laymen and the scientific world alike. One of the greatest achievements of the Museum under his régime, and certainly the most spectacular, was the organisation of the great scientific expedition to Mongolia. It was unfortunate that after some years of work, which had produced results of the greatest importance to science in palæontology, geology, archæology, and the other branches of research for which provision had been made, clash with Chinese authority should have brought the expedition to a close at a moment when Osborn was about to build up an organisation in China, which promised to emulate within its limits the achievement of the parent institution in New York.

Chromosome Behaviour and Protein Pattern

IT is announced in the *Oxford University Gazette* of November 6, that the curators of the University Chest have been authorised by Congregation to receive from the Rockefeller Foundation a grant of £500 a year for five years for the purposes of research in the application of mathematical analysis to biological problems, to be conducted by Dr. Dorothy Wrinch. Apparently this grant is to enable Dr. Wrinch to continue and develop her researches into relationships between chromosomes and protein aggregates which have been the subject of several notable contributions, three of which appeared in NATURE during the past year (**134**, 978; **135**, 788; **136**, 68). She graduated at Cambridge in 1916 and was a wrangler in the Mathematical Tripos. Since then she has had a distinguished career in teaching and research, having been successively lecturer in the Department of Pure Mathematics, University College, London; Yarrow scientific research fellow and Bertha Ayrton fellow of Girton College, Cambridge; and lecturer in mathematics and Susette Taylor fellow of Lady Margaret Hall, Oxford. While holding the two last-named fellowships in 1931–34 she spent part of the time at the Universities of Vienna, Paris, and Prague. So long ago as 1921, Dr. Wrinch contributed a paper to NATURE, with Dr. Harold Jeffreys, on "The Relation of Geometry to Einstein's Theory of Gravitation"; and among many other subjects of wide interest with which she has dealt in papers to scientific societies are the theory of probability, principles of scientific inquiry, relations of science and philosophy, and boundary problems of mathematical physics. Her recent work on the structure and behaviour of chromosomes in relation to protein aggregates is a new field of inquiry from which further results of high importance may be confidently anticipated.

The King of the Belgians

AT the general meeting of the Linnean Society of London held on November 7, His Majesty The King of the Belgians was unanimously elected an honorary member of the Society. His Majesty is known to take a keen interest in natural history. When Crown Prince, he made a voyage to the Dutch East Indies in 1928–29, one result of which was a very important collection of specimens for the Royal Museum of Natural History in Brussels. He has also taken an active interest in the preservation of the fauna of Africa by the establishment of Nature reserves. The great Parc National Albert in the Belgian Congo, the area of which has recently been greatly extended, owes much to His Majesty's patronage and influence, and constitutes one of the most important experiments ever made in the conservation of wild Nature.

American Stratosphere Balloon *Explorer II*

A NOTABLE achievement falls to the credit of Capts. A. W. Stevens and Earl A. Anderson of the U.S. Army Air Corps, who, according to the reports in the daily Press, have successfully piloted their stratosphere balloon up to the record height of 74,000 feet. The previous record was held by the ill-fated Russian balloon *Osoaviakhim* which probably reached a height of 72,000 feet on January 30, 1934. After the first set-back of last July, when the top of *Explorer II* burst and released 375,000 cubic feet of helium, another occurred on Monday, November 11, when a 20-ft. rent in the envelope, produced during its inflation, had to be repaired at the last moment. The ascent was made at 7 a.m. from a point eleven miles west of Rapid City, and a safe landing was made in the evening at White Lake, South Dakota. Capt. Stevens reported by wireless that at his maximum height the external temperature was −55° C., the cosmic ray intensity 150 times that at the earth's surface, and that the sky had become a jet black awning.

Imperial Airways New Programme

SPEAKING at the annual meeting of Imperial Airways, Sir Eric Geddes outlined the possibilities of, at least experimental, passenger- and mail-carrying operations across the North Atlantic next summer. A 'Mayo' composite aircraft in which a large seaplane, with good 'get off' characteristics, carries a smaller long-distance machine upon its back, releasing it at a suitable height, and also a large flying boat of more normal design are under construction, both of them having sufficient range to fly the Atlantic with adequate reserve. The westward journey will probably be London, Azores, Bermuda, New York, the latter stage being operated in conjunction with Pan-American Airways. Eastwards the direct line New York, Port Botwood (Newfoundland), Cork or Bantry Bay (Ireland), London has been surveyed, although the intermediate stations in Canada and Ireland are not yet definitely settled. The longer route outwards is necessary as stops are needed for refuelling. The prevailing west to east winds make it impossible to fly the more direct route, without landing between Ireland and Newfoundland, with sufficient fuel and still to have an economic load-carrying capacity. On the return journey, this following wind not only reduces the air mileage but also increases the relative speed.

THE distance from Newfoundland to Ireland is about 1,900 miles, and a flying boat with only a little more nominal air endurance will actually have a considerable reserve, owing to the almost constant following wind. There are also envisaged extensions to this route across Canada to Vancouver, Khartoum to Nigeria from the England–South Africa route, and Hong-Kong to Penang from the main Australian route. Sir Eric stressed the fact that there is a great difference between speeds technically possible and those commercially practicable, and stated that there is a greater demand for a reduction in fares than for an increase in speed. Nevertheless, the new aircraft on order will give substantial increases in speed next summer, subject to ground organisation being provided of a suitable standard. For example, it is expected to reach Australia in seven days, South Africa in four days and India in three, with normal schedule working.

Rebuilding Birkbeck College

IN the murky atmosphere of a Strand tavern on a dreary December evening more than a century ago, the germ of a great ideal first struggled into existence. George Birkbeck, who presided on the occasion, was a man of vision, but it is to be doubted whether even he had more than a glimmering of what the future held for his latest child. Since that night—the gathering of a couple of thousand working men did not disperse until 3 a.m.—Birkbeck College has become an integral part of the body scientific. The appeal launched at the Mansion House on November 7 for funds for rebuilding Birkbeck College is of the highest importance not only to the College alumni but also to scientific workers throughout Great Britain. The Lord Mayor (Sir Stephen Killick), an old student of the College, presided, supported by the Duke of York, president of the College, accompanied by the Duchess, the Archbishop of Canterbury, the Vice-Chancellor of the University of London (Dr. Eason) and the chairman of the Governing Body (Mr. W. L. Hichens). Owing to the general election, Mr. Ramsay MacDonald, another old student, was unable to attend, but wrote a letter strongly supporting the appeal.

THE Lord Mayor said the present buildings of Birkbeck College are inadequate, and that the University of London has offered a position for a new building on the Bloomsbury site. Generous grants towards the rebuilding fund have been offered by the University, the London County Council and the City Corporation. About half of the £250,000 required has been promised. The Vice-Chancellor contributed interesting information about the work of the College, referring particularly to its 200 post-graduate research workers and to Prof. P. M. S. Blackett's research work on cosmic rays, to which £1,150 has been contributed from the Mond Fund of the Royal Society. As the Archbishop of Canterbury pointed out, the movement to bring the worker to the university rather than the reverse process is an ideal to which the energies of all should be directed. The academic record of Birkbeck staff is high, and an increasing volume of significant research is being prosecuted under their direction; research which, in the words of Mr. Ramsay MacDonald, is fraught with possibilities of the highest importance to our great industrial centres. The appeal merits a speedy and generous response. Let him who hath give; and let him who hath not, proclaim the worthiness of a common cause.

School and Museum in London Education

IN order to take fuller advantage of the exceptional opportunities afforded by the museums of London of adding background to the curriculum of the schools, the London County Council decided early in the current year to add to the staff of its inspectorate an officer who would serve as a liaison between museum and school. School visits to the museums have long figured in the time-table; but it had become evident that some organisation of objective was necessary to secure the full return for the time which these visits demand. The resolution of the Council has been given effect by the appointment of Dr. Louis W. G. Malcolm to the post; and arrangements have been made already under his supervision for an extension of the system of school visits and lectures in the museums to cover a wide field of subjects of topical and educational interest. In the Imperial Institute, for example, geographical films are being shown and lectures given on the Mediterranean, Malta, Gibraltar, Cyprus and Suez, and these will be followed by illustrations of the industries and occupations of the more distant parts of the Empire. In the London Museum, the history of London from prehistoric to Stuart times is to be demonstrated. Among other

museums at present participating in the scheme are the Victoria and Albert, Horniman and Geffrye Museums. Dr. Malcolm, who was a research scholar in anthropology of Christ's College, Cambridge, and obtained his Ph.D. degree for a thesis on the history and development of medical museums, not only has a wide and varied experience of museum work, but he has also devoted much attention to the practical development of the museum collection as a part of the machinery of education. His work will be supported by a strong and informed committee of the County Council.

Research on Carcinogenic Compounds

THE thirty-first Bedson Lecture was delivered by Prof. J. W. Cook, of the Cancer Hospital, London, to the Bedson Club at Armstrong College, Newcastle-on-Tyne, on November 8. Prof. Cook took as his subject "The Synthesis and Biological Effects of Carcinogenic Hydrocarbons", and said it has long been known that certain forms of skin cancer are due to occupational causes, such cases being prevalent among workers in the coal-tar and allied industries, in the shale oil industry and among mule spinners in cotton mills. This is due to the action of a common constituent of coal tar, and shale and lubricating oil, the isolation and identification of which was successfully accomplished about three years ago in the research laboratories of the Cancer Hospital, London. A very valuable guide in the difficult task of separating this substance from the other constituents of the mixtures was provided by the fact that these tars and oils having carcinogenic properties are all strongly fluorescent. An investigation of the nature of this fluorescence spectrum directed attention to the benzanthracene group of hydrocarbons. Many of these have been prepared artificially in the laboratory, and some have been shown capable of producing cancer in mice. The cancer-producing constituent of coal tar, etc., benzpyrene, belongs to this group. More recently, it has been found possible to bring about the artificial conversion of substances normally present in the human body, namely, cholic and deoxycholic acids, into a hydrocarbon of the benzanthracene type, methylcholanthrene, and this was found to be more powerfully cancer-producing than any other substance yet investigated. The chemical changes by which it was obtained are of the type which are well known to occur in the body, and it may be that cancer in man is due to some such substance as a bile acid undergoing decomposition in an abnormal manner, with conversion into cancer-producing substances.

Chemistry in the Universities and Schools

"THE Teaching of Chemistry" was the subject chosen by Prof. Arthur Smithells, director of the Salters' Institute of Industrial Chemistry, for his Harrison Memorial Lecture to the Pharmaceutical Society on November 12. The chief difficulty of the university professor of chemistry lies in dealing with a subject in which the advance has been of unparalleled rapidity and, most recently, in changes on the theoretical side which have not only led to the acquisition of tracts of new knowledge, but also have affected science at its very base. Prof. Smithells believes that these advances have placed a great burden on the student, and especially on his memory. The reduction and emendation of the curriculum would result in a gain far exceeding in importance any possible loss in its range. Passing to the teaching of chemistry to those whose dominant interest is its application to some particular calling, reference was made to students of medicine as an example. Prof. Smithells himself had placed such students in a course apart, where he had striven, without any intellectual sacrifice, to invest the teaching throughout with facts and illustrations connected with the medical calling. The teaching of chemistry in schools, after a period of rapid growth, became a mere small-scale replica in contents and form of the early chemical course of a university. This teaching led to the revolt, headed by Prof. H. E. Armstrong, who from then to the present day has stood as the great campaigner against all that has seemed unsound in chemical education, wherever it has appeared, but, above all, in its earlier stages. The influence exerted inevitably by the university teacher has been far beyond what is warranted. Relief of the crowded curriculum has been sought by relegating to the schools so much higher work in science that there is a real danger existing of just that kind of over-balance of one kind of subject, as was the case with classics when science first sought admission to the curriculum.

Weights and Balances in Ancient Egypt

AT the Friday evening discourse at the Royal Institution on November 8, Prof. S. R. K. Glanville discussed "Weights and Balances in Ancient Egypt". The actual weights recovered from Ancient Egypt divide into eight main standards, derived from a much larger number in very early times. What we have go back to prehistoric times and show a gradual fusion of the standards, a process which is completed by the seventh century B.C. The balance may be traced from the Old Kingdom, with a possible example of a balance beam from pre-dynastic times. The New Kingdom balance, which lasted at any rate until the Ptolemaic period, was very efficient, and shows a greater accuracy in its design than the small Roman balance which succeeded it. There is evidence of a standard of exchange in ordinary transactions from the Old Kingdom, though whether this standard was a piece of metal, which could be passed between buyer and seller, is questionable at this period. The explanation of the lack of evidence for such mediums of exchange is probably in the nature of the organisation of the country in earliest times as a huge estate owned by the king, and later as a number of big estates controlled by governors and priesthoods, a condition which to some extent exists to-day. These estates being largely self-sufficing, it was possible to conduct their economic affairs without resort to anything approaching currency. There is, however, evidence of the use in the Middle Kingdom of copper pieces, and of a much more frequent use in the New

Kingdom of silver pieces which gave way to copper as the State grew poorer, the whole standard being backed by gold. It is difficult to decide how far the balance was used for general purposes, as its representation on tomb paintings is almost confined to the weighing of gold, silver and precious stones, either domestically for distribution to the metal workers on private or public estates, or as a registration of income or taxes from within the State or of 'tribute' or prizes of war from abroad.

Sewage Purification

MR. JOHN D. WATSON, in his presidential address delivered on November 5 to the Institution of Civil Engineers, dealt with the phases of public works which have engaged his attention for more than half a century, and showed how the development of sanitation and improved water-supplies has brought about a very considerable reduction in the death-rate. He spoke of the Iddesleigh Commission, the reports of which showed that the disposal of sewage into an adequate volume of clean water—either salt or fresh —is sound and proper, not only on the grounds of efficiency and economy, but also on strictly scientific principles. As a matter of principle, purification by land-irrigation is sound and still fairly popular. Percolating filters are now popular, and while this method of purification has a direct relationship to the contact-bed method, it produces a more consistently uniform effluent, is more generally reliable and the operating costs are less. Although almost unknown twenty years ago, bio-aeration or activated sludge is now established beyond question as one of the most useful methods of sewage purification. It has proved itself to be scientifically sound, and, when the plant is well designed, it is economical and freer from nuisance than any method yet discovered. Having stated the most desirable lines for future development and discussed several noteworthy schemes, Mr. Watson emphasised the extent of loss resulting from lack of co-operation, and concluded his address by pointing out that, while the nation owes a great deal to the Ministry of Health, there is still much to be done before the goal is reached when there will be no river-pollution. In his opinion, a central authority is necessary, and this should be the Ministry of Health rather than the *ad hoc* body suggested by the Royal Commission, provided that power is given to set up a research department wide enough to include the excellent work which has been done in recent years by the Water Pollution Research Board.

South African Association for the Advancement of Science

THE South African Association for the Advancement of Science held its annual meeting at Paarl on July 1–6. On July 1, Prof. M. M. Rindl, professor of chemistry in Grey University College, Bloemfontein, president of the Association, delivered an address entitled "A Plea for the Establishment of a National Research Council and for the Limitation of a National Research Policy in South Africa". Replying to criticisms of the Association and its policy, Prof. Rindl said that provision of funds for fostering research in the form of fellowships, scholarships and research grants in South Africa is not ungenerous. Much of this is directly attributable to the persistent agitation of the Association. In its early days, the Association and the Royal Society of South Africa were the only bodies providing research grants from their own funds. Furthermore, the annual award of the South Africa Medal and Grant to a prominent research worker in South Africa has done much to stimulate competition among investigators. As a result of the Association's action, a national committee of intellectual co-operation has been appointed, and it is hoped that the outcome will be the establishment of a National Research Council, and the inauguration of a national research policy on lines similar to those adopted in Great Britain, the Dominions and in many industrialised countries oversea. Another activity of the Association has been to appoint a committee to collect authentic data of the early history of scientific endeavour and industrial achievement in South Africa. With this end in view, the committee is approaching pioneers of science and industry to place on record their reminiscences and the history of the development in the industries which they founded, or with which they have been associated.

AT the conclusion of his address, Prof. Rindl presented the South Africa Medal and Grant to Dr. Edwin Percy Phillips, and the British Association Medal and Grant to Miss Margaret Orford. His Excellency the Earl of Clarendon, Governor-General of the Union of South Africa, has graciously accepted the invitation of the Council to become the president of the Association for the year 1935–36. This will be the thirty-fourth annual session and will be held at Johannesburg. For this year the Association is departing from its normal procedure of meeting in July, and the Johannesburg session will be held on October 5–10. Members attending the meeting thus will have opportunity of visiting the Empire Exhibition, which is being staged for several months in Johannesburg.

Mellon Institute of Industrial Research

IN accepting the Chemical Industry Medal for 1935, at the meeting of the American Section of the Society of Chemical Industry, at the Chemists' Club, New York, on November 8, Dr. Edward R. Weidlein, director of the Mellon Institute of Industrial Research, Pittsburgh, Pa., described some of the scientific investigations at the Institute. The Mellon Institute is an industrial experiment station, a training school for industrial scientific workers, a centre for research in pure, as well as applied, chemistry, and a clearing-house on specific scientific information for the public. Dr. Weidlein said that the Mellon Institute has shown about 3,600 American companies, either as individuals or as members of industrial associations, that scientific research, properly carried out, is profitable to them. Most of the problems accepted for study during 1911–35 have been solved satisfactorily. The Institute has also

been active in stimulating research in other laboratories and in collaborating with other research establishments, both in the United States and abroad. It is best known, however, by the commercial processes that it has evolved (582 U.S. patents) and by its additions to the literature of chemistry and allied sciences (18 books, 122 bulletins, and 1,727 papers). During the past twenty-four years, the Institute has received more than 10,000,000 dollars from industrial fellowship donors to defray the cost of scientific investigations conducted for these companies and associations. Dr. Weidlein referred to no less than ten new industries that have come from these researches. In conclusion, he said that they hope to occupy the Institute's new building early next year.

Relief of Animal Suffering

THE ninth Stephen Paget Memorial Lecture of the Research Defence Society was delivered last June by Sir Frederick Hobday, the Principal of the Royal Veterinary College, who chose as his subject "The Relief of Animal Suffering" (*The Fight against Disease*, **23**, No. 3). The attacks of anti-vivisectionists are directed not only against research work for the relief of human suffering, but also against research on diseases of animals, so that the subject of Sir Frederick's address was opportune. After some preliminary remarks on the statistics of the animal population of Great Britain and the diseases that affect them and on the training of the veterinary surgeon, he first mentioned the electric killer. The animal receives a shock of 70 volts by touching it on the head for a few seconds with the instrument connected to a source of electric supply, and it is claimed that the animal is thus rendered unconscious for 2½ minutes, during which time the blood may be withdrawn. Remarks were then made on articles accidentally swallowed by animals and their treatment, and finally on glanders, mange and other diseases affecting animals, and their prevention and treatment, illustrating everyday cases brought to the veterinary surgeon. At the annual general meeting of the Society, which followed the lecture, the honorary treasurer, Sir Leonard Rogers, pointed out that the expenditure of the Society somewhat exceeds its income, and additional subscriptions and donations would, therefore, be welcome.

Artificial Drying of Grass and Other Fodder

IN the agricultural world, much has been heard recently of the high nutritive value of grass and fodder crops when cut at a very early stage, and also of the possibility of preserving these special qualities by artificial drying. The Committee appointed by the Agricultural Research Council to investigate these questions has now issued its report, "The Preservation of Grass and other Fodder Crops" (London: H.M. Stationery Office. 1*s*. net), which provides an up-to-date authoritative account of the whole subject. After surveying the methods at present available for hay-making, ensilage, etc., the committee shows that the artificial drying of grass in the usual hay stage does not promise to be a paying proposition. Drying grass cut young at frequent intervals throughout the season, however, has a good prospect of economic success, particularly in districts of moderate or high rainfall on land in good condition. The report then gives a full account of the methods for cutting and collecting young grass, the physical principles of drying grass, the special practical requirements of a farm drier, the cost of drying and the methods of processing and storage. Descriptions are also given of driers now on the market or those shortly to appear there, those suitable for farm as apart from large-scale factory use receiving special attention. The report concludes with a bibliography for those desirous of still further information.

Safety in Mines Research

WE have received from the Mines Department the thirteenth annual report of the Safety in Mines Research Board for the year 1934. This contains a large amount of interesting and valuable matter. The report proper, after a general introduction, deals with safety instructions, and then there is an important section (Part 3) on the progress of safety researches, dealing with coal-dust explosions, firedamp explosions, spontaneous combustion of coal, mining explosives, falls of ground, haulage, wire ropes and mine ventilation, while the next part deals briefly with various health researches reported by the Health Advisory Committee of the Mines Department. The report is followed by a number of appendixes which are of great importance, and cover the work of the various local committees; it is interesting to see that the value of protective equipment is becoming more widely recognised by the miners.

The Colonial Institute of Holland

WE have received the annual report of the Royal Colonial Institute, Amsterdam (Koninklijke Vereeniging Koloniaal Instituut, Amsterdam), which has now been in existence for twenty-four years. It gives an account of the activities of the Institute, its funds, the museum, and scientific expeditions, and of the affiliated institutes in the Dutch East Indies. A list of the staff and of their publications is given, together with a summary of the research work carried out. The last-named includes investigations on rhinoscleroma, dengue and food-poisoning, and on the mosquito fauna of Holland.

Meteor Observations in U.S.S.R.

WITH the object of studying the acceleration of the velocity of a meteor, the Moscow branch of the U.S.S.R. Astro-Geodetical Society has installed a camera of focal ratio *f*2 behind a two-bladed fan, which interrupts the exposure on a star field nine times per second, at Koutchino, twenty kilometres east of Moscow. Prints of two photographs—one of a meteor and another of a meteor spectrum—together with a note upon meteor observations, have reached us from Moscow. From a typical example of observations collected (to be described in the *Monthly Notices of the Royal Astronomical Society* by

MM. Fedynski and Stanjukowitsch) it appears that the velocity decreases by 37 per cent as the meteor falls from 90 km. to 55 km. in height. The same group of observers conducts observations of meteor spectra with a prismatic camera; forty-seven lines were recognised by M. Fedynski in a meteor of stellar magnitude − 3, of which the strongest were those of ionised calcium. A third exposure, made in a camera distant 1·5 km., enables the observers to compute the height of the meteor at any point on its illuminated path.

A Naked-Eye Sunspot

A GROUP of sunspots, large enough to be seen with the naked eye, has been in transit across the sun's disk (Nov. 3–15), in solar latitude 29° south; the time of central meridian passage was Nov. 9·5. The group, which was of 'stream' or 'bipolar' type, consisted of a very large circular spot with smaller followers. The leader, with an area of 800 millionths of the sun's hemisphere (800 millionths = nearly 950 million square miles), was the largest single spot observed since February 1931; the maximum total area of the present group was 1,200 millionths of the sun's hemisphere. On the few occasions when the weather permitted spectroscopic observations to be made at Greenwich, the group was not unusually active. Observations made on Nov. 9–11 show another large stream of spots extending in longitude for nearly 80,000 miles in lat. 21° north. The time of central meridian passage was Nov. 13·3. During the last two or three months there has been a marked increase in the sun's general activity, as shown by the increased frequency of spots—mainly of small or moderate size—dark and bright hydrogen and calcium markings on the disk and prominences at the edge of the disk.

Announcements

THE following have been elected as officers of the Cambridge Philosophical Society for 1935–36. *President:* Dr. F. W. Aston; *Vice-Presidents:* Prof. A. Hutchinson, Dr. E. D. Adrian, Sir J. Barcroft; *Treasurer:* Mr. F. A. Potts; *Secretaries:* Mr. F. P. White, Dr. J. D. Cockcroft, Dr. H. Hamshaw Thomas. *New Members of the Council:* Mr. R. A. Hayes, Dr. F. Kidd, Sir G. P. Lenox-Conyngham, Dr. R. G. W. Norrish.

THE fifth German Congress of the Scientific Associations on Corrosion will be held in Berlin on November 18–19. The theme of the Congress will be "The Corrosion of Metallic Materials of Construction by Cold Water". Further information can be obtained from the Verein deutscher Chemiker, Berlin W 35, Potsdamer Str. 103a.

MR. CYRIL C. BARNARD, librarian of the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1, informs us that, in view of the numerous requests he has received for a copy of the classification used by him at that Library, he is considering the issue of a small edition in the form of a cloth-bound volume of 144 pp., royal 8vo., at 10*s.* 6*d.*, containing not only the schedules of the classification but also a full explanatory introduction, local list, index of parasites, and alphabetical subject index. Mr. Barnard can only undertake publication if sufficient promises of support are forthcoming.

THE following appointments have recently been made by the Secretary of State for the Colonies: F. J. Pound, to be agronomist, Department of Agriculture, Trinidad; N. H. Sands, to be agricultural officer, Malaya; F. W. Toovey, to be botanist, Department of Agriculture, Nigeria; W. E. Miller Logan, to be assistant conservator of forests, Gold Coast; A. C. Russell, to be assistant conservator of forests, Gold Coast; T. N. Wardrop, to be assistant conservator of forests, Nigeria; J. B. Alexander, to be geologist, Nyasaland; A. Cawley, to be engineering geologist, Tanganyika; W. H. Reeve, to be assistant field geologist, Tanganyika; B. N. Temperley, to be assistant field geologist, Tanganyika; W. J. B. Johnson, to be canning officer, Department of Agriculture, Malaya; A. A. Abraham, assistant agricultural superintendent, to be agricultural superintendent, British Guiana; G. W. Lines, late superintendent of agriculture, to be superintendent of agriculture, Nigeria; T H. Marshall, senior agricultural assistant, to be district agricultural officer, Tanganyika; R. J. M. Swynnerton, agricultural assistant, to be district agricultural officer, Tanganyika.

THE Council of the Institution of Civil Engineers has decided that, in future, the Press can attend and report the discussions at any of the ordinary meetings of the Institution. Abstracts or advance copies of the papers to be read are available on application to the Secretary.

MESSRS. EDWARD ARNOLD AND CO. announce the early publication of a new edition of "The Structure of the Alps" by Prof. Leon W. Collet, of Geneva; and also "The Oyster and the Oyster Fishery" by Prof. J. H. Orton, of the University of Liverpool, embodying the Buckland Lectures for 1935.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

An assistant to the research chemist of the London Shellac Research Bureau—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (Nov. 26).

An assistant lecturer and demonstrator in physics in the University of Leeds—The Registrar (Nov. 26).

A pomologist to the Royal Horticultural Society—The Secretary, Royal Horticultural Society, Vincent Square, Westminster, S.W.1 (Nov. 30).

A lecturer in geography and education in the University of Dublin—The Registrar (Dec. 2).

A professor of mining in the University of Edinburgh and Heriot-Watt College—The Secretary of the University (Dec. 31).

An assistant master to teach engineering in the Dover Technical Institute—The Principal.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 798.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

The Electric Currents Flowing over Rusting Iron

THE electrochemical mechanism of 'rusting' is generally recognised, but our knowledge of the distribution and strength of the currents rests upon somewhat indirect methods. In the corrosion of a horizontal iron surface by filter-paper wetted with sodium bicarbonate solution, it has lately been found possible to study the current flowing horizontally through the paper without any interruption of the circuits. This is accomplished by shunting a small fraction through two non-polarising electrodes of superficially oxidised copper surrounded by filter-paper soaked in the same liquid and separated by waxed paper.

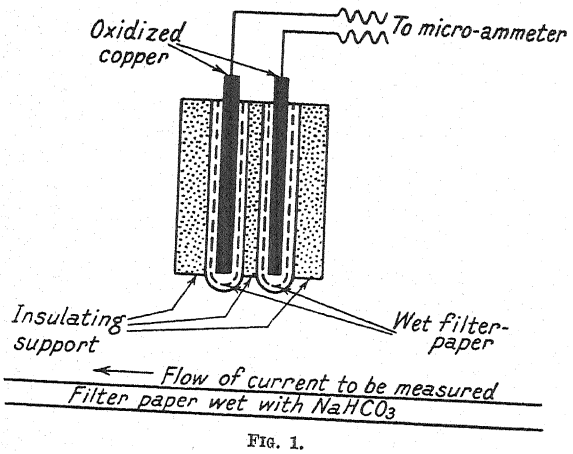

FIG. 1.

The apparatus, shown in Fig. 1, is mounted in a hinged frame, which allows it to be brought down momentarily at right-angles to the filter-paper in which the current is to be measured, and raised again as soon as the deflection of the micro-ammeter joined to the two coppers has been read—thus minimising disturbances to the corroding system. The relation between the deflection and the current to be measured is obtained by calibration on similarly wetted filter-paper strips through which known currents are forced from an external source. The form of the calibration curve indicates a satisfactory absence of polarisation, but calibration must be conducted before and after every experiment—as the sensitivity varies slightly with time; no great accuracy is claimed for the absolute values, but the general shape of the curves connecting current-strength and distance from the seat of corrosion is not in doubt.

Fig. 2 shows a curve obtained for soft iron corroded by $N/100$ sodium bicarbonate. The iron was abraded, degreased, exposed to dry air for 24 hours, and then a single scratch line was ruled across the centre just before application of the wet paper. Intense rusting quickly occurred along the scratch-line, and nowhere else. The change of the direction of the current near the scratch-line indicates that here the anodic (corroding) strip is surrounded by cathodic areas on *each* side. Since the difference (di) between the current-strength at two points separated by distance (dl) represents the current taken from or given up to the metal, the anodic or cathodic current

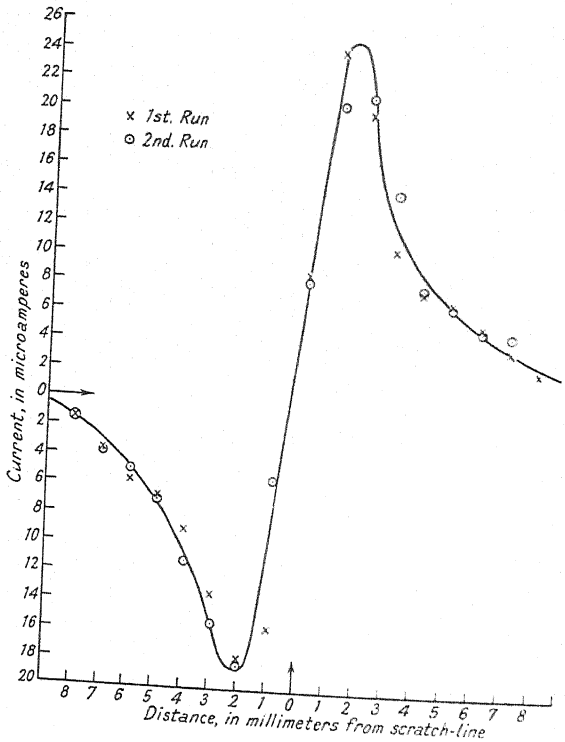

FIG. 2.

density, for a strip of breadth B, is represented by di/Bdl. Curve gradients sloping upwards to the right indicate *anodic* areas, and it will be noticed that there is intense anodic action immediately around the scratch, where corrosion is rapid; gradients sloping downwards to the right indicate *cathodic* areas, and these are free from attack.

Very similar curves have been obtained with irons of other purities, other surface conditions and other salt concentrations; but on some specimens (notably those of steel), rust appears not only along the scratch-line but also at isolated spots elsewhere; in such cases the curves show irregularities at the rusting points, important rust-spots being associated with

anodic gradients recognisable on the curves. Qualitative experiments without filter-paper on specimens covered with a layer of liquid and without a scratch-line indicate that here also corrosion is connected with electric currents, but the capillary disturbance of the liquid surface at the moment of tapping interferes with serious measurement.

The definite association of corrosion and immunity with well-separated anodic and cathodic areas, respectively, accords with the electrochemical mechanism of corrosion, as developed in previous papers with Bannister, Britton, Hoar, Borgmann, Mears and Lewis[1].

Absorption of Short Wave-length X-Rays

WE have recently had the opportunity of measuring the absorption coefficients of a number of substances for short wave-length X-rays. The radiations were produced at 250 k.v. (constant potential) using a filter of 3 mm. lead, 2 mm. tin and 3 mm. aluminium.

Spectroscopic evidence shows a narrow band of X-rays with a mean wave-length of 59 X.U. The measurements were carried out using a carefully controlled parallel plate chamber equipment with a compensation method of measurement as in setting up such apparatus for standardisation in roentgens[1]. Care was taken to reduce the scattered radiation entering the chamber, and the error in absorption coefficient due to it is estimated at not greater than two per cent. The absorption coefficients of a number of elements are given below.

Element	Form	Mass absorption coefficient μ/ρ	Electronic absorption coefficient $\times 10^{24}$
Lithium	Metallic blocks in petroleum	0·107	0·408
Beryllium	Powder	0·110	0·413
Carbon	Graphite blocks	0·123	0·407
Oxygen	Liquid	0·120	0·398
Magnesium	Metallic blocks	0·121	0·405
Aluminium	Metallic blocks	0·119	0·409
Sulphur	Powder	0·121	0·401
Calcium	Shavings	0·135	0·447
Iron	Sheet	0·138	0·490
Copper	Sheet	0·154	0·558
Selenium	Powder	0·168	0·645
Rhodium	Sheet	0·246	0·928
Palladium	Sheet	0·232	0·887
Tin	Sheet	0·310	1·213
Iodine	Crystals	0·325	1·282
Tantalum	Sheet	0·658	2·70
Platinum	Sheet	0·684	2·83
Lead	Sheet	0·847	3·53

The mean absorption per electron for light elements up to calcium is, for this wave-length, $4{\cdot}06 \times 10^{-25}$, in fair agreement with the predictions of the Klein-Nishina formula[2] ($4{\cdot}00 \times 10^{-25}$ for $\lambda = 59$ X.U.) This result is of some biophysical interest in view of the problems of the physical basis of the effects of such radiations on living materials[3]. The photo-electric absorption coefficient per electron μ_τ, defined by $\mu_\tau = \mu_e - 4{\cdot}06 \times 10^{-25}$ is found by us to vary according to the law $\mu_\tau = kZ^{3\cdot0}$, where k is constant and Z the atomic number of the element[4].

We have also measured, for the same wave-length, the absorption coefficients of two liquids containing hydrogen, namely, water and ethyl alcohol, as well as deuterium oxide. The values are given below.

Substance	μ/ρ	Form
Water	0·133	Distilled
Ethyl alcohol	0·142	A.R.
Deuterium oxide	0·118	99 per cent purity (Norwegian origin)

For short wave-lengths, the mass absorption coefficient for hydrogen should be approximately twice that of any other light element owing to the low ratio of atomic weight to atomic number. This appears in the results as an increase of 11 per cent in the mass absorption coefficient of water and 18 per cent for alcohol. Deuterium, on the other hand, would be expected to behave as a normal light element and this is verified in the value of μ/ρ obtained for deuterium oxide.

It may be observed that absorption measurements of this type serve to count electrons per atom, as distinct from the more usual method of weighing isotopic nuclei.

New Technique for Obtaining X-Ray Powder Patterns

To obtain the X-ray diffraction pattern of a flat specimen such as is met with in metallurgical practice, the specimen may be mounted in a circular camera and inclined at a small angle to the beam. This is illustrated in Fig. 1. With the usual diaphragm, we have observed that diffraction lines making a small

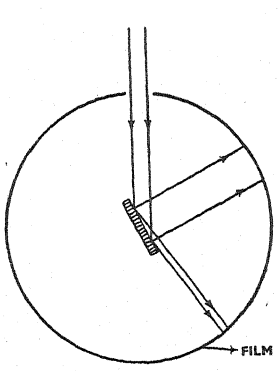

FIG. 1.

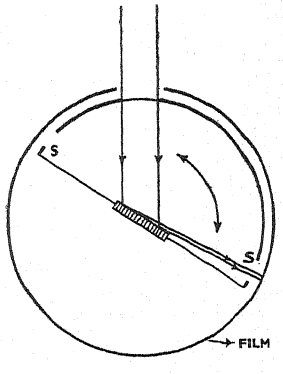

FIG. 2.

angle with the surface of the specimen are particularly sharp, but become broader as the angle between the diffracted beams and the surface of the specimen increases.

For a measurement one requires all the lines to be sharp, and so a camera according to Fig. 2 was devised, which can be used to record all or, if desired,

only a few reflections. In this camera, a shutter in which two slits, S, are cut, is arranged to rotate with the specimen, so that diffracted beams only reach the film when they make a small angle with the specimen surface.

To make full use of the principle, as wide a parallel beam as can be obtained from the focus of the X-ray tube is utilised. Very good results are obtained by means of a multiple diaphragm system as shown in Fig. 3.

If only a few lines, for example, within a region of 12° to 15°, are desired, the specimen may be kept stationary or, perhaps, oscillated over the region.

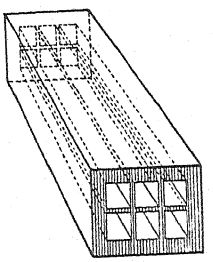

FIG. 3.

A useful application of the principle is to obtain a narrow intense beam of polarised monochromatic X-rays. A single crystal of copper cut with its plane surface at an angle of about 40° to the (311) plane is used as a polariser[1], and is irradiated by a wide beam of copper $K\alpha$ radiation (defined by a multiple diaphragm).

The advantages of the new method described above may be summarised as follows:

(*a*) a flat specimen such as is met with in metallurgical practice is used—this is an important point;

(*b*) the intensity of each line in the photograph can be calculated without difficulty—this is not so with the usual rod-shaped specimens;

(*c*) the sharpness of the lines can be controlled;

(*d*) in the case where the specimen is maintained stationary or oscillated over small angles, there is a much decreased time of exposure owing to the more efficient use of the available radiation.

Further details will be given elsewhere.

Negative Attenuation of Wireless Waves

WE are interested in the measurements which Khastgir, Chandhuri and Sen Gupta described in a recent letter to NATURE[1], apparently confirming the occurrence of 'negative attenuation' of wireless waves first noticed by Ratcliffe and Barnett[2]. Some years ago, we attempted to extend the measurements which Ratcliffe and Barnett had made on the 1,600-metre transmissions from the Daventry Station of the B.B.C., so as to include measurements on the same wave-length but with a shorter transmitting aerial[3]. The results of these further measurements led us to question the interpretation of Ratcliffe and Barnett's results. We began by using measuring apparatus similar to that used in the original investigation, and consisting of a tuned loop circuit with a Moullin voltmeter placed directly across the tuning condenser. With this apparatus we reproduced the curve of Ratcliffe and Barnett quite closely. We then had occasion to make measurements with an apparatus in which the signal produced a deflection in a galvanometer attached to the output of an amplifier, this deflection being matched by injecting a calibrated E.M.F. into the loop circuit. This method of measurement showed no sign of the 'negative attenuation' effect. Closer investigation of the disagreement led us to the conclusion that the measurements made by the Moullin voltmeter method were vitiated by the fact that, owing to the flow of grid current, the damping which the voltmeter produced in the loop circuit was a function of the signal amplitude. The increased damping for the larger signals caused the signal strength to be progressively underestimated as the apparatus approached nearer to the emitter, and gave the appearance of 'negative attenuation'.

We were able to show that the magnitude of the apparent 'negative attenuation' effect was accounted for by the measured values of the grid current. We now believe that the apparent 'negative attenuation' observed by Ratcliffe and Shaw[4] with a wave-length of 30 metres is due to the same cause.

In the discussion of a paper read to the Institution of Electrical Engineers[5], attention was directed to the possibility of errors of this kind when using the Moullin voltmeter method.

When measuring with the injected E.M.F. method we have not been able to observe any 'negative attenuation' on 1,600 m. wave-length from the Daventry emitter, on 360 m. from Brookman's Park, or on 1,600 m. from an experimental emitter at Cambridge. We are therefore surprised that Khastgir, Chandhuri and Sen Gupta have observed the effect, and we wonder whether they, too, can have been misled by using the Moullin voltmeter method. We consider that their curves would have been more convincing if they had observed more points on the all-important rising part of the curve. It is unfortunate that the only measurement shown on this part of the curve is that at the origin; if for any reason this was in error, the whole nature of the curve would be altered.

Photochemical Reactions connected with the Quenching of Fluorescence of Dyestuffs by Ferrous Ions in Solution

IT has been found recently that ferrous ions exert a strong quenching effect on different fluorescent dyestuffs in solution[1]. According to previous theoretical discussions[2], in the elementary process of quenching, the light quantum ($h\nu$) is transferred from the excited dyestuff molecule ($D_s h\nu$) to the Fe^{++} ion by a collision of the second kind. Unlike the case of direct irradiation, when the Franck-Condon principle is observed, we can gain here some energy from the potential energy of the heavy particles. Thus in this case the hydration energy of the ions formed in the process and the binding energy between dyestuff and H-atom can be used according to:

$$(1)\quad Fe^{++} + HOH + (D_s h\nu) = Fe^{+++} + OH^- + (D_s - H).$$

By irradiating different dyestuffs such as brilliant-cresylblue, methyleneblue, thionine, uranine (in water),

chlorophyll (in 60 per cent CH_3OH) in an (H_2SO_4) acid solution of $FeSO_4$ with the visible radiation of a strong carbon arc (oxygen being excluded) a considerable change in colour or bleaching is produced by the action of light, due to the formation of the reduced dyestuffs. The formation of these leuco-dyes takes place irreversibly, when the Fe+++ ions formed simultaneously are removed from the solution (for example, precipitated by hydrolysis). But with certain dyestuffs (for example, brilliant-cresylblue, methyleneblue, thionine) in acid solution the process is completely reversible in the dark, the Fe+++ formed being reduced by the leuco-dye. With these reactions it is proved that in general the binding energy between the radicals formed and the dyestuff can contribute an important part of the energy for the primary process of sensitisation (Reaction 1).

In analogy with other cases we have also been able to find the direct (unsensitised) photo-chemical process by irradiating an (H_2SO_4) acid solution of ferrous sulphate ($\frac{1}{2}$ molar) with ultra-violet light (from a strong mercury arc) which is strongly absorbed by the ferrous sulphate.

If oxygen is excluded, molecular hydrogen is formed in this process, with simultaneous formation of Fe+++ ions according to the electron affinity spectrum of Franck and Haber[3]:

$$(2)\quad Fe^{++} HOH + h\nu = Fe^{+++} + OH^- + H,$$
$$2H = H_2.$$

The quantum efficiency with respect to formation of molecular hydrogen was found to be of the order $\sim 0{\cdot}1$ (20° C.) and was practically independent of the concentration of the acid within the range 0·08–0·25 molar H_2SO_4, but was strongly dependent on the initial concentration of ferric salt present in the solution. These facts indicate that a reverse reaction, the reduction of Fe+++ by H atoms

$$(3)\quad Fe^{+++} + H = Fe^{++} + H^+$$

plays an important part, competing with the recombination of the H atoms giving molecular hydrogen.

The reactions discussed above may be of some interest for certain biological problems.

The fact that by sensitisation in the presence of Fe++ ions it is possible to produce H atoms from water with the radiation of the visible spectrum (in spite of the binding energy H — OH being 115 k.cal.) may be of importance for the assimilation process of green plants (regeneration of the chlorophyll). Noack[4] recently found a relatively high content of ferrous compounds, present in simple inorganic form, in the chloroplasts of green plants.

On the other hand, the reversible bleaching of dyestuffs with light in the presence of the Fe++/Fe+++ system can be regarded as the most simple model for the visual process.

I would like to thank Prof. F. G. Donnan for his continuous interest and valuable discussions.

Optical Rotatory Power of Solutions in an Electric Field

PREVIOUS work has shown that a relationship exists between the rotatory power of an optically active solution and the electric moment of the solvent. It has been found that, in general, the rotation varies in the opposite sense to the electric moment of the solvent throughout a series of solvents derived from the same parent hydrocarbon. An explanation of this observation has been advanced in terms of dipolar association between solvent and optically active solute, and numerous results have been brought forward in support of this hypothesis.

These observations suggested the possibility that an electric moment induced in the solvent molecules by an external electric field might have an effect similar to that of a permanent moment. Previous experience had shown that solvent influences are best observed with optically active compounds of simple molecular structure with a strongly polar group or groups situated near the asymmetric centre. For this reason, 2-*l*-menthyl-3-nitro-hydrogen phthalate was considered a suitable optically active solute, while solvents with zero or very small permanent electric moment were thought to be most advantageous for the proposed investigation; accordingly benzene and toluene were employed as solvents. Indeed, when an external electric field was applied to the solution, changes in rotatory power were observed. The tube with two parallel platinum electrodes, containing the solution, was placed in a Schmidt and Haensch half-shadow polarimeter reading to 0·01°. Rotations as large as 0·59° were obtained for the solution; the electric field was varied between about 500 and 11,000 absolute units. The rotation (change of rotation) increased at first slowly with increasing field, reached a maximum at about 4,000 absolute units and remained then constant, an effect which distinguishes this phenomenon clearly from the Kerr effect; but the two phenomena have in common that the effect is enhanced when the angle between the direction of the field and the plane of polarisation of the light is increased by rotating the tube in an anticlockwise direction. We expected this effect, that is, a decrease of the rotation, but we were surprised to find an increase in rotation by rotating the tube in a clockwise direction.

That the effect is not due to temperature changes in the solution is shown by the fact that in every case where a change due to the electric field was recorded, the change took place instantly and the rotation almost instantly returned to its original value, when the field was removed. These results have been repeated.

A solution of 2-ethyl-3-nitrohydrogen phthalate in toluene was submitted to an electrostatic field in the polarimeter tube. This compound is optically inactive and much less soluble in toluene than the corresponding menthyl ester. The solution was made by heating the ester and toluene, and while hot was poured into the tube; when under the influence of the field it was about 2 per cent with respect to the ester. The rotatory power was again a function of the potential difference between the electrodes, reaching a maximum at about 3,000 volts with both direct and alternating electric fields. It was very difficult to repeat these results, as the solution seemed to change continuously during the experiment. With the same field strength, the polarimeter readings were very erratic, for example, at one observation the

application of a field of 14,300 volts caused an instantaneous rotation of $\alpha = +3{\cdot}01°$, but in a few seconds, whilst the field was still on, it dropped to $\alpha = 0{\cdot}35°$. After the solution had been standing for three days, even the most powerful field had no effect on it; however, with a fresh hot solution rotational changes were again observed. The effects obtained with the ethyl ester appear to be distinct from those exhibited by the menthyl ester.

It is hoped to continue these investigations.

Separation of the Mercury Isotopes by a Photochemical Method

WHEN a mixture of mercury vapour and oxygen is irradiated with the mercury resonance line λ 2537, the mercury becomes oxidised. Since excitation is a necessary stage in the oxidation, Mrozowski[1] has suggested that it should be possible to produce a separation of the mercury isotopes by exciting them selectively. If the reaction consists of the primary photochemical process

$$Hg^{+} + O_2 \rightarrow HgO + O$$

only the atomic species which are excited by the incident light should be oxidised.

In my experiments the light from a mercury arc was passed through a Mrozowski filter[2] consisting of a column of mercury vapour in a magnetic field. This transmitted only the hyperfine structure components of the resonance line corresponding to the isotopes 200, 202. After an irradiation of between 10 and 30 minutes, the isotopic composition of the remaining mercury or of that recovered from the oxide was examined by the method of absorption of single hyperfine structure components[3]. The results of the experiments show:

(1) The separation is in every case only partial, so that besides the primary process, secondary reactions must take place.

(2) An addition of nitrogen assists the separation ($p_{O_2} : p_{N_2} \sim 1 : 1$, $p_{O_2} \sim 1$ mm. Hg).

(3) It has been possible to obtain samples in which the ratio $\frac{p_{200,\ 202}}{p_{198,\ 199,\ 201,\ 204}}$ was modified by a factor of four.

More detailed information will be published in the *Helv. Phys. Acta*.

Dissociation Energy of Carbon Monoxide

IN a former communication[1] we suggested 8·41 volts as the most probable value for the energy of dissociation of carbon monoxide. This was based upon a predissociation which we found in the upper level $B^1\Sigma$ of the Angström bands[2] and in the upper level $b^3\Sigma$ of the third positive group[3], at a height of 11·08 volts above the normal state of the molecule. Both predissociations we ascribed to the dissociation state ^3P (oxygen) + ^1S (carbon). To fix the dissociation energy with certainty, however, it is necessary to find another place of predissociation caused by a different state of the dissociation products.

An attempt in this direction was made by Schmid and Gerö[4]. They found predissociation in the higher level of the Herzberg bands at 0·48 volt above the predissociation mentioned above. This difference may be compared with that between two dissociation states of the molecule. As Fig. 1 shows, the difference between $^3P + {}^1S$ and $^1D + {}^1D$ is 0·53 volt, that between $^1S + {}^3P$ and $^1D + {}^1S$ is 0·46 volt. Schmid and Gerö believe that here the former difference must be taken, hence assuming an error of 0·05 volt, which is much larger than the triplet splitting in the atomic energy states concerned. Therefore we believe that the dissociation energy of carbon monoxide was still left uncertain.

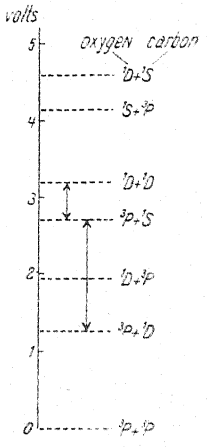

FIG. 1.

In examining the fourth positive group of CO, we found a sudden disappearance of the band lines in the bands with $v' = 10$, which points to a predissociation in the upper level $A^1\Pi$ of these bands. With the known band constants, the height of the dissociation state which causes this predissociation is calculated to be 9·66 volts above the normal state of the molecule. Comparing this predissociation with that in the upper level of the Angström bands at 11·08 volts, we find that the difference 1·42 volts corresponds exactly with that between the $^3P + {}^1D$ and $^3P + {}^1S$ states. Therefore we are sure of the following results: (1) the predissociation in the $A^1\Pi$ level is caused by $^3P + {}^1D$; (2) the predissociation in the $B^1\Sigma$ level is caused by $^3P + {}^1S$; (3) the dissociation energy of CO is 8·41 volts.

A New Technique in Cookery

THE leading article on "Food, Farmer and Future", by Prof. H. E. Armstrong, in NATURE of October 12, p. 565, encourages me to invite attention to what is, I believe, a new technique in the art of cooking.

It is commonly held that meat should be roasted in an oven at a temperature of 300°–500° F. and that the oven should be very hot for the first fifteen minutes so as to 'seal up the nutritive juices', particularly in the case of brown meat such as beef or mutton. It was, therefore, with some trepidation that my wife permitted a Sunday joint, a 6 lb. shoulder of mutton, to be put at 9 p.m. on a Saturday night into an oven thermostatically controlled at 212° F. She did not encourage me to experiment

with an expensive joint and the mutton cost 5½*d.* per pound. As things turned out this was fortunate, for we found that, despite its cheapness, the joint after fifteen hours cooking was delicious beyond all expectation.

The next experiment was with a boiling fowl which, when roasted in the same way for fifteen hours, was found to be as tender as a chicken and as full-flavoured as a turkey. Further tests with beef and mutton have confirmed the superfine quality of meat cooked at a low temperature, and the cooking of fish and other comestibles is now being studied.

It is important to observe that this method of cooking has been made practicable by the development of the heat-insulated thermostatically controlled oven. Strangely enough, however, it does not appear to have been discovered by the cookery schools or by the experts who advise the stove manufacturers.

In my household, the adoption of the new technique results in a saving estimated at not less than one penny per head per day: when it is realised that for the population of Great Britain a saving of one penny per head per day amounts to £70,000,000 a year, it is evident that scientifically directed experimental inquiry into the cooking of foodstuffs is of considerable economic importance.

In the great renascence promised by Prof. Armstrong we may find perhaps the answer to Rumford's question: "How many cheap articles may there be of which the most delicate and wholesome food might be prepared, were the art and the *science* of cooking them better understood?"[1]

Dementia nomenclatorica americana

FOLLOWING upon the protests against the proliferation of nomenclature in the Foraminifera that have appeared in NATURE, I observe that in the fascicle of Protozoa in the "Zoological Record" for 1934 three hundred and fifty-four new genera, species and varieties are added to the nomenclature.

American protozoologists are not the only offenders (if offence it be), for no less than seventy-three of these new species are recorded in Part 3 of the "Discovery" Reports on the Foraminifera, published in 1934.

Now comes a letter from Dr. Hans E. Thalmann, the most diligent and accurate bibliographer of the Foraminifera since Dr. C. D. Sherborn, in which he says:

"With great interest I read a few weeks ago your article in NATURE and I would be more than glad if many of our American colleagues would read it earnestly as well. My 'Bibliography of Foraminifera for the year 1933' (at present in press) contains not less than 390 papers dealing with Foraminifera—and therein are published not less than about 40 new genera and subgenera, 390 new species and varieties. The manuscript for the year 1934 so far counts about 340 papers, 25 new genera, more than 300 new species. I am sure that more than 80 per cent of these so-called new species can easily be placed amongst already published forms, and that most of all the new generic names since 1927 have only subgeneric value. This *dementia nomenclatorica americana* is not only a serious problem to-day but will burden the poor minds of future workers in Foraminifera. It is really to be deeply deplored that at present only a few systematists and taxonomists realise the fact that nomenclature is *not* a science, but should be an aid to science."

Estimation of Ascorbic Acid by Titration

SOME time ago I observed an increase in the ascorbic acid value of cabbage on cooking[1]. McHenry and Graham[2] have found a similar increase in cauliflower, carrots, parsnips, beets and potatoes, though not in cabbage, and have expressed the view that the increase on boiling was due to the setting free of bound ascorbic acid, possibly from an ester. Van Eekelen[3], however, is of the opinion that the apparent increase is due to the destruction of an oxidase present in these vegetables.

Working with Darjeeling cabbage obtained from local markets, I have repeatedly obtained a very much increased ascorbic acid value by boiling for 10 minutes before extraction with 20 per cent trichloracetic acid. The value obtained in the cold is about 13 mgm. per 100 gm. vegetable, and increases to 40 mgm. per 100 gm. after boiling. Even boiling with water alone yields an appreciably richer extract than that obtained with cold trichloracetic acid.

It is evident that at least in this case no destruction of an oxidase is concerned, because in the cold the vegetable was ground up under 20 per cent trichloracetic acid. The view of McHenry and Graham may appear to be more plausible.

Presence of Roes in New Zealand Marlin Swordfishes

IN view of the scarcity of data on the breeding of marlin swordfishes, the following note may, perhaps, be of interest. Swordfishing has been a popular sport in this locality, the Bay of Islands, New Zealand, since 1911. Yet in spite of the fact that many fishermen and scientific workers have examined the fish caught, primarily to distinguish the sexes and, if possible, discover secondary sexual characters, no swordfish with ovaries containing roe had been discovered. With the view of increasing our knowledge of the breeding habits of these fish, I examined systematically a number of them, and on February 28 of this year dissected a Striped marlin, *Makaira* (*Tetrapturus*) *mitsukurii*, Jordan and Snyder, weighing 238 lb., which contained well-filled, firm ovaries measuring approximately 37 cm. in length and 5·5 cm. in diameter in the widest part. The ova were separate and measured 0·004 inches. On April 3, I examined the roes of another Striped marlin of similar proportions. These fish seemed to exhibit no outstanding sexual characteristics.

In the previous month, however (March 12), a Black marlin, *Makaira* (*Tetrapturus*) *mazara*, Jordan and Snyder, had been caught, of the roes of which I have samples. This fish, weighing 436 lb., had roes containing ova of about the same size as those previously mentioned, but departed from all Black marlin previously caught in that it possessed a black dorsal band extending downwards for about six inches, the remainder of the sides and belly being silvery. Black marlin usually seen in this locality are of a dark, blackish-purple colour, fading gradually to a white ventral line.

Cleopatra's Temple at Armant

THERE existed at Armant until the year 1861 an extremely interesting temple built by Cleopatra the Great in honour of the birth of her son Caesarion. This was completely demolished between the years 1861 and 1863 and the materials were taken and used in the construction of a sugar factory; but, prior to that date, it had been visited and described by many travellers and fortunately, a number of drawings, plans and photographs of it were taken by them. We are engaged upon a reconstruction of this temple for publication and we should be very grateful for any help which readers of NATURE may be able to give us to make this as complete as possible. Any information about unpublished descriptions, plans, drawings or photographs of it would be of the greatest value.

A large number of travellers toured this part of Egypt in the eighteenth and nineteenth centuries, when the diary habit was strong, the standard of draughtsmanship high, and towards the end of the temple's existence, photography was just becoming popular. We believe that there may well remain important records in private collections which would be of great assistance in making some restitution for the vandalism of the last century.

ROBERT MOND.
OLIVER H. MYERS.

Points from Foregoing Letters

DR. U. R. EVANS illustrates an experimental arrangement which enables him to investigate the electric currents flowing over an iron surface in contact with bicarbonate solution during the process of rusting. The results obtained show intense anodic action immediately around a scratch where rusting is rapid, while the cathodic areas are free from attack.

Measurements by Dr. W. V. Mayneord and J. E. Roberts of the absorption of short wave-length X-rays (59 X.U.) indicate for elements of low atomic weight good agreement with the theoretical predictions of Klein and Nishina. For heavier elements the photo-electric absorption per atom is proportional to the fourth power of the atomic number. Owing to its large electronic content per unit mass, hydrogen has a larger absorption coefficient than other light elements. Deuterium proves, however, to be, from this point of view, the 'normal' light element.

A new technique for obtaining X-ray powder photographs from flat specimens is described by R. A. Stephen and R. J. Barnes. The principle also finds an application in obtaining an intense beam of monochromatic polarised X-rays.

Khastgir, Chandhuri and Sen Gupta have recently confirmed the negative attenuation of wireless waves, first described by Ratcliffe and Barnett. J. A. Ratcliffe and F. W. G. White point out, however, that upon further investigation they have found that the original results were due to the use of a Moullin volt-meter, which vitiated the experiments. They inquire, therefore, whether the results obtained by the Indian experimenters may not be similarly explained, and further suggest that more points might suitably be obtained by them on the rising part of the curve.

Dr. J. Weiss directs attention to a possible analogy between the reversible photochemical reaction involved in the bleaching of dyestuffs such as methylene blue by visible light in the presence of ferrous ions, and processes taking place in the retina; also between the production of hydrogen under the same conditions, atoms from water (in spite of the high energy needed) and the assimilatory process in green plants. In addition to these *sensitised* reactions in which the potential and binding energy of the heavy particles play a part, J. Weiss states that he has detected the *unsensitised* photochemical process by irradiating an acid solution of ferrous sulphate with ultra-violet light from a mercury lamp.

By placing a solution of the optically active and strongly polar compound 2-*l*-menthyl-3-nitro-hydrogen phthalate in benzene or toluene, in an electric field, Prof. J. Kunz and A. McLean have observed changes in the optical rotatory power. The change in rotation reaches a maximum when the strength of the field is 4,000 absolute units, which distinguishes the phenomenon from the Kerr effect. The authors ascribe the effect to the electric moment induced in a solvent by the electric field. Anomalous effects were observed with 2-ethyl-3-nitrohydrogen phthalate.

Taking advantage of the fact that ultra-violet light of wave-length 2537 excites and oxidises mercury atoms of mass 200 and 202 but not those of mass 198, 199, 201 and 204, Dr. K. Zuber has succeeded in producing a partial separation of ordinary mercury into fractions richer in those two groups of isotopes. The presence of nitrogen assists in their separation.

The structure of the fourth positive group of bands in the spectrum of carbon monoxide provides, according to F. Brons, definite confirmation that the dissociation energy of carbon monoxide is 8·41 volts, as has previously been suggested by Coster and Brons.

The amount of ascorbic acid (vitamin C) found in Darjeeling cabbage after boiling for ten minutes is greater (as in the case of other vegetables) than the amount obtained by extraction in the cold with 20 per cent trichloracetic acid. This, B. Ahmad considers, supports the view of McHenry and Graham, who ascribe the increase to the setting free of ascorbic acid from an ester compound, as against van Eekelen's opinion that the increase is only apparent and is due to the destruction of an oxidase ferment.

Research Items

Archæology in Australia

MR. D. S. DAVIDSON, who from April until July, 1930, was engaged in archæological reconnaissance in the Katherine River–Victoria River region of North Australia for the Museum of the University of Pennsylvania, points out in a discussion of the problems to which his investigations have given rise (*J. Roy. Anthrop. Inst.*, **55**, pt. 1) that very few serious attempts at excavation have been made, the few of any importance being those sponsored by the South Australian Museum. The absence of pottery and the nomadic habits of the aborigines make the location of a site a matter of difficulty, but the desert areas offer compensation in the preservation of objects perishable elsewhere. The use of caves in the wet season and of rock-shelters has provided material for investigation, but the aboriginal practice of burying implements and personal belongings for safe-keeping is a disturbing factor in stratigraphic study. Of the caves examined, some were still in occupation. It was not possible to estimate the antiquity of the material found. Natives must have inhabited the area for thousands of years, but the cave deposits give the impression that they might have been built up in a few centuries. The classes of objects found were not numerous. One of the problems of the future will be to distinguish important localised types. A tentative classification suggests that the 'pirioid' type of adze point appears to antedate the use of quartzite spear-heads, while these quartzite spear-heads quite definitely antedate the type of blade which is a product of the pressure flaking technique. This appears to be a fairly recent product as its use is only now spreading to north and central Australia, among the tribesmen of which the technique appears to have been unknown previously, while the former, the quartzite spear-head still in use, is the only one of the two occurring archæologically.

Serbian Gypsy Cult of the Anvil

DR. ALEXANDER PETROVIČ, in continuation of his study of the gypsies of Serbia and Bosnia, has described their cult of the anvil (*J. Gypsy Lore Soc.*, Ser. 3, **14**, Pt. 4). The gypsies of Rogatica make their own anvils, buying good iron or steel. Prayer precedes the making; and when the anvil is made it is wrapped in rags and brought into the tent where none may see it, until the appointed day, when the maker gives a feast and a sheep or hen is slaughtered. The anvil is exhibited after dinner, surmounted by three lighted candles, of which one has been saved from the preceding feast of St. Elias. After prayer, the anvil is struck for the first time with a hammer, and those present offer gifts of coin, gold if possible, with exclamatory wishes of good luck. During the rest of the day, neighbours come in to look at the anvil and make similar gifts. In olden times payment for any work done was not given to the smith, but placed on the anvil. On St. George's Day it is decorated with young boughs; and on St. Elias's Day and New Year's Day a lighted candle is stuck in the hole, again with an expression of good luck. When a young boy was apprenticed one of his fingers was placed on the anvil and struck three times with the hammer. The anvil was definitely regarded as sacred. An old anvil is never thrown away, but kept in the house "like an old man or an old woman". In cases of theft, suspected persons swear their innocence by the anvil, which is set up in the yard in front of the house of the injured party, surmounted by a lighted candle, some salt and a piece of bread. At Mirijevo, near Belgrade, an axe takes the place of the anvil. As sacred, the anvil and everything connected with the forge were believed to have healing powers. The water in the tub by the anvil, in which the heated iron is plunged, is holy and is given as medicine to both cattle and human beings. A similar cult and oath are found among other gypsies in connexion with the fiddle and money. It is thus evident that the Serbian gypsies venerate and regard as holy that by which they earn their living.

Noise and Efficiency in Works

REPORT No. 70 of the Industrial Health Research Board ("Conditions of Noise", by H. C. Weston and S. Adams) describes an experiment that has been made to test the effect of continual noise upon the efficiency of weavers. Noise is first defined as unpleasant or disturbing sound, such as obtains in the weaving sheds. Two groups, of the same efficiency, worked first for six months and then for a year in the same conditions and with the same materials. One group, of ten men, was exposed to the usual noise. The other, also containing ten men, was given ear-defenders which reduced the intensity of noise by 15 decibels or half the apparent loudness. At first the increased personal efficiency in the protected group was considerable. It became less so afterwards, but the average increase remained as high as 7½ per cent in the latter part of the experimental period. A similar experiment in 1932 rated the increase at 12 per cent, but possibly the conditions were more favourable. The workers liked wearing the ear-defenders, and even those accustomed to the noise and immune from its effects in respect of irritability and distraction were increased in efficiency. It is impossible, however, to infer from this experiment the value of decreased noise in cases where the work is different and the initial noise less.

Japanese Bopyrids

S. M. SHIINO describes a large number of Bopyrids in two papers, Bopyrids from Tanabe Bay (1 and 2) (*Mem. Coll. Sci., Kyoto Imp. Univ., B*, **8**, No. 3, 1933 and **9**, No. 4, 1934). Twenty-eight species are described, eighteen of which are new. It is a most interesting collection and several peculiar features are pointed out. Of the branchial parasites, a large number inhabit hermit crabs, but several other groups are parasitised, including two *Pencæopsis* and a *Solenocera*. The abdominal parasites are not so numerous. *Bopyrina giardi* Bonnier is recorded from *Hippolyte* sp., its general constitution being largely in accord with the characters given by Bonnier for the European form, but there are certain differences, notably that of the male cephalon being fused with the first thoracic segment in those from Japan, whilst it is separate in those from Europe, and anal spines are present in the latter, absent in the former. Four females, each carrying a male, were found in

the branchial cavity of one *Hippolyte*. The male has a coloured pattern on both dorsal and ventral surfaces. A common species inhabiting the left branchial cavity of the hermit-crab *Clibanarius bimaculatus* is a new species of *Pseudione*, *P. clibaricola*. It never occurs in the right cavity, which is sometimes occupied by another type of Bopyrid, also a new species, *Pseudione asymmetrica*, and this is never found on the left side. Sometimes both species are found in the same individual.

Movements of Copepods

THE importance of copepods in the ecology of fresh- and salt-waters is well established, but little is known of the actual mechanism of their swimming movements or of their methods of feeding. A recent paper by A. G. Lowndes ("The Swimming and Feeding of certain Calanoid Copepods". *Proc. Zool. Soc. London*, Part 3, 687–715; 1935) is therefore especially welcome. By a variety of methods, including the polygraph process and ultra-rapid photography with exposures up to 1/30,000 of a second, the movements of the appendages were examined in seven of the commoner marine species and three species of fresh-water copepods. Much evidence is brought forward to show that feeding cannot be regarded as purely automatic or non-selective. In this connexion the observation that *Diaptomus gracilis* caught in a pool, the waters of which were green with unicellular algæ, had been feeding on desmids on the bottom is of special interest. In this paper the author supports the theory that the Centropagina are a more primitive group of copepods than the Calanina. The theory is favoured partly on the grounds that their predatory method of feeding can be regarded as more primitive than the more highly specialised filter feeding. All observations were made with the animals living free in a large body of water approximating so far as possible to their natural environment. Much information is given on the rate of movement of limbs and the actions of the animal. It cannot be too strongly stressed that observations of this nature should prove invaluable in the elucidation of the habits and migrations of copepods as shown by field collections.

Growth Records on Fruit Trees

ONE of the difficulties encountered in pomological research is the amount of time and labour involved in the collection and recording of large numbers of data relative to the growth and fruit production of apple trees. A census method which reduces to a minimum the labour of recording summer growth has been developed by M. C. Vyvyan at the East Malling Research Station (*J. Pomol. and Hort. Sci.*, 13, 202; 1935). Various well-defined growth structures on the tree are classified into categories such as bearing or non-bearing, short or long, growing or non-growing, etc., each of which is denoted by a letter of the alphabet as a distinguishing symbol. The recorder examines each growth from the apex to the base of the tree or sample branch and calls out the corresponding symbols in order. These are then recorded and the numbers in each category counted simultaneously by the use of an ingenious combination of typewriter and reset counters. The result is a typewritten map of the whole tree forming a permanent record of the various growths and their positions, and this can be expanded at successive periods as growth proceeds.

Prediction of Rubber Yield

ONE of the chief problems confronting the rubber research worker is the length of time needed before reliable results as to the yield capacity of the plant can be obtained. The tapping test that is usually employed, conclusive as it is, is only applicable when the latex system is sufficiently developed, that is, a period of seven or more years has to elapse before comparative tests and selection of clones can be carried out. Genetical work is in consequence seriously hampered. A new method, however, has recently been evolved by H. Gunnery (*J. Rubber Res. Inst.*, 6; 1935), by which the yield can be accurately predicted at an early stage in the life-history of the plant. A detailed study of the anatomical structure showed that two distinct types of sieve tubes occur, one of small, the other of large diameter. The latter are invariably associated with latex vessels of wide bore, that is, occur in trees of high-yielding capacity, while the small type of sieve tube is found in low-yielding trees in conjunction with small bore latex vessels. Further, the type of sieve tube is constant in all parts of the plant and at all ages. By means of qualitative analyses of the phloem of young *Hevea* seedlings, therefore, low-yielding individuals may be eliminated at a very early stage, and much valuable time saved in all work of a selective nature.

Glacial Geology of Yorkshire

IN "The Glacial Geology of Holderness and the Vale of York" (published by the author, 61 Carr Lane, Acomb, York, 1935, price 4*s.*; cloth 5*s.*), Mr. Sidney Melmore gives a scholarly and conscientious review of the glacial problems in an important area. The boulder clays, buried cliff and raised beaches of Holderness, the Speeton shell-bed, the Kelsey Hill deposits (with list of fauna), the moraines and drift and high-level flanking deposits of the Vale of York, the Kirkdale bone cave, the Leeds hippopotamus, the relation between rivers and joints in the country rock, and many other topics of interest are treated from a historical point of view. The author's method of approach gives full credit to the achievements of the pioneers, Sedgwick, Buckland, Phillips, Prestwich, and to other workers such as Dakyns, Reid, Lamplugh. His quotations at the chapter headings alone would form an interesting short history of the progress of investigation. The division of the matter into numerous small chapters makes for freshness and easy reference; and the two dozen maps and diagrams are all that could be desired.

Effect of the Moon on Barometric Pressure

"THE Lunar Atmospheric Pressure Inequalities at Glasgow", by R. A. Robb and T. R. Tannahill (*Proc. Roy. Soc. Edinburgh*, 4, Part 1, No. 9), is a paper dealing with the effect of the moon on barometric pressure at Glasgow Observatory deduced from an analysis of a record, extending from 1868 to 1912, of hourly values of atmospheric pressure recorded photographically, and checked by daily control readings of a standard barometer at 10h, 12h, 14h, 18h and 22h G.M.T. A rough examination of these records had shown a strong diurnal variation, an effect at variance with determinations of the harmonic coefficients at other places made by Chapman, who found the semi-diurnal coefficient to be the chief one, giving an amplitude of 0·012 at Greenwich, 0·083 at

Batavia and 0·060 at Hong-Kong. In order to reduce accidental variations, Robb and Tannahill rejected all days on which the difference between the pressure at two successive upper transits of the moon exceeded 0·1 inches of mercury. Nine groups of observations were obtained by dividing the 45 years into three equal periods, into three seasonal groups—winter (Nov.-Feb.), equinoctial (March, April, Sept. and Oct.) and summer (May–Aug.), and three groups for which at the initial lunar upper transit the lunar semi-diameter was equal to or less than 14·99′, 15′–15·99′ and equal to or greater than 16·00′. The hourly inequalities for these groups and for the total data were corrected for any known variations with solar time that might, owing to the selection of data, have been only partially eliminated. The harmonic analysis of the corrected hourly inequalities gave for the whole period the following values for the first three Fourier terms:

$$0{\cdot}0640 \sin(\theta + 267°) + 0{\cdot}0156 \sin(2\theta + 285°) + 0{\cdot}0089 \sin(3\theta + 292°),$$

where the amplitude is in millibars and θ is reckoned from upper lunar transit. Estimates of the probable errors of the coefficients appeared to establish the reality of the first two, and the preponderance of the diurnal over the semi-diurnal variation at Glasgow accordingly appears to be a real phenomenon, for which no satisfactory explanation is offered.

Dielectric Constants of Liquids at Radio Frequencies

IN a paper published in *Hochfrequenztechnik und Elektroakustik* (46, 92; 1935), Dr. D. Doborzynski describes a somewhat novel method of determining the dielectric constant of non-conducting liquids at radio frequencies. The innovation consists in making use of the carrier waves of known frequencies received from broadcasting stations in place of a local source of oscillations. A tuned receiving circuit is set up with a main variable condenser in parallel with another variable condenser of small capacitance. For a fixed setting of the main condenser, the four frequencies required are those corresponding to the maximum and minimum settings of the small condenser, first with this in air, and next with it immersed in the liquid under examination. These frequencies are determined by simple interpolation over a small portion of the scale of the main condenser. Since it is known that, at the present time, most broadcasting stations attain a frequency constancy of an order better than 3 parts in 10^4, it is considered that in the neighbourhood of 1,000 kc./sec., the above four frequencies can be determined to within ± 0·25 kc./sec., resulting in an overall accuracy of the dielectric constant determination of better than one per cent. The method has been applied to the measurement of the dielectric constant of benzol and nitrobenzol at 20° C., the values obtained being 2·29 and 34·5 respectively. The possibility of extending the method to conducting liquids is now being explored.

Radioactivity of Actinium

ALTHOUGH actinium was discovered in 1899 by Debierne and has been much studied since, all attempts to find any effect due to the radiation from actinium itself have so far failed. The fact that the direct descendant of actinium is radioactinium, an isotope of thorium, indicates that a β-particle must be emitted in the disintegration of actinium, and since this has not been discovered experimentally it has been assumed that it is emitted with very low energy. The discovery by Sargent in 1933 of the relation between the decay constants of β-emitters and the upper limits of their energy spectra made the behaviour of the actinium β-particle seem anomalous. The modification of the tube counter devised by Libby, in which a screen is substituted for the usual solid wall, makes it possible to detect electrons of very low energy, and D. E. Hull, W. F. Libby and W. M. Latimer (*J. Amer. Chem. Soc.*, **57**, 1649; 1935) have in this way detected the β-radiation of actinium. The radiation is half-absorbed in 0·0023 gm./sq. cm. of aluminium and is easily deflected in a magnetic field. The maximum energy of the β-particles is about 220,000 electron-volts, which fits well on the lower Sargent curve. The paper contains full details of the chemical methods of purification of the actinium, the most difficult problem being the removal of radioactinium. Co-precipitation with thorium perhydroxide was the method finally adopted. The radiation was identified as due to actinium itself by the excellent agreement between the theoretical and experimental growth curves.

Thermal Data for Purine Derivatives

THE importance of the thermal data for purine derivatives in biochemistry is recognised, so that some recent accurate determinations in this field are of interest. R. D. Stiehler and H. M. Huffman (*J. Amer. Chem. Soc.*, 57, 1734; 1935) have measured the heats of combustion and heat capacities of adenine, hypoxanthine, guanine, xanthine, uric acid, allantoin and alloxan, and from the results have calculated the heats of formation, entropies and free energies. All the compounds except adenine had been previously burned by earlier workers, and discrepancies of 0·1–2 per cent with the older data are found. The measurements were made with the best modern technique and the results may be summarised as follows. The free energy values are believed to be accurate to 300–600 gm. cal. The data are at 298·1° Abs. The heats of combustion, in k.cal., are at constant pressure and the water liquid, per mole.

	Heat of combustion	Free energy Δ F.° (in gm. cal.)
Adenine	663·74	70,420
Hypoxanthine	580·20	17,250
Guanine	596·89	10,220
Xanthine	516·02	− 40,730
Uric acid	458·84	− 91,460
Allantoin	409·55	− 107,470
Alloxan	273·58	− 182,880

When the free energies are compared, some interesting facts are brought out. In going from adenine to hypoxanthine and from guanine to xanthine, both of which involve the same type of deamination in different parts of the six-membered ring, decreases of 53,170 and 50,950 gm. cal., respectively, are observed. In the changes adenine to guanine and hypoxanthine to xanthine to uric acid, all of which reactions involve the addition of an oxygen atom and a shift of a hydrogen with the corresponding opening of a double bond, the free energy decreases are, respectively, 60,200 gm. cal., 57,980 gm. cal. and 50,730 gm. cal. These changes indicate that, in the crystal at least, the bond energies are distinctly affected by their positions in the compounds.

British Medical Association

Annual Meeting at Melbourne

THE one hundred and third annual meeting of the British Medical Association was held in Melbourne, Australia, during the week commencing September 9, under the presidency of Sir James Barrett of Melbourne. This is the first occasion on which the Association has met in Australia. In spite of its remoteness from the Old World, the meeting was one of the largest, if not actually the largest, in the history of the Association. The total number of registered attending members was nearly 1,500; and there were more than 300 overseas visitors. Of the many distinguished visitors from Great Britain may be mentioned Lord Horder, Sir James Purves-Stewart, Sir Thomas Dunhill, Sir Ewen Maclean, Sir William Willcox, Sir Henry Gauvain, Prof. Edwin Bramwell, Prof. Hey Groves, Prof. A. M. Drennan, Mr. H. S. Souttar, Dr. J. S. Fairbairn, Dr. Robert Hutchison, Dr. S. Watson Smith (the retiring president), Dr. E. Kaye le Fleming and Dr. E. W. Fish. Members of the Association from South Africa, Egypt, India, Ceylon, Canada, New Zealand, Holland, China and Japan were present.

The adjourned annual general meeting took place on September 10 in the Town Hall, in the presence of Their Excellencies the Governor General of the Commonwealth, Sir Isaac Isaacs, and Lady Isaacs, and His Excellency the Governor of Victoria, Lord Huntingfield, and Lady Huntingfield. The principal events of the meeting were—an opening address by Sir Isaac Isaacs; induction of the new president, Sir James Barrett, who delivered his presidential address on the subject of hospital policy in Australia; the transmission to His Majesty the King of a message of loyalty from the Association, to which a reply was received before the meeting ended; and presentation of the flag of the City of Melbourne to the Association by the Lord Mayor.

A meeting of the Royal Australasian College of Surgeons took place on September 12, under the presidency of Mr. R. B. Wade. Honorary fellowships were conferred on Prof. Hey Groves and Mr. H. S. Souttar; and Prof. Hey Groves delivered the first Hamilton Russell Memorial Oration, entitled "The Romance of Surgery".

Before describing the discussions of the scientific sections, it is appropriate to mention the 'museum' which was housed in the University Anatomy School. The remarkably comprehensive and beautifully displayed collection was assembled specially for the occasion by a committee of which Prof. F. Wood Jones was chairman and Dr. E. S. J. King secretary. The exhibits embraced almost the entire range of human pathology as well as certain aspects of anthropology, parasitology, radiology and public health. Many of the exhibits were designed to form an illustrative accompaniment to some of the sectional discussions. On four mornings during the week, demonstrations of special subjects in the museum were given by the exhibitors.

The Section of Medicine, presided over by Lord Horder, discussed obesity, anæmia, and, on the third day in conjunction with the Section of Surgery, thyreotoxicosis. Other subjects dealt with in occasional papers were diabetic gangrene, hæmolytic jaundice and gallop rhythm of the heart. The most interesting discussion was that on thyreotoxicosis along with the surgeons, a meeting which had an attendance of nearly six hundred, easily a record for a sectional meeting. Lord Horder and Sir Thomas Dunhill opened the discussion. The principal point emerging, and one which was particularly stressed by Lord Horder, was that the pathogenesis of thyreotoxicosis is still unknown, and that the beneficial results of thyroidectomy do not necessarily justify the conclusion that the condition is one of primary thyroid dysfunction.

The Section of Surgery, with Sir Thomas Dunhill as president, discussed hydatid disease, the surgery of the pancreas, prostatectomy, cancer of the colon, and, along with the Section of Medicine, thyreotoxicosis. Apart from the last, the most notable debate was that on hydatid disease, opened by Prof. H. R. Dew. Almost all aspects of this subject were embraced in the course of the discussion; which was well supplemented by the excellent collection of specimens of hydatid lesions and the life-history of *Tænia echinococcus* which were available for study in the special museum already described.

The Section of Obstetrics and Gynæcology, under the presidency of Dr. J. S. Fairbairn, discussed Cæsarean section, placenta prævia, the late toxæmias of pregnancy, and the remote results of puerperal sepsis. With respect to Cæsarean section, there was a decided opinion, voiced particularly by Dr. J. Bright Banister, that this operation was often too lightly undertaken without adequate reason, and that there was need of careful formulation of the indications justifying the operation.

The Section of Radiology and Radio-Therapeutics, with Mr. H. M. Moran presiding, discussed radiation treatment of cancer of the breast and of cancer of the tongue, radiological diagnosis of diseases of the lung, diagnosis of bone tumours, radiological education and skiagraphic examination of the stomach and duodenum. The work of the section was well supplemented and enhanced in value by a series of skiagrams illustrating the several subjects, which were displayed in the museum. The discussion on the diagnosis of bone tumours, opened by Dr. H. R. Sear, was of particular interest, as it emphasised the importance of recognising various types of metastatic tumours which might simulate primary tumours of bones.

The Section of Diseases of Children, with Dr. Robert Hutchison as president, discussed hare lip, infant feeding, pink disease and intussusception. The discussion on pink disease, opened by Drs. A. J. and I. J. Wood, provided a very complete epitome of existing knowledge of this illness, the pathogenesis of which is, however, still unknown.

The Section of Neurology and Psychological Medicine was presided over by Prof. Edwin Bramwell. Its first session was devoted to a consideration of the diagnosis, prognosis and treatment of brain tumours fifty years ago, and now. Prof. Bramwell's opening paper on this topic provided an excellent

survey of the growth of our clinical knowledge of brain tumours. Advance has come principally through the use of special methods of clinical investigation, from the introduction of the ophthalmoscope up to our present-day use of such methods as ventriculography and encephalography. The second session of the section discussed the psychoses of adolescence, and the malarial treatment of neurosyphilis, the latter subject being illustrated by exhibits in the museum.

The Section of Ophthalmology, under the presidency of Dr. A. J. Ballantyne, discussed glaucoma, false binocular projection and abnormal retinal correspondence, idiopathic cyclitis and several minor subjects. On all the topics, the discussions were of considerable interest, and contained original work or ideas.

The Section of Orthopædics, presided over by Prof. Hey Groves, discussed fractures of the neck of the femur, osteoarthritis of the hip and knee, fractures of the spine, and the role of physiotherapy in orthopædic practice.

The Section of Oto-Rhino-Laryngology, under Mr. F. Muecke, considered maxillary and nasal sinusitis, chronic suppurative otitis media, sphenoidal sinusitis in relation to the pituitary gland and actinotherapy in laryngeal tuberculosis.

The Section of Pathology and Bacteriology was presided over by Prof. A. M. Drennan. At its first session various aspects of pathological calcification and bone disease were discussed, the principal paper being one on the pathology of osseous tissue by Prof. Drennan. A paper on leukæmic infiltrations was read by Prof. J. B. Cleland; and one on the neural components of teratomata, by Dr. R. A. Willis, this being amplified by photographs and maps exhibited in the museum. The second meeting of the section was largely devoted to bacteriology. A discussion on anærobes in disease was opened by Prof. H. A. Woodruff with an informative paper on anærobic infections in animals; and Dr. F. M. Burnet introduced a discussion on virus diseases, stressing the frequent occurrence of mild, but immunising, attacks of these and other infections. A new method of hæmoglobin estimation, based on the formation of globin picrate, was described by Dr. Bolliger.

The Section of Pharmacology, Therapeutics and Anæsthesia, under the presidency of Sir William Willcox, discussed hypnotic drugs, urinary antiseptics, premedication and basal narcosis, gas anæsthesia, and spinal anæsthesia; and Prof. W. A. Osborne contributed a paper on a vaso-constrictor principle in the frog's skin.

The Section of Public Medicine, under Sir Henry Gauvain as president, dealt with tuberculosis, industrial and tropical medicine, and racial problems. At its first meeting the subject of pleural effusion in artificial pneumothorax was introduced by an informative paper by Dr. D. B. Rosenthal; and Mr. M. P. Susman opened a discussion on tuberculous empyæma. At the second meeting of the section, which was combined with the Section of Medical Sociology, the principal subject was racial pressure problems in Australia and its neighbourhood, opened by Sir R. W. Cilento.

The Section of Medical Sociology, with Dr. E. Kaye le Fleming as president, discussed the Australian medical aerial services, the social aims of mental hygiene, and along with the Section of Public Medicine, racial pressure problems opened by Sir Raphael Cilento. Sir James Barrett spoke of the difficulties of agricultural and pastoral activity in the Northern Territory, pointing out that on parts of the south coast of Java, which has a population of forty million people, areas resembling northern Australia are reported to be practically empty, and that for successful agriculture a rainfall of at least ten inches in the dry season is essential. Sir James Barrett then quoted an article by Mr. Wynne Williams, from the last number of the *Economic Record*, to the effect that apart from Queensland, Northern Australia is economically incapable of carrying a large population of any race. The difficulty is not physiological but entirely economic.

The Section of Dermatology was presided over by Dr. S. Watson Smith. The principal subject for discussion was the incidence of skin diseases in Australia, opened by Dr. Herman Lawrence. A main point brought out was the exceptionally high incidence in Australia of keratosis, rodent ulcer and epithelioma—called by Dr. Lawrence the "epithelial triad" and attributed by him largely to sunlight. An account of staphylococcal skin infections by Dr. Ivan Connor indicated the value of treatment by toxoids. Dr. J. C. Belisario contributed a paper on fungus infections.

Lumière and the Invention of Cinematography

A BRILLIANT gathering took place on the evening of November 6 at the Sorbonne, in honour of M. Louis Lumière, father of the cinema and of many other inventions in the field of photography.

The great hall of the University of Paris was resplendent with high officials, including the French President, M. Lebrun, the Diplomatic Corps, distinguished academicians and representatives of numerous scientific and industrial organisations.

M. Mario Roustan, Minister of Education, presided, and speakers vied with each other in paying tribute to the qualities which have enabled M. Lumière to devote half a century of an active and fruitful life to promote applied science.

M. Armbruster, president of the Renaissance Française, who took the initiative in organising the celebrations, supplied a historical outline. He mentioned how Lumière, son of a photographer, of Besançon, developed with his brother a successful manufacturing photographic plant at Lyons, which became known throughout the world. He recalled the first public presentation, on December 28, 1895, of moving pictures in the basement of a Paris café, at 14 bd. des Capucines, amidst much scepticism and sarcasm—which, however, did not prevent the rapid success and growth of the enterprise.

M. Ch. Fabry, the distinguished physicist, spoke of the numerous applications of Lumière's work. M. Ch. Delac quoted figures to show the great

economic importance of the cinema industry. M. Georges Lecomte, the well-known writer, enlarged upon the aesthetic value of the cinematographic art.

Sir Robert Mond, dean of the distinguished foreign delegates present, outlined the historical development of the photography of movement, and expressed the high regard in which Louis Lumière is held throughout the world.

Historically, for the beginning of cinematography, one may go back to the animated drawings devised by the Belgian physicist Antoine Plateau in 1830, which were used in the phenakitiscope. Improved by Clerk Maxwell in 1869 and enlarged by the American, Horner, the apparatus became known as the zoetrope. Molteni, in 1850, had his choreutoscope, consisting of a glass disc on which six different positions of a moving object were drawn, so that on turning the disc the appearance of movement was produced. In 1893 Edison devised his kinetoscope, consisting of an endless film about 20 metres long, moving at such a rate that 45 images were presented per second. It had the drawback of being visible to only one person at a time.

On the photographic side, we find the American Muybridge in 1872 utilising a series of thirty cameras to photograph a galloping horse. The astronomer Janssen devised a photographic revolver in which a circular photographic plate turns round, so that 48 pictures can be taken in 62 seconds; the physiologist Jules Marey developed his chronophotograph and M. Demeny his phonoscope.

All these separate inventions and improvements do not, however, detract from the great merit of Louis Lumière, that of having devised an apparatus which will both photograph an object in motion and reproduce it afterwards upon a screen so as to give the impression of movement, in the form in which we see it to-day.

The invention of the moving picture apparatus, though the most spectacular of Lumière's inventions, forms but part of his numerous activities. In 1899 he made an apparatus for taking 'rotary' photographs, so as to be able to make a complete tour of the horizon. In 1901 he devised a 'photoramic' method of projection, and in 1907, after numerous trials, he perfected the Lumière method of colour photography still used throughout the world.

During the War, Lumière had to divert his inventive genius in other directions. He devised a method of heating the cockpit of aeroplanes, and he improved artificial limbs for mutilated soldiers. To-day, at the age of seventy-one years, we find him still active in research and invention. Recently he gave before the Academy of Sciences an exhibition of stereoscopic cinematography. At his villa at Neuilly-sur-Seine, M. Lumière has installed several laboratories that enable him to carry out his investigations in cinematography and related matters.

No account of Louis Lumière would be complete without mention of his brother Auguste, by two years his senior, who has been a constant collaborator, though specialising in the fields of chemistry and biology. The original patent for a cinema apparatus in 1895 was, in fact, taken in the joint names of Auguste and Louis Lumière, but the elder brother has made it clear that in this particular case the originator of the idea was Louis. Both brothers are members of the Paris Academy of Sciences, and have received numerous honours from scientific bodies in France and elsewhere.

Human Genetics and Human Ideals*

TWO widely held opinions on human genetics may be summarised as follows: (1) It is essential in the interests of national hygiene that the unfit should be sterilised; (2) some races are superior to others, the members of which cannot rise to the highest levels possible to humanity.

Both theories are largely based on analogical reasoning from the breeding of domestic animals. Although the laws of heredity are the same in men as in other mammals, the analogy is suspect because our domestic animals are far more genetically homogeneous than any human groups, having been established by intense inbreeding and selection. We must, therefore, examine the evidence for these propositions in detail.

Abnormalities and Sterilisation

Human abnormalities which are genetically determined fall into five main classes:

(1) Those due to autosomal dominant genes, which determine the abnormality in all cases; for example, lobster claw, cleidocranial dysostosis. Here the abnormality is handed down only by affected persons, and to about half their children, regardless of sex.

(2) Those due to autosomal genes with manifestation in some, but not all cases. For example, blue sclerotics are due to a dominant gene with 100 per cent manifestation. A fraction of the patients develop bone fragility, deafness due to otosclerosis, or both. Huntingdon's chorea, due to a dominant gene, may not develop until the age of seventy years, though the average age is thirty-five. Such abnormalities run in a family, are handed down to less than half the progeny of affected persons, and often skip a generation.

(3) Those due to sex-linked genes. These are often manifested wholly, or almost wholly, in males and transmitted by females, for example, hæmophilia. But they may be incompletely recessive in heterozygous females, and affect a proportion of them, as with Leber's disease (atrophy of the optic nerve).

(4) Those due to autosomal recessive genes. These are not hereditary in the ordinary sense. They are very rarely handed down from ancestor to offspring, but occur in one or more children of a pair, both of whom are heterozygous. They are very much more frequent in the offspring of parents who are related to one another, for example, of first cousins, than in the general population. They include amaurotic

* Substance of a Sir Halley Stewart Trust Lecture delivered by Prof. J. B. S. Haldane, F.R.S., in the Memorial Hall, Farringdon Street, London, on November 5.

idiocy, some kinds of deaf mutism, and xeroderma pigmentosum, a skin affection two thirds of the victims of which die of cancer in less than fifteen years.

(5) Those due to the co-operation of many genes. It is highly probable that many of the milder forms of mental defect are of this kind, but the analysis is still incomplete.

No far-reaching eugenical programme can be framed until we know the relative frequencies of these five classes. They are not known at present.

Sterilisation of the unfit would be very effective against type 1, moderately so against types 2 and 3, slightly so against type 5, and wholly ineffective against type 4. Here the possible eugenic measures are the discouragement of inbreeding, and the termination of marriage, or at any rate breeding, in couples who have produced one defective child. In order to deal effectively with types 2 and 3 by sterilisation, it would be necessary to sterilise large numbers of fit persons. It is doubtful whether the sterilisation of all mental defectives would reduce the number in the next generation by as much as 15 per cent.

In all cases, other measures than sterilisation are available, for example, continence and birth control for mentally normal persons, and segregation for defectives.

RACIAL COMPARISONS

When we say that race *A* is superior to race *B* in a given respect, we may mean one of five things :

(*a*) Members of race *A* have had a better chance than those of race *B* of displaying the character in question. For example, the pre-Columbian inhabitants of America were severely handicapped in their progress to civilisation by the lack of domesticable animals.

(*b*) All members of race *A* are superior to all members of race *B*. No case of this kind is known.

(*c*) No member of race *B* can possibly reach the level attained by some members of race *A*. This may be true in some cases, but is certainly not scientifically proved.

(*d*) The median performance of race *A* is superior to that of race *B*. This is probably true with reservations. Thus it is likely that, in Europe, Europeans are more socially efficient than Negroes ; but the converse seems to be true in West Africa (the so-called white man's grave).

(*e*) Race *A* produces more exceptional individuals, for example, great musicians, than race *B*. This is also probably true in some cases, but as it may be due to greater variability, implies no superiority in the mass of the race.

It is emphasised that innate psychological characteristics of races overlap. Thus there is no evidence for an innate psychological characteristic found in all Negroes, but no Europeans. The so-called races of western Europe (Nordic, Alpine, Mediterranean, and so on) overlap in physical as well as psychological characteristics.

Our knowledge of the effects of human race-crossing is slight. In animals, such a cross may be advantageous in the first generation, but harmful in later generations, but there is no clear evidence as to whether this is true in man, though some facts seem to support this hypothesis.

Great caution is required in the application of our existing knowledge of human genetics, and far more extensive information is needed.

Educational Topics and Events

CAMBRIDGE.—On behalf of a body of subscribers, an offer of £540 has been made to the University to form a fund in memory of Dr. J. E. Marr, Woodwardian professor of geology. This fund is to be used to provide grants for the study of geology in the field.

The Council of the Senate recommends the approval of the plans for a new high-tension laboratory for the Cavendish Laboratory prepared by Mr. Charles Holden. The new laboratory will cost about £15,500.

OXFORD.—Henry Balfour has been granted the title of professor during his curatorship of the Pitt-Rivers Museum.

An exhibition to illustrate the work of Robert Hooke (1635–1704), in the Museum of the History of Science, will be opened by the Dean of Christ Church, on November 20, at 2.15.

The course of lectures on the scientific contributions of members of the Oxford Colleges has been continued by Dr. R. T. Gunther at New College and at All Souls. Although neither College was primarily endowed for the training of men of science, yet their early successes were remarkable. The physicians Bentley and Walter Bayley of New College, and Linacre, Warner, Bartlot, Recorde, Sydenham, Needham, Millington and Mayow of All Souls all achieved fame in various ways before a long period of quiescence in the eighteenth century. In the nineteenth century, the brothers Duncan of New College restored the Old Ashmolean as a zoological museum, while Acland of All Souls effected its removal to the new University Museum that he founded in the Parks. New College owns the house and observatory of Halley, Bradley and Bliss, and has attached to it the Savilian professorships of astronomy and geometry, which were held by Charles Pritchard, founder of the University Observatory, and H. H. Turner, who inaugurated the Seismological Department.

A COURSE of eight lectures on tropical hygiene for men and women outside the medical profession proceeding to the tropics will be given at the London School of Hygiene and Tropical Medicine, commencing on December 2. The lectures will be given by Lieut.-Colonel H. B. Newham, H. H. Clay and Sir Malcolm Watson. Further information can be obtained from the Organising Secretary, Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1.

ACCORDING to the recently issued report of the Commonwealth Fund Trustees, there were 150 applications for fellowships in 1935, and thirty-one appointments were made. These comprised twenty-four ordinary fellows, two Dominion fellows and five service fellows. The fellowships are offered to British subjects, and are tenable at certain American universities for two years. The same number is being offered for 1936. Women are not eligible for appointment. Further information may be obtained from the Secretary, Commonwealth Fund Fellowships, 35 Portman Square, London, W.1.

Science News a Century Ago

Auroral Display seen at Oxford

SOON after 8 p.m. on November 18, 1835, a vivid auroral display was witnessed near Oxford by the Rev. J. Guillemard, of St. John's College. A rapid succession of rays of light began to shoot up first in the east, and after vanishing there, appeared in nearly the same form in the west. When the display was over, a part of the sky filled with a faint silvery light diffused over a bank of clouds. (*Proceedings of the Ashmolean Society*, 9.)

The Duke of Sussex and the Royal Society

IN 1830, the Duke of Sussex accepted the presidency of the Royal Society in succession to Davies Gilbert; he held the office for eight years. On November 20, 1835, after the first autumn meeting of the Society, a correspondent, "F. R. S.", wrote to the editor of *The Times*: "On the recommencement of the annual session of the Royal Society, last night, it appeared that Mr. Lubbock had resigned his office of treasurer, for no other reason than the total want of co-operation in the objects and business of the society on the part of the Royal President, who on the alleged grounds of ill-health had not attended a single meeting of council. . . .

"Now, however, on the eve of the annual election, on St. Andrew's day, and according to the approved precedent of the last three or four years, a pathetic letter will be read to the general meeting, apologizing for past neglect, tendering a reluctant resignation, and in the hoped event of its non-acceptance, making large professions of improved conduct in the future.

"The shortness of the notice, and the utter unpreparedness of the society on the present occasion, preclude any other alternative than a sullen and indignant re-election and thus another blank session will accelerate the downward course of the society in scientific usefulness and consequent public estimation.

"It may not be too late in the course of the present session to avert so deplorable a result by some influential members taking measures for vindicating the paramount ascendency of science over rank, by making such a choice on a future election as shall atone for the original sin of not having placed a Herschell in the chair once occupied by a Newton and a Davy."

Trial of a Cornish Pumping Engine

A CENTURY ago, the pumping engines employed in the mines of Cornwall were among the finest of their kind. Quoting from the *Falmouth Packet*, the *Mechanics' Magazine* for November 21, 1835, said: "A steam-engine, lately erected on a copper mine in this neighbourhood [St. Austell], has been reported to have raised at an average rate of performance, upwards of ninety millions of pounds weight one foot high, with a bushel of coal. The correctness of this statement was questioned by rival engineers and others, and so seriously, that a challenge for a public trial was given and accepted. It took place last week, in presence of a number of most experienced mine agents from different parts of the country, and the result of twenty-four hours' trial was the unprecedented performance of lifting 125½ millions of pounds weight one foot high, with every bushel of coal consumed! The engine is of large size, the cylinder being 80 inches diameter. The principle is that of Boulton and Watt but improved in economising the heat when generated, so as in the greatest possible degree to apply it to the end of producing steam, and maintaining it until its work is performed. The engineer's name is West."

'Luminous' Appearance of *Oenothera*

DR. BUCKLAND discoursed in the Old Ashmolean Museum at Oxford on November 22, 1835, on the 'luminous' appearance of the flowers of *Oenothera*. It continued uninterruptedly for a considerable length of time; it did not appear to resemble any electric effect; and the opinion which seemed most probable was, that the plant has a power of absorbing light, and giving it out in peculiar circumstances. (*Proceedings of the Ashmolean Society*, 9.)

Societies and Academies

LONDON

Royal Society, November 7. F. W. G. WHITE and L. W. BROWN: Some measurements of the reflection coefficient of the ionosphere for wireless waves. The Breit and Tuve technique for ionospheric investigation is employed, the sender-receiver system being calibrated so that the reflection coefficient may be determined for a wave of any frequency within the range 2·80–6·50 Mc/s, from the relative amplitudes of the direct and the singly reflected atmospheric waves. Examples of measurements, made at noon during the period November 1934–May 1935, show that the total absorption suffered by the waves is very much dependent upon the critical phenomena at the transition of reflection from one region to another. The influence of the absorbing regions is estimated from the results. Estimates, based upon Appleton's theoretical formula, of the collisional frequency of the electrons with gas molecules in the F_2 ionised region of the upper atmosphere, are made. The collisional frequency is of the order 5×10^3 per second at a height of approximately 250 km. above the surface of the earth. J. P. GOTT: The electric charge collected by water-drops falling through a cloud of electrically charged particles in a vertical electric field. Measurements were made of the charge collected by a large water drop falling through a jet of the cloud containing equal numbers of positively and negatively charged cloud particles in a vertical electric field maintained between two horizontal field plates. When the upper plate was positive, the drop collected a negative charge, and when the upper plate was negative the drop collected a positive charge. This is in agreement with a theory proposed by Wilson in connexion with the mechanism of thunder-clouds. The quantitative agreement is as close as could be expected from the experimental arrangement. The experiments also afforded a test of the mechanism suggested by Elster and Geitel. If any charge was collected by the operation of this mechanism, it was too small to be observed.

PARIS

Academy of Sciences, October 14 (*C.R.*, 201, 629–692). CHARLES ACHARD, AUGUSTIN BOUTARIC and JEAN BOUCHARD: The comparative action of ordinary alkaloids and genalkaloids on the fluorescence

of uranine solutions. The genalkaloids are alkaloids in which the amino group has been converted into an amino-oxide, and, while possessing the same therapeutic actions as the original alkaloids, are less toxic. The alkaloids examined have an inhibiting effect on the fluorescence of uranine solutions, but the genalkaloids do not possess this property. The authors regard the marked attenuation of the toxic effects of the genalkaloids as due to the disappearance of their antoxygen properties. PIERRE DE VANSSAY: General bathymetric map of the oceans. CLAUDE CHEVALLEY: The theory of bodies of classes. JEAN BRAÏTZEFF: The generalisation of preceding results relating to Dirichlet series. F. MARTY: The role of the idea of the hypergroup in the study of non-Abelian groups. NICOLAS LUSIN: A new method in the theory of descriptive functions. ANDRÉ CHARRUEAU: Remark relating to a thin circular rod, articulated at its two extremities and submitted to a normal and uniform pressure. BERNARD LAFFAILLE and FLORIN VASILESCO: The *flambage* of thin cylindrical plates. S. SLIOSKINE: The question of the plane movement of heavy fluids. WILLEM UYTERHOEVEN and CORNELIS VERBURG: The effects of the periodic variation of the concentration of the neutral atoms of the vapour in a sodium lamp with alternating current. An oscillogram is reproduced showing the variation of the current, electromotive force and intensity of the yellow light. A theoretical explanation is given accounting for the observed facts. RAYMOND ZOUCKERMANN: The explosive potential of hydrogen with high-frequency current. A discussion of the effects of impurities in the hydrogen, especially mercury vapour, on the explosive potential and appearance of the discharge. FÉLIX TROMBE: The paramagnetism of metallic gadolinium above its Curie point. The ferromagnetic Curie point of gadolinium is 16° C., the paramagnetic Curie point is 29·5° C. The paramagnetic moment of the metal is 39·28 Weiss magnetons, practically identical with the moment calculated from the oxide by Cabrera, 39·25. LÉON BLOCH, EUGÈNE BLOCH and CHOONG SHIN-PIAW: The absorption spectrum of selenium dioxide. A description of a new series of absorption bands in the ultra-violet. V. KUNZL: A new method of focalisation in spectrography with X-rays. MME. THÉRÈSE GRIVET-MEYER: The absence of notable gamma emission in the collision of rapid neutrons with protons. F. BOURION and MLLE. O. HUN: The cryoscopic determination of the total hydration of the ions of sodium nitrate. M. BOBTELSKY and MLLE. R. COHEN: The conditions of formation of trivalent manganese chloride in hydrochloric acid solutions and on its decomposition in the presence of complex catalysts. RENÉ DALMON, JEAN CHÉDIN and LOUIS BRISSAUD: The nitration of cellulose by nitric anhydride. Nitrogen pentoxide in organic solution (carbon tetrachloride) is capable of nitrating cellulose to the maximum (14·1 per cent nitrogen) with a very good yield. ADOLFO T. WILLIAMS: The absorption spectra of metallic and organic colloidal solutions and the absorption of metallic films. For organic substances, the structure of the absorption spectra in colloidal solution is much the same as in true solution. EDMOND BAUER and MICHEL MAGAT: The Raman spectrum of liquid heavy water. The frequency 170–176 is nearly the same in H_2O and D_2O, but the bands 350–500 cm.$^{-1}$ and 500–700 cm.$^{-1}$ are clearly displaced towards the lower frequencies. JACQUES LEFOL: The hydrates of monocalcium silicate. RAYMOND ROHMER: The system, water – sulphuric acid – nickel sulphate. ROBERT VANDONI: The disengagement of nitrogen monoxide during the decomposition of the nitrocelluloses. The gases arising from various modes of decomposition of nitro-cellulose contain nitrous oxide in important proportions, usually higher than the proportion of free nitrogen. JULES JARROUSSE: The oxidation of diphenylpyruvic acid. JEAN GRARD: Cellulose triacetate. Details of method of preparation. ALEXANDRE DAUVILLIER: The determination of atmospheric ozone. A comparison of the spectrographic and chemical methods. The results by the two methods, while not identical, agree fairly well, considering that the collection of one sample is local and that the concentration of ozone near the soil may vary rapidly. PIERRE CAPPE DE BAILLON: A new strain of *Baculum artemis*. GUILLAUME VALETTE: Study of the fixation of quinine on *Paramecium* by means of the microscopical examination of the fluorescence. Cells of *Paramecium caudatum* show a maximum quinine absorption in the neighbourhood of the digestive vacuoles. EMILE CESARI, JEAN BAUCHE and PAUL BOQUET: A strain of *Vipera aspis* with white venom. GILBERT RANSON: The determinism of the seasonal fixation of *Navicula fusiformis*. Its experimental culture in ostreaculture. GASTON RAMON: The favourable effect of certain lipoid substances on the immunising action of antigens. MAURICE DOLADILHE: Contribution to the study of the globulins of the blood in relation with its alexic power. ALEXANDRE BESREDKA, ISRAËL MAGAT, PIERRE LAVAL and PIERRE BESNARD: Intracutaneous vaccination against Pearce-Brown epithelioma.

CAPE TOWN

Royal Society of South Africa, September 18. I. DONEN: Studies in deciduous fruit (3). The chemical changes in Kelsey and Gaviota plums during growth. The life of the Kelsey and Gaviota plum on the tree may be divided into three stages. During the first stage the growth of the stone predominates over that of the flesh. The rate of growth, and of increase of all constituents of the flesh, except alcohol-insoluble residue, is comparatively slow. The concentration of total solids, alcohol-insoluble residue and nitrogen falls rapidly during this period, but acid concentration remains high. Starch is present in the plum at the beginning of this stage only. The second stage of growth commences when the stone is fully developed. It is characterised by a rapid rise in the rate of growth of the plum and in the rate of increase of total solids, sucrose, nitrogen and acid per fruit. These rates of increase finally reach a maximum value at the end of this stage. The third stage of growth is a period of maturation. The rate of accumulation of constituents per plum falls rapidly. Sucrose and nitrogen accumulate in the flesh so long as the plum remains on the tree. D. G. HAYLETT: Studies on dropping-berry in Waltham Cross grapes (*Vitis vinifera*). J. L. B. SMITH: Some interesting new fishes from South Africa. Two noteworthy additions, one of a genus, the other of a family, new to the South African marine ichthyfauna list are described and figured. *Scymnus brevipinnis*, n.sp., is a shark from deep water off Algoa Bay. Species of this genus have hitherto been recorded only from the North Atlantic and from Japan. *Taeniolabrus marleyi*, n.sp., recently obtained at Durban, is a member of the little-known family Trichonotidæ, hitherto recorded only from the Indo-Australian region.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Sunday, November 17

BRITISH MUSEUM (NATURAL HISTORY), at 3 and 4.30.—M. A. Phillips: "Reptiles".*

Monday, November 18

BRITISH MUSEUM (NATURAL HISTORY), at 11.30.—H. W. Parker: "Reptiles of the Galapagos Archipelago".*

UNIVERSITY COLLEGE, LONDON, at 5.—Dr. Phyllis M. Tookey Kerridge: "The Physiology of Hearing" (succeeding lecture on November 25).*

UNIVERSITY OF LEEDS, at 5.15.—Dr. W. F. P. McLintock: "The Gravitational Method of Investigating Geological Structure".*

ENGINEERS' GERMAN CIRCLE, at 6.—(at the Institution of Mechanical Engineers, Storey's Gate, Westminster, S.W.1).—Robert Kronfeld: "Neuzeitlicher Segelflug" (Modern Methods of Gliding and Soaring).*

ROYAL SOCIETY OF ARTS, at 8.—Dr. Bernard Smith: "Geological Aspects of Underground Water Supplies" (Cantor Lectures. Succeeding lectures on November 25 and December 2).

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Dr. G. N. Humphreys and E. Shackleton: "The Oxford University Ellesmere Land Expedition, 1934".

Tuesday, November 19

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, at 5.—Sir Walter Langdon-Brown: "The Integration of the Endocrine System" (Victor Horsley Memorial Lecture).*

EUGENICS SOCIETY, at 5.15.—(in the rooms of the Linnean Society, Burlington House, Piccadilly, W.1).—J. V. Quilliam, Mrs. C. B. S. Hodson and Dr. C. P. Blacker: "Voluntary Sterilisation—The Work of the last Two Years".*

CHADWICK PUBLIC LECTURE, at 5.30.—(at the London School of Hygiene, Keppel Street, W.C.1).—Prof. R. C. McLean: "The Bacteriology of the Atmosphere".*

BRITISH PSYCHOLOGICAL SOCIETY, at 6.—Dr. J. N. Langdon: "Monotony and Industry".

UNIVERSITY OF LEEDS, at 8.—(in the Philosophical Hall, Park Row, Leeds).—R. A. Watson Watt: "The Weather House".

Wednesday, November 20

ROYAL METEOROLOGICAL SOCIETY, at 5.—J. Edmund Clark, Ivan D. Margary and C. J. P. Cave: "Report on the Phenological Observations in the British Isles, December 1933 to November 1934".

Thursday, November 21

ROYAL SOCIETY, at 4.30.—A. R. Ubbelohde, J. W. Drinkwater and A. Egerton: " 'Proknocks' and Hydrocarbon Combustion".

D. T. A. Townend and E. A. C. Chamberlain: "The Influence of Pressure on the Spontaneous Ignition of Inflammable Gas-Air Mixtures. (4) Methane, Ethane, and Propane—Air Mixtures".

HALLEY STEWART TRUST LECTURE, at 6.—(in the Memorial Hall, Farringdon Street, London, E.C.).—Prof. Julian Huxley.*

CHEMICAL SOCIETY, at 8.—Discussion on "Some Aspects of the Interaction between Gases and Solids", to be opened by Prof. E. K. Rideal, followed by Dr. J. K. Roberts and Dr. R. M. Barrer. Other speakers: Prof. A. J. Allmand, Dr. R. C. L. Bosworth, Dr. A. Farkas, Prof. W. E. Garner, Prof. J. E. Lennard-Jones and Dr. H. W. Melville.

ROYAL SOCIETY OF MEDICINE (NEUROLOGY SECTION), at 8.30.—Prof. E. D. Adrian: "Electrical Activity of the Cortex".

Dr. J. H. Quastel: "Enzymic Activity of the Brain".

Friday, November 22

INSTITUTION OF PROFESSIONAL CIVIL SERVANTS, at 5.30.—(at the Royal Society of Arts, John Street, Adelphi, W.C.2).—H. A. Tripp: "The Problem of Road Casualties".*

INSTITUTE OF FUEL, at 6.—(at the Institution of Electrical Engineers).—Kenneth Gordon: "Development of Coal Hydrogenation by the I.C.I., Ltd."*

ROYAL INSTITUTION, at 9.—Prof. John Read: "A Musical Alchemist".

Saturday, November 23

ROYAL INSTITUTION, at 3.—Dr. Lawrence Binyon: "Chinese Painting" (succeeding lecture on November 30).

Economics of Plenty*

FEW problems have astonished the modern world so much as the apparent paradox of "poverty in the midst of plenty" yet, as Sir Josiah Stamp pointed out in his Norman Lockyer Lecture to the British Science Guild, delivered on November 13 and entitled "The Calculus of Plenty", the problem is by no means new, for just a hundred years ago, Carlyle could write that "In the midst of plethoric plenty, the people perish". As the years have gone on, the term 'plenty', while still covering the glaring maladjustment of things made, longed for but unused, has gradually widened in content to mean much more. In the last few years, it has become so nebulous and over-suggestive as to be, in Sir Josiah Stamp's words, almost an intellectual menace. The conception for which it stands, however, is in all conscience, he said, serious enough, though we should not be overawed or confused by it. The rigorous analytical examination to which Sir Josiah subjected the term 'plenty' in the course of his lecture provides an important contribution to the elucidation of the various problems involved, which only too often are lumped together to the confusion of clear thinking. Adopting a main threefold classification with various sub-heads, he classified 'plenty' as first that of physical or scientific potentiality; secondly, as that of unused or unmarketed production; and thirdly, that of unused capacity.

The plenty of potentiality is mainly a conception of the engineer and man of science, and it was developed to its greatest extent by the exponents of technocracy, who have left a sinister trail of dreams and pseudo-statistics over the whole field of thought and inquiry. Generally speaking, it expresses the facts of output in terms of reduced man-power for a given output. But the crude figures of engineering potentiality need to be qualified before the net figures of economic potentiality are deduced. It may well be that on the manufacturing side all the attendant supplies and processes cannot be speeded up to correspond, or the full and even load postulated may not really be available. Further, even supposing a considerably lower price is possible for the larger quantities available, after allowing for every production difficulty, it is not certain that the amount will be taken by the public at that price or even at any price. It might be a boon to make 100 fire grates with the ease with which one is now made, and yet not really a greater boon in any realistic sense to make 1,000 for every one now. Technical possibility has to be considered against a background of economic and psychological relativity. A further serious limitation will arise if in fact there are only one or two of the new machines in existence, and the bulk of supply comes from older equipment. In this event, the alleged plenty does not actually exist, nor is it actually potential; it is only hypothetically or ultimately potential.

The current concept of plenty popularly linked in almost causative association with poverty is fed from three main sources: the concept of things not hitherto made but now capable of being made, the concept of things already made and standing unused, and the concept of things that have not but could have been made.

Large dynamic ideas are scientifically dangerous if they remain unmeasured. Technological and scientific conceptions of plenty are capable of measurement and quantitative statement, but an accepted technique for this purpose is still lacking,

* The Calculus of Plenty. By Sir Josiah Stamp. (The Norman Lockyer Lecture, 1935.) Pp. 35. (London: British Science Guild, 1935.) 1s.

and no recognised units of productivity have yet been devised which are capable of being fairly aggregated and compared. The problem, however, goes much further than the mere measurement of plenty, since successive increments of productivity of apparent equality in measurement may have different values in practice. It may be, for example, that an invention can only be brought into full use gradually; fuller utilisation of unused capacity may involve greater proportionate expense for each unit, or increased supplies may only be demanded if the price is reduced.

The technocrats made grossly excessive claims about the potentialities of science and invention, nearly always stated quantitatively, and with great apparent exactness, thus conveying an impression of realisable plenty were it not for someone's stupidity or the faults of society. Some of the processes of technocratic computation, it would seem, assumed that machinery would be kept working 24 hours a day, or that what was true for an isolated process was true for a whole industry.

The gross possible theoretical or technical capacity based on engineering ideas has to be brought down to the more important economic capacity in several stages. First there is the operating margin. A 100 per cent use is in practice unattainable; a part amounting to something like 20 per cent must serve as a reserve for breakdown, repairs, irregularity of supplies, etc.

Secondly, there is unco-ordinated surplus capacity, since industries are not so perfectly integrated as to make possible a flow of production which will keep all stages fully employed. An intensified demand may quickly bring out some limiting factor. Allied to this, there is seasonal surplus capacity, and plant cannot be deemed to have a yearly capacity equal to its seasonal capacity multiplied by the full term.

Thirdly, it is possible that two industries may have surplus capacity technically equal yet vastly different in practical potentiality. For example, people might be desiring radio sets more and more and pianos less and less, and not generally both. Abundant purchasing power means much greater demand for the one, very slight extra demand for the other. Clearly potential 'plenty' cannot be regarded as the aggregate of these two unused sets of plant. Further, the advance of science and invention may render certain productive units obsolescent, or capital may be invested in production which is economically misplaced.

Consideration must also be given to the demand side. Suppose there is an efficient up-to-date plant for the production of a certain article which is only 70 per cent utilised, but which could be fully utilised without difficulty. Then we could only call the 30 per cent "plenty in the midst of poverty" if additional employment or spending power enhances total demand at the former price, so that an enhanced total supply produced at the same cost is marketed. But if increased spending power gives a relatively less increased demand for this article and the increased supply is at a relatively higher cost, we certainly could not.

The destruction of actually produced wealth when men are in need strikes the imagination much more than mere unused capacity; it seems so wanton. But this, as Sir Josiah Stamp pointed out, is by no means entirely a modern phenomenon, for the throwing overboard of Eastern produce to maintain the price of the remainder has in a former century been the producers' strike against an elastic demand schedule.

Stocks 'carried over' have not all the same quality. A glut of plums in Worcestershire not worth the cost of picking and getting to market is not effectively 'plenty', though if there is a canning factory then it may well be plenty. Here, of course, the demand schedule for canned fruit is quite another thing than that for fresh fruit. Then there is obviously a 'quality of position', for a surplus of tons of produce in Australia can well be different from tons in Smithfield. Perhaps the best-known example of the actual destruction of 'plenty' is the recent burning of coffee in Brazil, but not everybody has realised that the probable cause of the whole episode was an attempt on the part of producers, not merely to maintain prices but even to raise them. The excess supply of wheat of late years seems enormous when stated absolutely in bushels, but if it is measured in relation to total consumption, namely, 2·05 per cent, it becomes quite reasonable.

Sir Josiah Stamp also discussed the measurement of invention 'plenty'. Often innovations take a long time to get fully adopted if their margin of advantage is not revolutionary. The laboratory case may be proved up to the hilt, the engineer may be positive but the capital market is slow in moving; and, in Sir Josiah's view, there is no reason to suppose that socially-owned capital would be more progressive and risk-taking than privately-subscribed capital, so as to reduce the lag between an idea and its practical development.

Woman: Past and Present

Woman: an Historical, Gynaecological and Anthropological Compendium
By Hermann Heinrich Ploss, Max Bartels and Paul Bartels. Edited by Eric John Dingwall. Vol. 1. Pp. xiii+655. Vol. 2. Pp. xii+822. Vol. 3. Pp. viii+543. (London: William Heinemann (Medical Books), Ltd., 1935.) 3 vols., £8 8*s*. 0*d*. net.

FOR fifty years the various editions of "Das Weib" have had a considerable reputation on the Continent, in Great Britain and in the United States. The later editors revised and enlarged the book originally written by Dr. H. H. Ploss and added numerous new illustrations, and it has thus become a unique compilation on womankind. Hitherto there has been no English translation, but now English students can study with ease the accumulated data of the eleventh edition. This work, however, is not a mere translation, as the English editor, Dr. E. J. Dingwall, has made corrections and added supplementary matter, thus bringing it up to date so far as was possible. This laborious task has been performed in a most praiseworthy manner, and we have also to thank him for the very extensive bibliography. A noticeable feature of the work is the excellence of the illustrations, which are more than a thousand in number, but some of them could easily have been dispensed with. Loaded paper is used throughout on account of the illustrations and this makes the volumes uncomfortably heavy to hold; vol. 2 weighs nearly 6 lb.

This is a really remarkable compendium of the very voluminous literature that deals directly or incidentally with what appertains to women. The information is culled from ancient and modern authors and from the records of travellers and trained investigators among innumerable backward peoples as well as among the backward elements in modern communities. The external and internal anatomy of women is described and illustrated in detail, and sufficient physiological information is given for those who are not physiologists. Matters of interest are provided for those who occupy themselves in the history of medicine and obstetrics; but it is to anthropologists especially that the work will be of value, as it places at their disposal a wealth of material which otherwise it would be impossible for them to acquire. But it is to be feared that the great cost of the work will prevent most anthropologists from procuring it.

The exigencies of space precluded that any one section of the social aspects of womankind could be treated in anything like a complete manner. Probably enough has been given to satisfy ordinary requirements, but many recent field-workers will look in vain for the facts and inferences which are familiar to them. The ethnologist has much provided for him, but he will have to search elsewhere for further details and for other explanations of the significance of what is recorded.

The lengthiest discussion of social practices and institutions is that on the development of the institution of marriage. To the authors, man appears from the very beginning as a gregarious animal, and according to them it is really absurd to assume a monogamous institution in mankind. They go so far as to say that every form of 'marriage' conceivable among human beings occurs among animals and that all of them are dependent upon the care of the offspring. This is not the occasion to add to the unnumbered discussions of the origin of marriage or (as the authors hold) the priority of matriarchy to patriarchy and similar topics. Many modern ethnologists regard these subjects from a different point of view, or look upon them as being unprofitable to discuss.

The authors have very little to say concerning certain social and legal aspects of the position of women in a community. Much has been written, for example, about men's dread of contamination from women and about the various methods adopted to prevent or nullify it. This attitude certainly exists, but it is also well recognised that a man pays very little attention to restriction when he desires a woman. Individuals frequently break away from the standardised pattern of behaviour in regard to social barriers to marriage, forbidden degrees of relationship and the like. Irregular marriages are so frequent in some communities that there is a definite mechanism for socialising them, as it is recognised that strict adherence to custom is impossible in certain circumstances and it is necessary to regularise and establish the position of the children in society—which is one of the main functions of marriage. Common-sense usually prevails in primitive communities in a conflict between theoretical morality and what actually takes place.

Further, certain social practices in connexion with young women are best understood if those persons are regarded as property—more especially corresponding to property in trees. An essential idea of property is work done, and in many places a man who plants a fruit tree owns it and its

usufruct in perpetuity irrespective of who happens to own the land on which it is planted. The parents of a girl have had to do work in rearing her; when she marries, this work is usually recognised in payment by the groom or his group, or by the groom working for her parents. The loss of a woman to a group is also the loss of her prospective children; thus the groom may have to pay for the rearing of the girl and also for her usufruct, and these payments may extend over a number of years. This conception of property applies to the rape of an unmarried girl, which is described as a theft from the father or guardian, and that of a married woman from her husband. The transference of ownership is ratified not only to the husband or to his group by gifts, such as *lobola*, or whatever term may be used for this transaction, but also by bodily markings, a ring, adornment or other means. The recognition of ownership is in rare cases enforced by a chastity belt. The idea of property is, however, only one of the sentiments connected with marriage.

The method adopted in this work is of great value for those interested in comparisons and distributions, but it necessarily precludes any precise or even general conceptions concerning the place of woman in the life of communities. Woman is cut out of the picture. Those who desire to learn how women's activities and emotions are related to the functioning of particular communities must consult such books as "The Sexual Life of Savages in North-Western Melanesia" by B. Malinowski, who deals in a very thorough way with the Trobriand Islanders of Papua, and in "The Sorcerers of Dobu" by R. F. Fortune, who shows in another Papuan island the working of a society in which the wife and her village dominate the husband, who is always an alien. Dr. Margaret Mead illustrates the functioning of the very unpleasant family life of the people of Manus, Admiralty Islands, in her wrongly entitled book "Growing up in New Guinea", and in her "Coming of Age in Samoa" she gives a picture of a very different kind of family life. It is not fair to criticise authors for not doing what is outside the limits they have set themselves, but within these limits they have produced a work of great value.

A. C. HADDON.

Insect Morphology

Principles of Insect Morphology

By R. E. Snodgrass. (McGraw-Hill Publications in the Zoological Sciences.) Pp. ix+667. (New York and London: McGraw-Hill Book Co., Inc., 1935.) 36*s*. net.

THE author of this book ranks as the foremost American worker on insect morphology. His contributions on the subject are notable for their clarity and originality of thought, and the appearance of a volume, embodying his ideas in comprehensive form, is sure of a hearty welcome. In its preparation, Mr. Snodgrass has incorporated the results of much first-hand study with those of many recent investigators in the same field. He has produced an outstanding book wherein knowledge of facts is combined with that of function and, at the same time, theoretical conceptions of the origins and relationships of organs and parts are not overlooked.

The book is divided into nineteen chapters, each concluding with a glossary of the special terms used: the definitions are exact, and should help to eliminate prevailing ambiguities of terminology. The general subject of morphology is opened with a short chapter on arthropod organisation as a background, while the fundamentals of insect structure are reviewed from the development point of view. The body-wall and its derivatives are dealt with at length, and a clear exposition of the physico-chemical properties of chitin is included. The subject of sclerites and segmentation forms another chapter, which is followed by one on the general morphology of arthropod limbs. In this connexion, the author follows Störmer (1933) in rejecting the view that trilobite limbs are truly biramous, the so-called exopodite being interpreted as an epipodite. Mr. Snodgrass stresses the fact that 'biramous' limbs are peculiar to Crustacea, and that there is also no sound evidence of their occurrence in any Tracheata. In the chapters dealing with the structure of different body-regions, and their appendages, lucid explanations of their morphology are given, while the usually neglected subject of myology comes in for adequate treatment. The application of this latter aspect to the interpretation of the labium has clarified the prevailing inaccuracies of nomenclature.

The chapter on wings and flight is of special interest in that the author expresses original views on the anal group of veins and on the relations of the chief veins to the articular sclerites: the subject of wing regions also comes in for special discussion.

Under the title of 'Organs of Ingestion', the mouth-parts of individual orders and their larvæ are described at length, together with their musculature and methods of functioning. The various internal organs and systems are discussed in separate chapters.

In dealing with the nervous system, the author takes due account of the extensive work of Hanström in regarding the proto- and deuto-cerebral ganglia of the brain as secondary differentiations of an original prostomial archicerebrum, the tritocerebrum being interpreted as the first ganglionic centre of the ventral nerve cord. The histology of the nerve centres is very fully treated in the light of recent neurological research. In coming to the sense organs, the account, although adequate in most respects, says little of the tympanal organs of Lepidoptera, and no mention seems to be made of the halteres of Diptera or of the modern conception of general stimulation organs.

The final chapter on the genitalia is a full and well-illustrated treatment of a complex subject. The book concludes with twenty-two pages of up-to-date bibliography. In a short notice little more than an indication of the scope of this work is possible, but it remains to be emphasised that it is a really sound scientific treatise of first-rate importance, which no worker on the subject can afford to neglect. A. D. IMMS.

A Poet's Picture of Life and Philosophy

The Mystery of the Mahābhārata

By N. V. Thadani. Vol. 1 : A Vision of the Vedas. Pp. lxiv+432. 12 rupees. Vol. 2 : The Systems of Hindu Philosophy and Religion. Pp. xviii+371. 8 rupees. Vol. 3 : The Story and the Essence of the Epic. Pp. lii+462. 8 rupees. Vol. 4 : The Explanation of the Epic, Part 1. Pp. xlvii+378. 8 rupees. Vol. 5 : The Explanation of the Epic, Part 2. Pp. xvi+379–924. 8 rupees. (Karachi : Bharat Publishing House, 1931–1935.) £4 the set.

IT may not be unknown to most readers that the Mahābhārata, or Great Bharatiana (that is, things about the Bharat clan, as the title is usually understood), is to Indian literature what the Iliad is to that of Greece, only immensely longer, the long period of its compilation being of equally indefinite date. The only portion of it with which they are likely to have any direct acquaintance is the episode known as the Bhagavadgītā, or Song of the Blessed One, best known to us in the translations of Edwin Arnold, Dr. L. Barnett and that in the sacred books of the East.

Mr. Thadani, late principal of the Hindu College, and rector of the University of Delhi, agrees with Indologists in seeing in the vast work, of which tradition holds that only a summary—and that being 100,000 lines !—has survived, the hand of many writers (possibly, before that, the voice of many Sayers). But he does not concede that the many are a succession of editors, incorporating new values, altering, dropping out superseded values. He is before all a poet, and has a vision of "a great school of thought which seems to have flourished in India in the past". He does admit that his 'school' will have included results of new knowledge from time to time. But he claims that from first to last the epic has 'unity of design', and that this design was to give a "picture of all systems of philosophy and religion in story-form", and incidentally "an account of the universal history of Man or the human race".

Enough said—at least for present limits of space. I do not recommend the study of these volumes to scholars ; they are too poor in first-hand knowledge and in historic perspective for such. Nor to the serious inquirer at second-hand, and for the same reasons. The account given, among the 'systems', of Buddhism, shows these weaknesses perhaps at their worst—or is it because there I am better able to judge ? But for the literary reader and for the student of racial types in authors, it may prove an interesting (and in style very readable) mine of curious information. Especially perhaps where the venerable cosmic 'egg', as the primary unit of life at the creation, appears in modern dress as 'the cell', and in the theory of Sanskrit as having been deliberately constructed "as a picture of Brahm'anda, that divine egg". A poet runs the great danger of seeing his perspective just like that : "as a picture", and often an ancient picture at that. I mean one in which the time-quality is either represented merely as background, or all as in the foreground. A book which can set out to give a picture of the history of man, by way of 'systems' of religion and philosophy, without any mention in its index—and it is one of forty pages !—of man's will and man's becoming, can scarcely contain even the rudiments of that history, of that real nature.

C. A. F. RHYS DAVIDS.

A Neglected Aspect of the Calculus of Variations

Variationsrechnung und partielle Differentialgleichungen erster Ordnung
Von Prof. Constantin Carathéodory. Pp. xi+407. (Leipzig und Berlin: B. G. Teubner, 1935.) 22 gold marks.

THE work of Euler and Lagrange in the middle of the eighteenth century proved that the essence of theoretical mechanics lay in the calculus of variations, which was itself something that included not only all mechanics but also much else besides. Mechanics is a class of partial differential equations; the calculus of variations corresponds to a similar but bigger class, whose essential properties differ only in detail from those of the former class. Jacobi in particular stressed, in 1836, the intimate relation that subsists between systems of partial differential equations of the first order and equations arising out of the calculus of variations.

There for the next forty years the matter rested; no doubt for lack of some of those essential principles which were in that period changing from fluidity to solidity, there is small evidence of development in the direction to which Jacobi's researches seemed to point. Then in 1879 appeared the work of Weierstrass, which gave the calculus of variations its independence from its first parent, mechanics, an independence which it maintained only until it was adopted by the new and comprehensive calculus of functionals.

From the time of Weierstrass the evolution of the general theory of the calculus of variations proceeded in directions which appeared to loosen the primal association with partial differential equations, an association which, though noticed in a casual manner from time to time, all but disappeared from sight. Thus those landmarks of the period, the textbooks of Bolza (1909) and Hadamard (1910), tend away from, rather than towards, the Jacobian point of view (though Hadamard clearly realised that there was still much to be revealed), whereas the more recent and more highly specialised books—that of Morse (1934) may be quoted as a distinguished example—pass still further away.

In his preface to the book now before us, Carathéodory tells how he has been endeavouring for many years to pick up the threads of the connexion between the calculus of variations and partial differential equations left by Jacobi and his pupils. The old-fashioned theories of partial differential equations proved inadequate for this purpose because they were evolved with the view of forcing the equation to disgorge a solution—or at least the skeleton of one—and were often in the nature of artifices the scope of which was limited and power unreliable. That moderately complete knowledge of the essential nature of a solution which has now been gained, together with the modern weapons of mathematics, such as the tensor calculus, provide an equipment both necessary and effective for weaving new matter into the older fabric.

In order that an adequate account of the theory of partial differential equations, refined and recast in moulds of precision, should be always at hand, the author has devoted the first ten chapters (163 pages) of his book to developing this theory. With as great a generality as is possible without making the existence theorems somewhat repulsive, yet at the same time without imposing tiresome restrictions on the work he is leading up to, the author establishes the basic theory of characteristics, canonical transformations of systems of equations, contact transformations and the Pfaff problem. Though it was designed as a necessary preliminary to the second half of the book, and indeed serves that end to perfection, it is actually an account remarkable in itself for lucidity and completeness.

Apart from an introductory chapter on maxima and minima in the ordinary sense, the second part of the book is devoted to founding the theory of the calculus of variations on the basis that has been mentioned. But though the basic association with partial differential equations is emphasised throughout, the link is not stressed to breaking point. Except in the examples by which the author illuminates the theory and puts its powers to the test, everything is stated in terms of many-dimensional space. Incidentally, the examples—they have an index of thirty entries to themselves—are extraordinarily interesting, and made all the more valuable by some clear and striking diagrams. Naturally the limits of space imposed upon the author have restricted the scope of the work, excluding discontinuous solutions and other topics to which the contributions of Carathéodory himself have been considerable. But the essence is there—in places perhaps a little concentrated, but never turbid. In brief, the author treats of the simple and the parametric variation problems, the second variation, the boundary problem, closed extremals and the Lagrange problem. An extensive bibliography is accompanied by ample indications to sources of information about those topics which are not contained in the text. In sum, this book is indispensable. E. L. I.

Die wichtigsten Lagerstätten der "Nicht-Erze"

Von Prof. Dr. O. Stutzer. Band 6 : Die Lagerstätten der Edelsteine und Schmucksteine. Von Prof. Dr. O. Stutzer und Dr. W. Fr. Eppler. Pp. xvii+567. (Berlin : Gebrüder Borntraeger, 1935.) 43.50 gold marks.

IN this book, the first section, which is an enlarged and rewritten version of an earlier work by Dr. Stutzer, gives an interesting account of the diamond fields of the world, plentifully illustrated with maps, diagrams and photographs. Statistical tables are given, and these emphasise the enormous extent of the diamond industry, accounting for more than 90 per cent of the world's trade in precious stones. In 1929, the total production reached nearly eight million carats, more than half of which came from pipes and gravels in the Union of South Africa.

The second and slightly larger section, written by Dr. Eppler, is entirely new, and provides a useful survey of all the more important sources of the precious and semi-precious stones, arranged according to their chemical composition. The section concludes with a long chapter on amber (much in favour in Germany just now) and a note on jet. The treatment of each species consists of a brief summary of its chief mineralogical characters, followed by a description of the geology of the most important deposits, and a note on the commercial aspect of its production. Pyrites, which is extensively used in cheap jewellery as 'marcasite', receives no mention, nor do sphene, andalusite, or phenakite—while on the other hand, such rarities as benitoite and euclase are included in this section.

Although not free from minor errors, omissions and misprints, the book can be recommended as a most useful monograph on the subject. B. W. A.

Hydrographie

Von Prof. Dr. Friedrich Schaffernak. Pp. ix+438. (Wien und Berlin : Julius Springer, 1935.) 46.50 gold marks.

PROF. SCHAFFERNAK, from the store of his knowledge and experience as an exponent of the principles of hydrography at the Technical High School of Vienna, has compiled a textbook on the subject which should be extremely useful to students, as also to others who are engaged in observational and experimental work of this nature. The volume is divided into three main parts, the first of which deals with the taking and assembling of hydrographical, meteorological and morphological observations, including rainfall, water-levels and discharges of rivers and streams ; the second with statistics in an analytical and graphical form ; and the third with a consideration of important special problems and their solution.

There is a fully illustrated description of the various instruments and appliances which are used in connexion with the field work of hydrology, and a variety of information concerning the taking and classification of readings ; while the mathematical side also receives attention. The illustrations and diagrams are clear and easily intelligible, and there is a serviceable index. B. C.

Head, Heart and Hands in Human Evolution

By Dr. R. R. Marett. Pp. 303. (London : Hutchinson and Co. (Publishers), Ltd., 1935.) 10*s.* 6*d.* net.

IN this volume Dr. Marett has brought together a number of addresses, lectures and essays, ranging from three presidential addresses to the Sociological Institute in 1933–35, and the Donellan Lecture delivered at Trinity College, Dublin, in 1933, to a number of miscellaneous papers, including contributions to publications of a popular or semi-popular character. Notwithstanding their varied character and purpose, they have a certain unity, which is suggested by the author's choice of a title. Between them all they cover the sum of human activities, through which man expresses himself as a member of a society, as a being in relation to a spiritual world, and as an exploiter of his material environment, whether for the practical needs of everyday life or for the expression of an æsthetic impulse.

Dr. Marett is an evolutionist in so far as that term is applicable to the consideration of man's cultural development ; but he is too expert in handling philosophical categories to allow himself to be entrapped into the crudities which are attributed, not always justly, to that school. In the first of his addresses to the Sociological Institute he is careful to expound the distinction which is to be drawn between the implications of the biological terms 'evolution' and 'progress' in cultural development. On the other hand, he shows that the evolutionary position in anthropology conforms to the requirements of the biological concept in that, rightly understood, it neither postulates, nor claims to find in the evidence, the unilateral progression which is said to be its characteristic defect.

Civilisation and the Growth of Law :

a Study of the Relations between Men's Ideas about the Universe and the Institutions of Law and Government. By Dr. William A. Robson. Pp. xv+354. (London : Macmillan and Co., Ltd., 1935.) 12*s.* 6*d.* net.

DR. ROBSON traces the growth of 'law' from its origin as an observed order in early societies and as conformity to the will of a ruler, divine, or of divine quality, to that of modern times, in which natural law as the ordered process of natural phenomena stood over against human law, which enforced obedience to a rule of conduct to be observed in any given community. He shows how the institutions of government have been influenced successively by magic, superstition, religion and science. The modern scientific outlook, however, he holds, has produced a profound modification in the conception of the character of natural laws as based upon objective reality. Hence he seeks to show that the gap between natural law and human law may now be bridged in a synthesis —the human mind, which formulates them—in other words, in the creative powers of the human intellect. Dr. Robson has written a stimulating book, which prompts a re-examination of certain fundamental sociological and juristic conceptions in the same way as it is now necessary in the light of modern theory to examine fundamental concepts of natural sci

Heavier-than-Air Aircraft:
a Brief Outline of the History and Development of Mechanical Flight with reference to the National Aeronautical Collection, and a Catalogue of the Exhibits. By M. J. B. Davy. (Board of Education, Science Museum: Handbook of the Collections illustrating Aeronautics, 1.) Second edition (revised and enlarged). Pp. 125+26 plates. (London: H.M. Stationery Office, 1935.) 2*s*. 6*d*. net.

THE second edition of this handbook contains an outline of the history and development of mechanical flight from the beginning to the present day, with special reference to the National Aeronautical Collection, and a complete catalogue of the exhibits at South Kensington.

The National Aeronautical Collection, which was founded as a historical exhibit in 1919, has enlarged rapidly since that date, and is now probably the most comprehensive exhibition of its sort in the world, and one of the most popular of the collections at the Science Museum. Much original historic apparatus has been acquired, and the collection is certainly richer in this respect than any abroad. It includes the gliders of Lilienthal, Pilcher, Chanute and Weiss; the original Wright aeroplane which made the first flights in 1903, the Vickers-Vimy aeroplane which made the first crossing of the Atlantic by air in 1919, the Supermarine Rolls-Royce Seaplane S.6.B., which secured the Schneider Trophy for Great Britain and created a world speed record of 407·5 miles an hour. A note on the development of air transport to the year 1934 is included in this edition, and some new illustrations have been added. The catalogue portion includes the additions to the Collection which have been made since 1929.

The Chemical Formulary:
a Condensed Collection of Valuable, Timely, Practical Formulæ for making Thousands of Products in all Fields of Industry. Editor-in-Chief: H. Bennett. Vol. 1. Pp. x+604. Vol. 2. Pp. ix+570. (London: Chapman and Hall, Ltd., 1933–1935.) 25*s*. net each vol.

THESE two volumes consist of numerous receipts for the manufacture of a wide range of materials dealt with under such varying headings as adhesives, alloys and metals, food products, explosives, ceramics, insecticides, plastic materials, etc., to waterproofing of materials. The information used in compiling these books has been obtained from a variety of sources, including industry and patent literature, and has been carefully considered by a board of editors drawn from a large number of educational institutions and industrial firms.

Although correct quantities may be used, much depends upon the method of compounding and other factors if the best results are to be obtained, and so experimental work or consultation with other workers in a similar field may be necessary. Nevertheless, the contents of these volumes supply much useful information on how various products can be obtained, and are therefore very suitable works of reference to both the educationist and the industrialist.

Wasserbauliche Strömungslehre
Von Dr. Paul Neményi. Pp. viii+275. (Leipzig: Johann Ambrosius Barth, 1933.) 28 gold marks.

DURING the past twenty years, a complete change of outlook has occurred in all subjects involving the mechanics of fluid motion. In the main, this is due to intensive aeronautical research originating in the War period. Almost without exception, writers of textbooks of hydraulics have ignored this advance and have merely rearranged and expanded the older material. Dr. Neményi, on the contrary, almost creates a new subject. The scope and arrangement are new, and much of the subject matter is ably abstracted from recent original papers.

Written primarily for the civil engineer, or perhaps rather for the advanced student, it is for the most part an exposition of the fundamental principles of flow, classified under a variety of boundary conditions. Mathematical treatment is occasionally used, but only where the matter really warrants it. Ample references, however, are given to the original papers where the full treatments can be found.

Some idea of the scope may be given by the following random selection from chapter headings: river-bed and silt movements, ice in relation to the river problem, underground water, jets and sprays, the layout of a laboratory for hydraulic model testing. All are fully illustrated by photographs, curves and line diagrams.

As this work is likely to have far-reaching influence, it is to be hoped that the author will be able to arrange for an English translation.

Hand- und Jahrbuch der chemischen Physik
Herausgegeben von A. Eucken und K. L. Wolf. Band 6: Elektrizität und Materie. Abschnitt 1B: Dielektrische Polarisation. Von O. Fuchs und K. L. Wolf. Pp. x+237–460+12. (Leipzig: Akademische Verlagsbuchhandlung G.m.b.H., 1935.) 27 gold marks.

THE subject of "Dielectric Polarisation" acquired a new interest and importance, to chemists as well as to physicists, when Debye in 1912 showed how the dipole moment of a gas could be deduced from the temperature coefficient of the dielectric constant, and J. J. Thomson in 1914 showed how, either by this method or by comparing the dielectric constant with the square of the refractive index, gases could be divided into two classes, according as their molecules do or do not possess a permanent dipole moment. Subsequent years have been marked by intense activity in correlating dipole moments with molecular structure, and especially with the configuration of molecules in space of three dimensions. In this way, many physico-chemical problems have already been definitely solved, and other subjects, such as the principle of free rotation, have been illustrated and elucidated. A monograph of 234 pages, with more than 60 figures, is supplemented by a table containing all the previously determined dipole moments, with references to 319 papers in which the data in question are recorded.

Some Geological Aspects of Recent Research on Coal*

By Prof. H. G. A. Hickling

I BELIEVE that coal is not only in itself worthy of more attention at the hands of the geologist than it has been generally accorded, but also is likely to repay that attention by shedding light on some of the major problems of geological science. Later, I shall revert to the conception of coal as a metamorphic rock. The idea is ancient, but the data necessary for its establishment and more precise definition have been lacking. Perhaps they are now to hand. If that be so, we have in this familiar rock an indicator of crustal conditions far more delicate than any of the index minerals of the metamorphic petrologist; so delicate indeed, that should it come within range of even the lowest grade of metamorphism, as usually understood, it is completely shrivelled up and leaves only a trace of graphite as witness of its former self.

Structure of Coal

So far back as 1831, Henry Witham had prepared microscopic sections in which he had seen plant structure, and in January 1833, a paper was read before the Geological Society of London, by William Hutton, based on the examination of a considerable collection of thin sections. It was, unfortunately, published in brief abstract only, but the original manuscript, at present in my possession, shows that he had observed most of the features which were noted by later observers until very recent times. This was the first serious attempt to determine the structures of the different kinds of coal, and little advance was made in this matter for more than half a century.

The modern period of coal petrology is clearly the offspring of the palæobotanical research on petrified coal which culminated at the close of the nineteenth century. This work gave us a precise knowledge of the structure of the plants which formed the Carboniferous coals, and a clear picture of the condition of some of the coal peats at the time of their deposition. It was inevitable that this should be followed by more determined attempts to see these structures in the coal itself, and was equally natural that such attempts should be made quite independently by a number of workers.

The 'Uniform Brown Substance'

Before the time of Witham and Hutton, coal was often regarded as a deposit from 'solution' in water—as a kind of vegetable 'extract', which might consequently be expected to possess a distinctive composition, independently of the materials from which it was derived. The earlier microscopic observations at once limited this idea by demonstrating the presence of plant remains which retained their organised structure; but Hutton directed attention especially to a 'uniform brown substance' as the dominating constituent of the commoner types of coal. This clearly appealed to many observers as the essential feature, and many references to the 'coal substance' seem to be more or less clearly identified with it. The foremost question in coal petrology has been, in fact, the nature of this brown substance—in particular, as to whether it is, in more modern phrase, a colloidal precipitate, or whether it represents actual fragments of plant material. Since it forms probably quite 75 per cent of all our common coal, this question is of the first importance.

All recent workers have directed attention largely to this dominating material. E. C. Jeffrey named it 'lignitoid material'. He regards it as representing pieces of plant tissue, largely woody, in which all trace of the original organisation has been destroyed by decay. Thiessen differed from Jeffrey chiefly in his belief that the structure of the original plant material is rarely quite obliterated, and that it can nearly always be detected if the sections and the microscopic technique be sufficiently good. He named the material 'anthraxylon'.

In 1919, Dr. Marie Stopes essayed a classification of the types of coal substance which can be distinguished by eye in an ordinary bituminous seam. While earlier writers had usually been content to describe the coal as divisible into 'bright' and 'dull' layers, together with occasional bands of 'mineral charcoal' or 'mother of coal', she directed attention to the additional fact that the 'bright' coal might be separated into two portions. The general mass of the bright substance has a just perceptible fine lamination which gives it a silky sheen; but interbanded with it are many thin layers which at once strike the eye by the mirror-like reflection from their perfect cleavage surfaces. She applied distinctive *names* to the different types of laminæ, adopting the French *fusain* to replace the questionable English term 'mineral charcoal', and devising corresponding terms for the other types of coal: *durain* for the true dull bands; *clarain* for the ordinary silky

* From the presidential address to Section C (Geology) of the British Association, delivered at Norwich on September 6.

bright coal; and *vitrain* for the brilliant glassy-looking substance.

Turning to the microscopic characters of these types of coal, she observed that the clarain bands were mainly composed of this uniform brown substance, finely interspersed with other ingredients, and often showing its original plant structure; while vitrain consisted entirely of similar material, free from admixture with other substances, but seemed to show no trace of structure. The development of technique during the past decade has shown, however, that this latter distinction was apparent only. In direct proportion as the methods of preparing thin sections or of etching coal surfaces have been improved, an ever-increasing proportion of the 'uniform brown substance' of the bright coal has been shown to retain the structure of the plants of which it is composed.

Nature of the 'Uniform Brown Substance'

Thus the 'uniform brown substance' for the most part, at least, represents portions of plant tissue with their organised structures exquisitely preserved; and there are those who regard it as made up entirely of such fragments, each of which now consists only of the remains of the organic substance of which that particular plant fragment was originally composed. The alternative view is that a large part of the substance of the original vegetation was reduced by early decay to the condition of a true fluid, some of which was absorbed into those plant fragments which retained their organisation, while other portions of the fluid may have solidified as a truly structureless gel, and acted as a cement to the whole mass. Whatever may be the amount of truth in this latter hypothesis—and there is considerable evidence that material which must have been absorbed in a fluid condition is present in some cases—it is absolutely unquestionable that the plant remains which now form this translucent coal substance have been rendered jelly-like, whether by their own decay or by absorption of extraneous material. In nearly all cases, cell-walls which were clearly rigid have been flattened and folded without rupture. Often the entire tissue has been contorted into the most fantastic forms but still remains unbroken.

In any case there is little reason for supposing that the essential nature of this substance is very different whether the plant-structure be discernible or not; all our evidence points to a remarkable general uniformity. Its ash-content is always found to be amazingly low. Not only is it a mere fraction of that present in the rest of the coal substance, but it is much below that in any average aggregate of modern plant materials. There is no reason for supposing that the vegetation of the coal-forests was abnormal in its content of inorganic matter, so we must presume either that the inorganic content of this part of the coal has been reduced, by leaching out, or that there has been a very large addition of pure organic substance. Further, this material shows extremely little variation in its organic composition, as compared with the other constituents of the coal. While the hydrogen content, for example, in the different ingredients of a single block of bituminous coal may be found to range from $3\frac{1}{2}$ to 8 per cent, the variation among samples of vitrain from the same block will rarely exceed a twentieth of that amount. It is because most coals consist mainly of this substance that they differ so little from one another. Prof. Wheeler and his colleagues have shown that it is mainly composed of ulmin compounds.

In the absence, hitherto, of any generally accepted name to denote this most important of all coal constituents, I propose for the present to adopt the term recently suggested by Dr. Stopes and call it *vitrinite*.

Other Components of Coal

We must now take stock of the other materials which go to the make-up of an ordinary coal seam. Though they are subsidiary in amount to the vitrinite in most portions of the seam, it is the character and varying quantity of these other materials which primarily differentiate the quality of the coals.

Most conspicuous and familiar is the 'mineral charcoal' or fusain. This illustrates at once the fact that in some cases the mode of preservation of the plant-substance may be of greater import than its original nature. The fusain is usually woody tissue, clearly identical originally with much of that which has been converted into vitrinite. But how different in its present form! Devoid of any organic substance in its cell-cavities; every cell-wall so brittle as to break at a touch; always extremely low in its content of hydrogen and oxygen, and correspondingly high in carbon. Physically and chemically it stands in the strongest possible contrast. On account of its porous nature, it has commonly formed the receptacle for much of the mineral matter which has been deposited from solution in the coal, and is consequently a great carrier of ash. Quite moderate variation in the amount of fusain in the coal has important effects on its utility for various purposes.

The next group of coal components may for the purpose of this review be designated the 'high-hydrogen' group—the outer coatings of stems, leaves and spores which are characterised by an accumulation of waxes, fats, resins and allied substances. They differ so strikingly in chemical

properties from the rest of the coal that by the roughest chemical treatment the remainder of the coal can be broken down while the spore-coats and cuticles are left little altered. They are then seen under the microscope to differ in structure little, if at all, from their condition in a living plant. Their obvious relative indestructibility has resulted in their accumulation in the coal in quantities much in excess of their natural proportion—in extreme cases, even to the total exclusion of other materials.

Associated with the cuticles and spores in respect of chemical peculiarities and durability, but differing somewhat in the manner of distribution in the coal, are the resinous secretions of the plants. Since the resins were originally contained in the wood or bark, they are found largely in the vitrinite of the coal. On the other hand, they are often found in local aggregations among the more disintegrated plant debris, in such a manner as to suggest that the aggregates may represent the resinous content of a tissue which has, for the rest, been almost entirely destroyed.

There is one other distinctive ingredient in most ordinary coal seams, characterised by its minute state of fragmentation. It forms a kind of paste made up of particles of 1 or 2 microns or less in diameter. Obviously it represents quite a distinct stage in the degradation of the plant material; and there is some indication that it has distinctive chemical peculiarities. It is of very dense colour, and is consequently opaque except in the thinnest sections. It is essentially characteristic of the dull coals. So far it lacks a generally recognised title and has been merely described as the 'residuum'. Dr. Stopes would christen it 'micronite'.

'Sapropelic Coals'

The foregoing account of the components of coal deals with those to be found in our normal bituminous coals of Carboniferous age. So far as my knowledge extends, the account does not require material modification in reference to the coals or lignites of other ages. But there are other types of coal, particularly the cannels and bogheads, which have a widely different structure and at least one very different component material; namely, the microscopic oil-bearing algæ. In the last few years these organisms have been carefully re-examined by Zalessky, by Thiessen, by P. Bertrand, and by my own colleague Dr. Temperley, who have not only demonstrated their structure in greater detail, but also have established their essential similarity (and possible identity) with the living oil-alga *Botryococcus braunii*. This constituent of the cannels affords the most striking of all examples of the effect of original materials on the composition of the coals. As the algal content increases, so the percentage of hydrogen in the coal rises, from about 6·0 per cent in those without algæ up to more than 12 per cent in the purest algal bogheads.

(*To be continued.*)

Birkbeck College

Past, Present and Future

THE successful inauguration of the appeal for the rebuilding of Birkbeck College, originally the London Mechanics Institution (see NATURE, Nov. 16, p. 787), will be welcomed universally by students of science. The College, established at a meeting of 'mechanics' held in the Crown and Anchor Tavern in the Strand on December 2, 1823, had as its original purpose to provide scientific education for the skilled craftsmen who were the aristocracy of the Industrial Revolution. That the objective was education and not mere technical training is proved by the motto of the Mechanics Institutes established throughout the country: "To make a man a better mechanic we must make the mechanic a better man".

In the early days, as Mr. Ramsay MacDonald, a former student of the College, has said, their science was simple and stimulating. "Its revelations were both startling and fresh; the controversies it roused were popular and the prospects it opened were inspiring." The opposition encountered by Birkbeck was essentially opposition to scientific training. "What is wanted," said Bell's *Weekly Messenger*, "is practical mechanics—instruction in trades . . . Science, in the very nature of things, must be confined to a few"; and the *St. James' Chronicle* asserted that "a scheme more completely adapted for the destruction of this empire could not have been invented by the author of evil himself. . .". Carlyle, in "Sartor Resartus", denounced its students as "professed Enemies of Wonder", cackling "like true Old-Roman geese and goslings round their Capitol, on any alarm, or on none"; as illuminated sceptics guiding people with rattle and lantern when the sun is shining. He resented "that progress of Science which is to destroy mystery".

Science has withstood these attacks and has captured some of the strongholds of the older culture. Birkbeck College can claim to have acted as *éclaireur* to the "march of mind" and to recapitulate the history of scientific instruction in Great Britain; this proud claim should ensure the success of its appeal.

The College, as we have said, stands for education in a broad sense, but it stands also for another great principle—part-time education. Hundreds of examples of the value of part-time education could be cited from the records of the College, but the one selected by the Archbishop of Canterbury in his speech at the Mansion House meeting is of outstanding interest. Sidney Gilchrist Thomas (1850–85), a police court clerk, attended George Chaloner's chemistry class in the College. The lecturer remarked that "the man who eliminates phosphorus by means of the Bessemer converter will make his fortune". From 1860 onwards, Sir Henry Bessemer and many others had studied this problem, a problem of great economic importance, since its solution would render available vast deposits of iron ore in England, Germany and the United States. Gilchrist Thomas solved the problem and received the promised guerdon. This wealth was not, however, the incentive to the discovery, for his biographer states that "he held 'advanced' political and social views and had he lived he had intended to devote his fortune to the alleviation of the lives of the workers". The money was spent in philanthropic objects after his early death. "A rare young man", as Gladstone observed! Let it be added that the scientific equipment provided at the College at this period was of the simplest. The room, said Bernard H. Becker in "Scientific London" (1874), might (were it not devoted to the use of science) be designated the back kitchen. A couple of glaring 'butcher's lights' illuminated a rough deal table from behind which Mr. Chaloner expounded the properties of carbonic acid gas. But he added, —and this sounds the keynote of the history of the College—"the lecturer and the audience evidently mean business".

In recent years, the College has catered for two groups of students who are to be found in large numbers in London and the surrounding districts. The first consists largely of teachers, civil servants, technical chemists and others who have missed the usual university training and are willing to give their evenings to working for a degree. The second group comprises graduates in arts and science of London and other universities who have a keen desire to pursue post-graduate studies and research. For many years the lecture rooms and laboratories have been seriously overcrowded by both types, and each year a number of keen and deserving students has been refused admission owing to limitations of space.

New buildings and more space are urgently needed to enable the College to serve effectively the needs of the present generation. When the College was founded in 1823, two men in every three and nine women in every ten could neither read nor write. When it was rebuilt in 1883, elementary education was in its infancy. To-day the mesh of the scholarship net is so fine that the time is not far distant when all who are fitted for university education will be provided for in the ordinary course.

What then is Birkbeck's future? It has provided adult education in fundamental subjects; it has led its students along the paths of the polytechnic, and inspired them to scale the academic heights by degrees—now it has entered upon a greater role —the provision of opportunities for research for those whose everyday occupations are in other fields.

Schmidt and the Eels

Danish Eel Investigations during Twenty-five Years

ON June 22, sixty miles west of Ringkjöbing, Jutland, the research ship *Dana*, built by the British Admiralty during the War and sold to the Danish Government in 1921, was sunk in collision with a German trawler in a fog. Happily there was no loss of life; but, with her, was lost all her scientific equipment and the material of her latest cruises. Johannes Schmidt, who made the *Dana* famous, had died all too soon, a comparatively young man, on February 21, 1933. When his ship went down, it was as if a chapter of oceanographical history came to an end. The little brochure "Danish Eel Investigations During Twenty-five Years, 1905–1930", recently issued by the Carlsberg Foundation, Copenhagen, may be regarded as the epilogue to the story.

There is nothing new in this publication. The text is taken from Schmidt's report of his famous voyage round the world. It was his intention that the report, written in Danish, should be done into

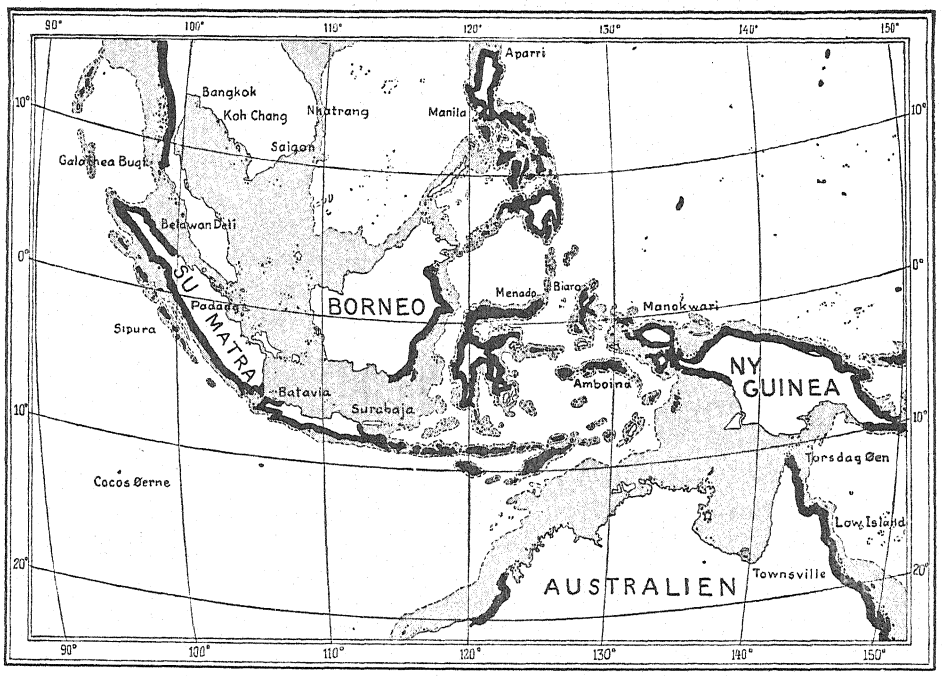

FIG. 1. Chart of Indo-Malaya showing distribution of the eel (in black). Shallow water (less than 200 metres deep) is shaded and deep water and land areas are white. Note that eels do not occur off coasts facing shallow water regions (Sumatra, Java, Borneo, Siam, etc.)

English, or at least French. That intention was not fulfilled, but Schmidt's summary record of the Danish eel investigations, of which he had been the leader since 1905, has been lifted out of the report and published in English. The record is illustrated and expanded by the addition of figures, with appropriate text, from others of Schmidt's papers, and the brochure concludes with a list of Schmidt's papers on eel investigations and a brief record, with illustrative charts, of his various eel expeditions. Three of the illustrations are reproduced herewith by courtesy of the Carlsberg Foundation.

For those who followed Schmidt's voyages as they took place, this paper is an interesting summary of their results, as regards eels, and of his conclusions from them. To the student approaching the question for the first time, it will be a stimulating introduction to what Schmidt describes as "the Eel question", and a useful guide to the literature. One cannot read it without a feeling of deep regret that he did not live to pursue the subject further and to check his own conclusions, as we may be sure that he would have done if he had not been cut off in his prime.

As a summary statement of the facts and Schmidt's interpretation of them, this document is a masterpiece of compression. Schmidt believed that he had successfully identified every species of the genus *Anguilla*. Besides the two Atlantic species —the European and the North American—he was sure of six species in the countries bordering the Indian Ocean, and "about twelve in the countries by the Pacific", of which some were common to both oceans. Actually, only ten non-Atlantic species are named in the paper, but this reflects the summary character of the statement. The main fact that emerges from his investigations is that all the fresh-water eels without exception require for spawning waters of great depth and high salinity. This fact is illustrated by charts,

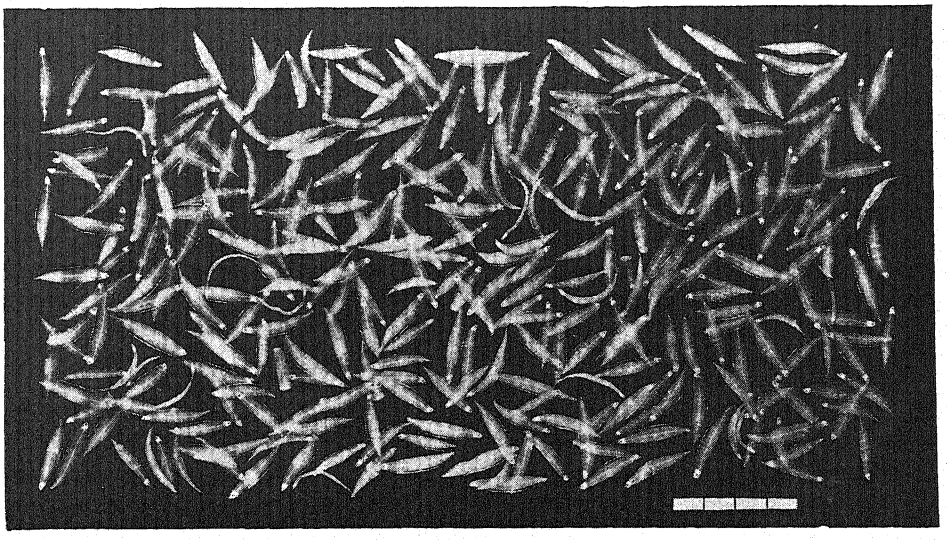

FIG. 2. Larvæ of the European eel from the Sargasso Sea. Note the small size and the uniformity of the larvæ. Scale shows centimetres.

which demonstrate in truly remarkable fashion how the concentrations of small larval eels are found in the deepest waters and how, even among the islands of Indo-Malaya, eels are not found at all on the coasts facing extensive areas of shallow water (Fig. 1).

Another important fact is that, just as the larval period of the North American eel, which has a less distance to travel, is appreciably shorter than that of the European eel, so the eels of Indo-Malaya, which Schmidt studied most intensively of the Pacific species, are still more rapidly metamorphosed. Although some of them reach a very much greater size than the European eel, their larvæ, both in the earliest and in the latest stages, are much smaller. Moreover, whereas in the Sargasso Sea a haul of eel larvæ will be all small and practically identical in size (Fig. 2), in the Mentawei Deep, west of and at no great distance from Sumatra, which is the spawning area of three species, they are found together at all stages of development, and, nearer to the coast, the larger larvæ and the elvers are found freely intermingled (Fig. 3).

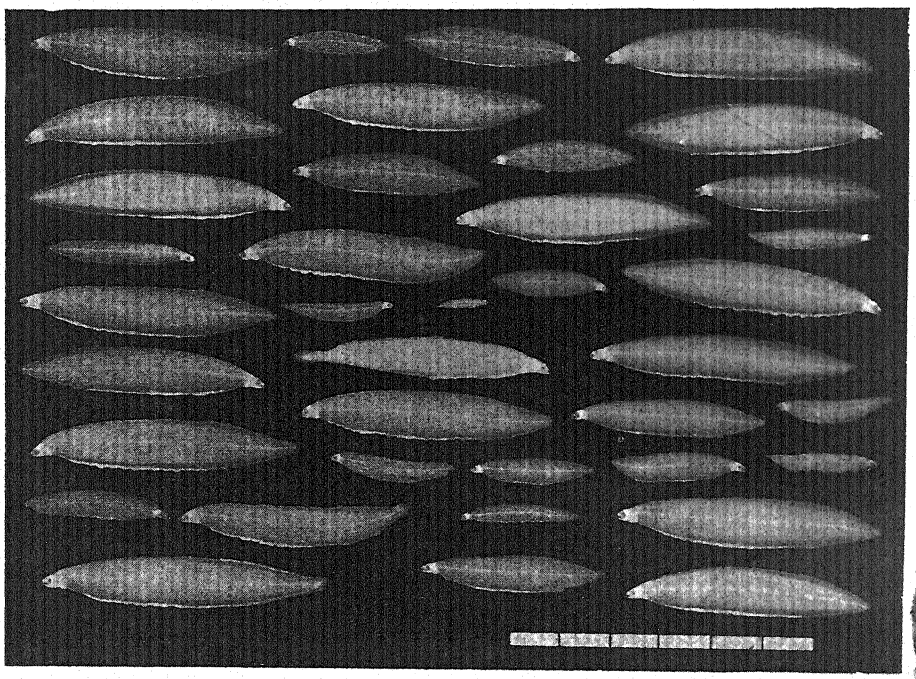

FIG. 3. Larvæ of freshwater eels from the Mentawei Deep, west of Sumatra. All stages of development are present. Scale shows centimetres.

Schmidt's most remarkable conclusion is that not only are all the fresh-water eels of tropical origin, but also that "the most westerly equatorial Pacific is the domicile of the Eel genus from which it has distributed itself over those parts of the world where conditions are favourable for it to thrive". Considering that no eels are found on the east or west coast of South America, and none on the west coast of Africa, it is difficult to reconcile with this conclusion the distribution, as proved by Schmidt, of the European and the North American eel, unless, indeed, one glances back in imagination over the ages to some remote, cataclysmic change of the earth's crust and of the distribution of the oceans.

One may hesitate to accept without question such a far-reaching conclusion, but one cannot read this paper without renewed admiration for Schmidt's genius. In particular, the thoroughness with which he did his work, and the forethought with which he laid his plans are remarkable. From 1922 onwards, thousands of eels from all parts of the world were examined at Copenhagen, with the view of obtaining information as to the distribution of each species and such knowledge of the adult eels as would facilitate the recognition of their larval forms. In 1926, Schmidt himself visited Australia, New Zealand and Tahiti, for the purpose of completing his records. Not until he was satisfied that he had thoroughly charted the distribution of the eels in fresh water did he embark upon his round-the-world expedition, the chief purpose of which was to chart their spawning places in the sea, and thus, while elucidating their life-history, to throw a new light on the European species, chiefly distinguished from its relations of the Pacific and Indian Oceans by its amazing instinct for travel.

Obituary

Prof. J. Goodman

JOHN GOODMAN, who died on October 28, was born on May 1, 1862, at Royston, Herts, receiving his school education at Gravesend and Cambridge. His engineering training followed the orthodox lines of that period—a long apprenticeship of five and a half years, followed by a spell of two years as an assistant to the chief engineer. During this period, by attendance on evening courses and private study, he acquired such a sound knowledge of the scientific principles upon which engineering is based that he was able in 1885 to win a Whitworth scholarship, and entered University College, London, when the chair of engineering was held by Sir Alexander B. W. Kennedy, and in 1886 he became an assistant to his professor.

A short period of service as chief assistant in the Broadway Testing Works, Westminster, was closed by Goodman's appointment in 1890, at the early age of twenty-eight years, to the chair of civil and mechanical engineering at the Yorkshire College, Leeds (now the University of Leeds), in succession to Prof. Archibald Barr, who had been appointed to the chair of engineering at Glasgow. Goodman held this chair for thirty-two years, and, when he resigned in 1922, was made emeritus professor, and was given special accommodation in the University Engineering Laboratories to enable him to carry on the research work which had always been such an important feature of his university work.

Prof. Goodman was an ideal engineering professor, a fluent, lucid lecturer, able always to maintain the interest of his students, and much beloved by them for his deep interest in the social side of their university careers, and by the special efforts he always made to assist them in securing a start in the practical side of their profession. His output of research work was remarkable in view of the amount of teaching work he undertook; the results of these researches, very largely in the field of lubrication of bearings, on the design of roller bearings, on anti-friction metals, and the stresses in crane hooks, etc., were published in numerous papers in the *Transactions* of the Institutions of Civil and Mechanical Engineers. The Institution of Civil Engineers, to which he was elected in 1887, becoming a full member in 1900, awarded him a Miller scholarship and a Telford premium; he became a full member of the Institution of Mechanical Engineers in 1890. Apart from these papers dealing entirely with the results of research work, Goodman was the author of a well-known textbook—"Mechanics applied to Engineering"—which has gone through several editions, and has been recognised as a standard work for the young engineering student.

During the Great War, Goodman was attached to the Royal Air Force with the rank of major, and did valuable work in the field of aircraft construction. He was never married. T. H. B.

Sir Temistocle Zammit, C.M.G.

WE regret to record the death, which occurred on November 2 at the age of seventy-one years, of Sir Temistocle Zammit, formerly rector of the University of Malta.

Temistocle Zammit was born in Malta in 1864 and educated at the local university, where he took the degree of M.D. in 1889. Entering the service of the Government of the island as an analyst, he became a member of the commission appointed by the Colonial Office and the Royal Society to investigate malaria. In 1904 he represented the Government on the Mediterranean Fever Commission, and in the following year became professor of chemistry in his University. To him was due the discovery which led to the recognition of the organisms of Malta fever in the blood of the native goat, and in 1908 he became a member of the Commission appointed to combat this disease. For the remainder of his life, such time as could be spared from his other pre-occupations was given to research in this direction. From 1920 until 1926 he was rector of the University. He was a member of the Council of Government and of the Executive Council of Malta. He received the Mary Kingsley Medal of the Liverpool School of Tropical Medicine in recognition of his services in medical research.

While Zammit's services to medical science were widely recognised among members of his own profession, he was far more widely known as an archæologist, more especially for his contributions to our understanding of the obscure archæological problems in the prehistory of Gozo and his native island. After he had been appointed curator of the Malta Museum in 1903, he discovered and excavated the neolithic temples of Tarxien and Imgiar, and took in hand and completed the excavations already begun in the other subterranean temples of Malta. In 1926, after his retirement from the rectorship of the University, he became director of the enlarged Museum Department, and brought together and arranged a remarkable exhibit of Stone Age antiquities such as is unsurpassed elsewhere. It is entirely owing to his enthusiasm and knowledge that the antiquities of Malta have been made more accessible and more easily intelligible to the visitor to the island, whether archæologist or layman, than in any other European centre of archæological interest. Under his editorship, the official publications of the Department became a valuable source of first-hand information. He was the author of "Malta, the Island and its History" (1926) and "The Neolithic Temples of Tarxien" (1930), indispensable to the student of the early history of the Mediterranean.

The honorary degree of D.Litt. was conferred on Zammit by the University of Oxford in 1920. He was made a C.M.G. in 1911 and knighted in 1930. He was also an honorary fellow of the Royal Anthropological Institute.

News and Views

Nobel Prize for Physics: Prof. J. Chadwick

THE award of the Nobel prize for Physics for 1935 to Prof. James Chadwick and that of Chemistry for 1935 to M. and Mme. Joliot-Curie are associated with two of the most important discoveries of recent years, that of the neutron and of artificial radioactivity. Prof. Chadwick worked in Lord Rutherford's laboratory, and M. and Mme. Joliot-Curie in that of Mme. Curie, and it will be felt by all how fitting it is that these two latest awards should be connected in this way with the two great founders of nuclear physics. In 1919, Prof. Chadwick went with Lord Rutherford to Cambridge from Manchester, where he had taken his degree and worked before the War. His first research in the Cavendish Laboratory, on the scattering of α-particles, still remains one of the most important direct determinations of the nuclear charge of the elements. Then for many years he worked in collaboration with Lord Rutherford on the artificial disintegration of the elements by α-particles. These fundamental researches really laid the foundations on which modern nuclear physics is built. The scintillation method of counting the particles was the only certain method available at that time, and further advance was checked by its limitations. Prof. Chadwick was intimately connected with the development of electrical methods of counting, and applied them to a detailed study of the disintegration of some of the light elements. These investigations were of the highest importance since they yielded precise information about the nuclear energy levels.

WHEN M. and Mme. Joliot-Curie reported the anomalous behaviour of certain radiations emitted in the transformation of beryllium by α-particles, Prof. Chadwick was able in a very short time to carry out a brilliant investigation which showed, beyond doubt, that the neutron had at last been detected. The possibility of such a particle had often been discussed, and as early as 1922 experiments were made in the Cavendish Laboratory in the hope of finding something of this nature. In his first communication, Prof. Chadwick gave quite an accurate estimate of the mass of the neutron, and with various collaborators began a thorough investigation of its properties, particularly that of its power to disintegrate other elements. Recently, by investigating the disintegration of the deuteron by γ-rays, he has obtained what is generally accepted as the most dependable value for the mass of the neutron. The importance of the discovery of the neutron may best be realised when it is remembered that it has changed completely and simplified our ideas of the structure of nuclei.

Nobel Prize for Chemistry: M. and Mme. Joliot-Curie

M. AND MME. JOLIOT-CURIE have long been distinguished for their work in various branches of radioactivity. After the discovery of the positive electron, they made several investigations of its mode of production, and quite early concluded that it could be formed in some manner other than by the action of γ-rays. In particular they observed positive electrons to accompany neutrons in the disintegration of certain light elements by α-rays. Further investigation of this led them to the striking discovery that while the neutrons were emitted simultaneously with the bombardment by the α-particles, the emission of positrons was an entirely separate process occurring after the source of α-particles had been removed. By a variety of experiments, they were able to show that they had formed new radioactive bodies, and in many cases they were able to verify the chemical nature of the substances by using their radioactive properties as an indicator. This is a discovery of fundamental importance, and has provided a new and powerful method of investigating the transmutations of bodies. In the last year this work has been much extended by the proof that the neutron is very effective in forming new radioactive bodies, and both these and all other investigations have only tended to increase the importance of this new phenomenon, which in addition to furnishing many new isotopic species, promises to throw great light on the true nature of radioactivity.

Medal Awards of the Royal Society

HIS MAJESTY THE KING has approved of the awards this year by the president and council of the Royal Society in respect of the two Royal Medals to Prof. C. G. Darwin, Tait professor of natural philosophy in the University of Edinburgh, for his researches in mathematical physics, especially in the quantum mechanics of the electron and in optics, and to Dr. A. Harker, emeritus reader in petrology in the University of Cambridge, in recognition of his distinguished work and influence as a petrologist. The following awards of medals have also been made by the president and council: Copley Medal to Prof. C. T. R. Wilson, emeritus professor of natural philosophy in the University of Cambridge, for his work on the use of clouds in advancing our knowledge of atoms and their properties; Davy Medal to Prof. A. Harden, formerly head of the Department of Biochemistry of the Lister Institute, for his distinguished work in biochemistry and especially for his fundamental discoveries in the chemistry of alcoholic fermentation; Hughes Medal to Dr. C. J. Davisson, of the Bell Telephone Laboratories, New York, for research resulting in the discovery of the physical existence of electron waves through long-continued investigations on the reflection of electrons from the crystal planes of nickel and other metals.

New Officers of the Royal Society

THE following is a list of those recommended by the president and council for election to the Council of the Royal Society at the anniversary meeting on

November 30: *President*, Sir William Bragg; *Treasurer*, Sir Henry Lyons; *Secretaries*, Sir Frank Smith and Prof. A. V. Hill; *Foreign Secretary*, Prof. A. C. Seward; *Other members of Council*, Prof. E. D. Adrian, Mr. D. L. Chapman, Prof. A. W. Conway, Dr. W. H. Eccles, Prof. A. S. Eve, Prof. L. N. G. Filon, Dr. J. Gray, Sir Daniel Hall, Dr. S. W. Kemp, Sir Patrick Laidlaw, Sir Gerald Lenox-Conyngham, Prof. G. T. Morgan, Prof. R. Robison, Dr. Bernard Smith, Prof. W. Stiles, Mr. W. Trotter.

Dr. P. Kapitza's Apparatus and the U.S.S.R.

A REPORT published on November 19 in the *Cambridge University Reporter* gives an account of a proposed arrangement for the transfer of apparatus from the Royal Society Mond Laboratory at Cambridge to a new laboratory which is being built for Dr. P. Kapitza in the U.S.S.R. It will be remembered that Dr. Kapitza was refused leave to return to England after his visit to Russia in September 1934. In the report of the Committee for the Laboratory, it is pointed out that much of Dr. Kapitza's work in Cambridge had been preliminary to the experiments with strong magnetic fields at the temperature of liquid helium which he was on the point of beginning before he left for Russia, and that members of the Laboratory would not care to take up these experiments if Dr. Kapitza wished to resume work at once in this field. It is therefore suggested that the large generator for the production of strong magnetic fields, together with its associated apparatus, should be sold to the Government of the U.S.S.R. for the use of Dr. Kapitza. The remainder of the apparatus in the Laboratory, including the apparatus for the production of liquid hydrogen and liquid helium, would not be transferred since it is in constant use and will be required for the future work of the laboratory. It is proposed, however, to supply duplicates of this apparatus for transfer to Russia, so that Dr. Kapitza will have equipment identical with that he had developed in Cambridge. With the sum received for this apparatus it is proposed to buy new equipment suitable for the future work of the Laboratory. Such equipment might include a large electromagnet which could be used for nuclear research or for the production of low temperatures by the method of adiabatic demagnetisation.

Prof. Ejnar Hertzsprung

IN connexion with the recent announcement that Prof. Ejnar Hertzsprung, professor of astrophysics in the University of Leyden, and assistant director of the Leyden Observatory, has been appointed director of the Observatory to succeed the late Prof. W. de Sitter, it may be recalled that Prof. Hertzsprung was awarded the Gold Medal of the Royal Astronomical Society in 1929. Prof. Hertzsprung's work covers an extremely wide range of astronomical subjects, and he has contributed to our knowledge in nearly every branch of the science. In particular, he is known for his work on double stars and on the clusters. The mass luminosity relation, the division of the late type stars into giants and dwarfs, and the connexion between absolute magnitude and spectral type (the famous 'seven diagram') are all associated with his name (together with that of Prof. H. N. Russell, of Princeton). He will have as his assistant director at Leyden, Dr. J. Oort, who is also well known in Great Britain, chiefly on account of his work on galactic rotation.

"Everyday Science" and Civil Service Examinations

FOR several years "Everyday Science" has been one of the obligatory subjects of the competitive examinations for the important administrative group of Government services, comprising the Indian and Ceylon Civil, the Foreign Office and Diplomatic, the Consular and Overseas Trade (Intelligence Officer) and Home Civil (Junior Grade of the Administrative Class). We notice with astonishment and regret, therefore, the announcement of the Civil Service Commissioners that, with effect from next year, the subject will be omitted; some *optional* questions on science will be included under the subject "Present Day". The scope of the "Everyday Science" paper, now to be discontinued, is indicated by the following passage: "Such knowledge will be expected as candidates will have who have studied science intelligently at school and have since then kept their eyes open. A liberal choice of questions will be given. Attention should be paid to orderly, effective, and exact expression". The other parts of the obligatory section of the examination are: Essay, English ("to test the understanding of English and the workmanlike use of words"), "Present Day" (being questions on contemporary subjects, social, economic and political, calling for effective and skilful exposition), auxiliary language and viva voce. The inclusion of "Everyday Science" must have exerted an influence on school and college courses, and its omission will be regretted by many who believe in the value of "general science" teaching in schools and hold it to be plainly wrong (to quote the words of Mr. C. M. Bowra in *Time and Tide's* recent university supplement on "More and More of Less and Less") that highly educated men should know next to nothing of the structure of the universe or of their own bodies.

Royal Institution: Legacy of the late Mr. Harry Brown

FROM a statement recently issued by the Managers of the Royal Institution, it is understood that the munificent bequest to the Institution by the late Mr. Harry Brown, of the residue of his estate, reported in April last, is expected to amount to approximately £28,000. This large sum has been given without restriction as to its use, but the Managers hope to apply it mainly to the extension of experimental research, one of the two principal objects of the Institution's work. Shortly after information as to the legacy had been received, the freehold of 19 Albemarle Street, immediately adjoining the Davy Faraday Research Laboratory and the rest of the Institution's buildings, came into the market. With the double object of investing Mr. Brown's legacy and providing for future extensions of the premises, it was resolved to purchase the property. The

purchase has now been completed. For the present, the Institution will use the top two floors of the new house for storage of books and apparatus, releasing valuable accommodation elsewhere for other purposes. It is proposed to let the lower floors, and to devote any income obtained to research purposes. Eventually, as the research activities are enlarged, it may prove necessary to occupy a larger part of the house.

Royal Institution: Reconstruction of the Library

ABOUT April last it was noticed that a sinking had occurred of the ceiling of the Library on the first floor at the Royal Institution, and of the floor of Sir William Bragg's rooms immediately above. The ceiling, which was old and of timber construction, was found to be defective. It was temporarily propped, and at the end of the lecture season a thorough examination was made. An astonishing state of disrepair was discovered. Not only was the heavy timber ceiling defective, but also the brick walls upon which it was supported were cracked and broken in all directions. The examination was carried down to the rooms on the ground floor and here a similar state of affairs was revealed. When in 1799 the Royal Institution was founded, a large town house was purchased and considerably altered to suit its new purpose. Further alterations have been made at intervals. Vulliamy added the Corinthian column front in 1837. In 1930 a large part of the building, including the lecture theatre, was completely reconstructed, but the Library and rooms below it were left untouched. These it has now proved necessary to rebuild, largely, it must be said, due to faulty workmanship in the past, as the various alterations to the structure have been made.

THE reconstruction is now in progress. The defective brickwork of the walls is being replaced, including that of the front wall, which is being worked at from the inside, so that the elevation to Albemarle Street will remain untouched. New fire-resisting floors are to be supported on a steel structure, which is being erected within the walls. The steelwork, the foundations for which are being carried to basement level, will also serve to strengthen the rebuilt walls. When completed, the rooms on the first and second floors will appear much as they were before, but advantage is being taken of the alterations to construct a large new research laboratory in the basement. The work is expected to be completed about April next, and it is understood that it will cost about £12,000.

November Floods

THE past week or so has been characterised by rains and floods of exceptional severity, extending over a widespread area in western Europe, including the Rhone Valley, the Riviera, parts of Switzerland and of Great Britain. At Avignon, in the south of France, a large section of the town was inundated in places to depths of so much as six feet, and the famous Pont d'Avignon has been seriously damaged. At Nîmes, the Rhone reached the record height of 26 feet, and about 125 square miles of the valley were submerged. As an unfortunate consequence of so disastrous a visitation, there has been much distress and several deaths among the inhabitants of Provence and Languedoc. One village, Aurlot, near Marseilles, has been almost destroyed, whilst in various districts, thousands of people have been rendered homeless. Damage has also been reported from Fréjus and Hyères. In Switzerland, wide areas near Geneva have been under two feet of water, and it is stated that no such floods have been recorded since so far back as 1890. The rainfall was particularly persistent and lasted without intermission for sixty hours.

IN Great Britain, inundations of considerable tracts have followed locally unprecedented rainfalls for November, the first seventeen days of the month having yielded about twice the amount of rain normally experienced at a number of places in the south of England. Flooded districts are reported from Swanage in Dorset and many parts of Kent and Sussex, while in the Midlands, the River Trent has overflowed its banks. The Thames valley has also been seriously affected. Presiding at the meeting of the Thames Conservancy Board on November 18, Lord Desborough, the chairman, said that the state of the river was causing some anxiety. The flow was exceeding the 'root figure' (when the river is flowing bank high) by a thousand million gallons daily. The 'root figure' for the discharge of the river is 4,500 million gallons a day measured at Teddington; the comparable November average is 1,486 million gallons a day. The rainfall in the Thames Catchment Area had been quite exceptional for the time of the year. In September, there was a rainfall of 4·59 inches; in October, 4·09 inches and for 17 days of November, 4·11 inches. The total for two and a half months was 12·79 inches. Looking back over previous records, Lord Desborough said he had not been able to trace a similar case. The unexpected and catastrophic occurrence of such floods serves to emphasise the importance of the national inland water survey, so repeatedly advocated in NATURE, and now in the hands of a committee of the Ministry of Health, appointed nearly a year ago, under the chairmanship of Sir Henry Lyons. It is obvious that only by accurate and reliable records of floods can adequate precautionary measures be devised and undertaken so as to remove a serious menace to life and property.

Brauner Memorial Lecture

FROM the time of the founding of the University at Prague in 1347 by Charles IV, Bohemia has been an important centre of learning. Komenský, Purkyně and Mendel all attained fame beyond the frontiers of their country, but the first Czech chemist to gain world-wide recognition was Prof. Bohuslav Brauner, who died on February 14 of this year. He had been a student at Manchester under Sir Henry Roscoe in the 'eighties, and whilst in England began some of his famous researches on the rare earths. He came to acquire an international reputation also by his advocacy of Mendeléeff's Periodic Law, to the

substantiation of which he directed his investigations, especially his redeterminations of atomic weights. He was elected an honorary and foreign fellow of the Chemical Society soon after the Great War, and the Society's Brauner Memorial Lecture was delivered by Dr. S. I. Levy on November 14. Dr. Levy has himself contributed to our knowledge of the rare earth elements and he was able to give a very lucid account of the way in which these very similar and difficultly separable bodies were isolated and identified as pure substances. Brauner's share in this work was very great, and is all the more noteworthy since it was very largely performed in adverse circumstances, for it was not until 1903 that the chemical institute of the Charles University of Prague was erected, largely as a result of Brauner's insistent pleas.

FROM his exhaustive researches, which led, among other things, to the fractionation of didymium into praseodymium, neodymium and samarium, Brauner came to the conclusion that the rare earth elements from lanthanum to lutecium should be placed together in the Periodic Table. Brauner's other contributions to chemistry include his work upon the compounds of cerium and tellurium, concerning the homogeneity of which he was for a long while doubtful. It is interesting to note that some of his atomic weight determinations, even those of forty years ago, remain the accepted standards even to-day. It has perhaps never been generally realised how great his contributions were to the fundamentals of inorganic chemistry. Few of Brauner's original British friends remain. They include Mr. W. Macnab, who came to move the vote of thanks to Dr. Levy, and who recalled how Brauner's fine physique and unconventional, friendly manner always attracted admiration. Reference was made by Dr. G. Druce in seconding the vote of thanks to Brauner's interest in the transcription of Russian names into English, concerning which he had written several times in NATURE, and to the rapid progress in scientific research in many fields at Czechoslovak universities, largely as a result of Brauner's inspiring influence and example.

Anatomy Department of St. Thomas's Hospital

IMPORTANT alterations and additions to the Anatomy Department of St. Thomas's Hospital Medical School, London, have just been completed, and an "At Home" was held in the Department on November 14 when it was visited by representatives of the universities and of various London hospitals. Three new research laboratories and a large radiological laboratory, together with a director's room and an office, are housed in the new block. The dissecting-room has been completely renovated, and a new terrazzo floor has been laid. The museum has been equipped with special lighting arrangements for the exhibition of lantern-slides, X-ray negatives, bottled specimens and models. The X-ray equipment is of the latest pattern, and is completely shock-proof, and will serve not only for the instruction of students in all normal radiological appearances but also for research. An optical bench for photomicrography and for the reduction of X-ray negatives has also been accommodated in the radiological laboratory, adjacent to which is a dark-room. The research laboratories are situated in the upper floor of the new block. They are magnificently lighted, and are furnished throughout with the most modern fittings. The visitors were afforded an opportunity of seeing some of the results of experiments which are being carried out in the Department in the use of the cinematograph for the teaching of anatomy. A composite film comprised portions of films showing respectively a dissection of the forearm, some examples of muscle-nerve paralyses, the surface anatomy of normal shoulder movements and a dissection illustrating the mechanism of the knee-joint. This Department is admirably fitted for the teaching of anatomy by modern methods, with emphasis on the study of living anatomy.

Sir James Walker and the University of Edinburgh

To commemorate the services of Sir James Walker, professor of chemistry at the University of Edinburgh from 1908 until 1928, to chemistry in general and to the Chemistry Department of the University of Edinburgh in particular, it is proposed to establish a fund for a Walker Memorial Lecture to be delivered annually by an eminent chemist invited to Edinburgh by the Edinburgh University Chemical Society for that purpose. Sir James Walker, who died in May of this year, was the leading exponent of physical chemistry in Great Britain for nearly fifty years. During the Great War he did valuable work in the manufacture of high explosives, and the new chemical laboratories which he designed and fitted up at Edinburgh are among the foremost, both in equipment and in research activity, in Great Britain. The Chemical Society of the University of Edinburgh enjoys the distinction of being the oldest chemical society in the world, since it has recently been established that it existed as far back as 1785 under the sponsorship of Joseph Black. It is felt that a yearly meeting at which the student members of this body may have the opportunity of making direct contact with the researches of distinguished investigators in chemistry from other universities will provide a most stimulating permanent memorial of the labours of Sir James Walker for the advancement of the science in Edinburgh and elsewhere. Former students of Sir James Walker and any others who may wish to assist in the project are invited to send contributions to Mr. J. E. Rocca, honorary secretary of the Edinburgh University Chemical Society, King's Buildings, West Mains Road, Edinburgh.

Memorial to Viscount Grey of Fallodon

LORD ARMSTRONG, president of the Natural History Society of Northumberland, Durham and Newcastle-upon-Tyne, has issued an appeal for subscriptions towards a permanent 'North Country' memorial to commemorate the life of Viscount Grey. It is proposed to place a tablet to the memory of the great statesman and bird-lover in the Hancock Museum and to found a trust fund, the income of which will be applied to the endowment of the Museum. This

is a purpose which Lord Grey himself would have applauded, for he took much interest in the Museum, and was concerned about the upkeep of the many valuable and historically interesting collections which it contains. The Museum itself was built in 1884 to house the natural history collections of the Society, and with subsequent additions it has cost approximately £45,000. But the cost of upkeep and staffing is more than the Society can bear, even although the membership is now greater than at any time during the hundred and six years of the Society's existence. A sum of £1,000 has been promised anonymously if three other donors are each prepared to subscribe a similar amount, but it is to the generosity of the many lovers of Nature, and particularly those of the north of England, that Lord Armstrong and the Society look for the safeguarding of the Museum and its collections.

Explorations in Ellesmere Island

THE Oxford University Arctic Expedition of 1934–35 under Dr. N. Humphreys was forced to winter at Etah in north-western Greenland instead of on Ellesmere Island; but during the summer of this year they split up into small parties, each accompanied by Eskimo, and explored various parts of the north and centre of Ellesmere Island. Three articles on their work have appeared recently in *The Times*. An attempt to cross the Grinnell Land ice-sheet failed, but a crossing was made to the south by the narrow isthmus between Flager and Bay fjords, thus linking up with Isachsen's former work on the west coast. A more important journey was made in Grant Land from Fort Conger, Greely's camp of half a century ago, via Lake Hazen to the lofty United States Range. From a summit of 9,000 ft. there was a good view clear to the north. The country seems to be entirely mountainous and difficult to cross. The lofty ranges to the northward were named the British Empire range. They appear to flank the northern side of Ellesmere Island, and their relation to the Challenger Mountains farther west, discovered in 1876 by Aldrich, will be of interest when revealed. These mountains are probably related to the Caledonian foldings of northern Greenland. A third party carried out some surveys in Scoresby Bay, which hitherto had been inadequately examined. The expedition returned to England in October bringing large collections.

Organisation of the Coal Industry

SIR HAROLD HARTLEY, addressing the Institution of Chemical Engineers on October 20 on "Our Nation's Coal Resources", surveyed the changes which, during the last twenty-five years, have so profoundly affected the prosperity of the British coal industry. He pointed out the need which has been disclosed for the National Coal Survey undertaken by the Fuel Research Board, and stated that the value of the work of the Survey is becoming more obvious as it progresses. He advocates extending the Survey to examine the suitability of coals for the different industrial purposes, so as to discover where need for conservation exists. Fuel economy in utilisation and other circumstances have reduced the production of coal; but methods of mining have made great progress, and both circumstances reduce the number of mine workers. Methods of transportation and distribution have not kept pace with the improvement with the methods of mining. Sir Harold condemned the widespread ownership of private waggons as a burden on cost of distribution and advocated a unification of interests at least up to the point at which coal is to be transferred to the consumer. A rational system of grading should replace trade practice of selling by description. Intensified research on the fundamental nature of coal was urged, and indeed the factors which seem to Sir Harold most promising are more research and better organisation. The latter may be unpalatable to some individualists, but seems to be inevitable.

The Press and the Post Office

IN the course of an address to the Post Office Telegraph and Telephone Society given at King George V Hall, St. Martin's le Grand, London, on November 18, by Mr. J. H. Brebner, press officer of the Post Office, it was emphasised that the development of the Press has been closely allied to the progress of the Post Office. The Post Office can claim a great share in the development of newspapers, for from its establishment, six postal officials entitled 'clerks of the roads' were the first newsagents in Great Britain, and were solely responsible for the distribution of newspapers to all parts of the United Kingdom. These 'clerks of the roads' derived some £8,000 a year from the sale of newspapers, £6,000 of which was used by the Post Office for the payment of pensions and increases of salaries to Post Office servants who were inadequately paid. At the beginning of the nineteenth century, the private telegraph companies maintained a press bureau which supplied the newspapers with general news. The newspapers, however, desired to organise their own press agencies on the ground that they were the better judges of the news the public required. Since the telegraph companies would not give up their press bureau, the newspaper proprietors joined the growing agitation for the nationalisation of the telegraph system. The Electric Telegraphs Bill was passed in 1868, and the State accordingly acquired the telegraphs. A special 'News Division' was created at the Central Telegraph Office, London, and was maintained until 1930, when the extended use of the telephone by the Press, and the leased telegraph lines to press agencies and newspapers, rendered this section with its special press wires unnecessary. The Press has taken full advantage of each step in the progress of communications brought about by the Post Office, and the rapid development of the telephone service, since its acquisition by the State in 1912, has enabled the speedier transmission of news not only from all parts of Great Britain, but also to and from all parts of the world.

Imperial Chemical Industries, Ltd.

MR. JUSTICE EVE has allowed the petition of Imperial Chemical Industries, Ltd., to confirm a

reduction of capital from £95,000,000 to £89,565,859, the petition being opposed by a committee representing more than 13,000 holders of Deferred shares. In evidence, Sir Albert Wyon, chartered accountant, agreed that the company is spending large sums of money on research which have yielded valuable returns. These returns appear in the accounts in the shape of increased revenue. In this connexion, it is of interest to recall that, when this great combine was formed, NATURE, in a leading article (January 29, 1927, p. 149), stressed its importance from the point of view of scientific research: "Of special interest, fully recognised by the promoters of the trust, is the question whether it will be possible to improve methods and results in scientific research. The record of the constituent companies in this respect is creditable enough, and the work they accomplished during the War earned the gratitude of the nation. But combination must tend towards greater economy and greater efficiency."

Cornish Engines Preservation Fund

CORNWALL occupies a unique place in the industrial history of Great Britain, owing to its contributions to the advancement of mining and the development of the steam engine. The natural pride Cornishmen take in the achievements of the inventors and engineers of the county has found expression in various ways, and a scheme has now been set on foot for preserving, before it is too late, some of the few remaining Cornish beam engines. At a meeting held at Murdock House, Redruth, on October 15, a committee was formed to further the scheme, and an appeal has been made for funds for the purchase of a winding engine at Levant Mine, designed nearly a century ago by Francis Mitchell, and probably constructed at Copperhouse Foundry, Hayle. The engine, which is of the beam type, has a cylinder 24 in. in diameter with a stroke of 4 ft. As the mine, after a life of 110 years, has been closed down, the engine can be purchased at scrap value and arrangement can be made for its preservation *in situ* with a right of way to it, the total sum required for the purchase of the engine, repairs to the engine house and for maintenance being estimated at £300. The honorary secretaries to the committee are Mr. W. T. Hooper, of Falmouth Observatory, and Mr. W. A. Michell, Couch Lane, Redruth, while the honorary treasurer is Mr. H. Michell, of Barclays Bank, Falmouth, to whom subscriptions should be sent.

Quarterly List of Scientific Books

THE Association of Special Libraries and Information Bureaux, 16 Russell Square, London, W.C.1, has recently issued a book list which is the first of a series of quarterly recommendations of recently published scientific and technical books (10*s*. 6*d*. a year for non-members). The main object of the list is to provide public and other libraries with a selected list of recent scientific and technical books, and the list has been compiled with the assistance of more than sixty specialist organisations which are able to assess the relative merits of new publications in their own fields. Only books in the English language, and, with few exceptions, those published in the last six months, have been included. No attempt has been made to introduce detailed classification, the books being listed under broad main headings, such as General Science and Technology; Chemistry and Chemical Technology; Physics; Metallurgy; Medicine, Public Health and Nutrition; Communications and Transport, etc. The books are further sub-divided into those suitable for general readers, books of an intermediate character or suitable as textbooks for students, advanced or highly technical books, and dictionaries, directories or encyclopædias and the like. The lists should thus be of real value to specialist, as well as to public, librarians, in dealing with the difficult problem of book selection, particularly in fields of which the librarian himself has no special knowledge.

Maimonides

DR. M. GASTER delivered a lecture on "Maimonides and his Works" at a meeting on November 14 of the Royal Asiatic Society in conjunction with the Society for Old Testament Study. He said that Maimonides was a man of strong faith which deeply influenced his activity. Fully conversant with the Hebrew and Arabic literature of the time, he displayed a threefold activity. First, his legal activity consisted in compiling for the first time a comprehensive code of laws which has remained the basis of Judaism to this very day, and prevented it from splitting up into sects. Secondly, his medical activity was intended to prove, besides furthering and stimulating medical research, that there is no incompatibility between science and faith; indeed, that they assist one another. Thirdly, his philosophical activity was intended to reconcile the tenets of faith with philosophic speculation. He endeavoured to answer some of the fundamental problems of human life, such as the existence of God, the problem of creation, the relation between God and man, revelation, sin and evil, punishment and reward, and immortality. With slight modification, the answers which he gave retain their value even at the present time.

Sir John McLennan, K.B.E., F.R.S.

IN the obituary notice of Sir John McLennan published in NATURE of October 19 (p. 633), it was stated that he went from Toronto to Cambridge with an 1851 Exhibition Scholarship. Prof. A. S. Eve now informs us that this statement is not correct. Dr. E. F. Burton, who succeeded Sir John at Toronto, has written: "Although most of the men who were at the Cavendish with Dr. McLennan held 1851 Exhibition Scholarships, he did not have one himself. As a matter of fact, he resigned his position at Toronto in order to go abroad entirely at his own expense. It was in the nature of a gamble for him at that time as his resources were very meagre, but he realised that this was the only possible course to take if he wanted to work in what was then modern physics. He was undoubtedly moved to do this by the meeting of the British Association for the Advancement of Science in Toronto in 1897, as it was just after this that he went to England."

Midland Section of the Institute of Physics

THE second Local Section of the Institute of Physics to be formed in Great Britain was inaugurated at a meeting held at the University of Birmingham on Friday, November 15. Prof. S. W. J. Smith was elected chairman, and Dr. J. H. Mitchell, of the British Thomson-Houston Research Laboratory, local honorary secretary, from whom further details may be obtained. The inaugural lecture was given by Dr. J. D. Cockcroft, of the Cavendish Laboratory, Cambridge, who took as his subject "Recent Work on Nuclear Transmutations". It is proposed to hold the meetings of this new Section in Rugby and Leicester and possibly other towns in the Midlands during the session.

Forthcoming Eclipse of the Sun in U.S.S.R.

THE Academy of Sciences of the U.S.S.R. has issued a report ("Bulletin de la Commission pour les recherches du Soleil", 13) by Profs. Gerasimovič and Ščerbakova, dealing with the circumstances of the forthcoming total solar eclipse. The eclipse will take place on June 19, 1936, and the line of totality crosses the U.S.S.R. from the North Caucasus, over the Volga steppes, and over Siberia to the far eastern provinces. The track passes over both Omsk and Tomsk, which are of course large cities which will offer facilities to observers. In the present report, an account is given of the meteorological data which have been specially collected since 1933 at various stations along the track of totality, in order that prospective observers of the eclipse may have the best choice of stations likely to enjoy clear weather on the day of the eclipse.

Astronomical Spectrography

MESSRS. HILGER'S new catalogue of astronomical spectrographs and spectroscopes shows that this firm is maintaining its reputation for keeping abreast with the latest developments. Among the major instruments which it has recently constructed are the 3-prism spectrograph for the 36-in. reflector at the Royal Observatory, Edinburgh, and the spectrograph for the 74-in. reflector at Toronto. The first of these follows the general design of that at the Dominion Observatory, Vancouver, but contains many improvements; the second is designed for radial velocity work with a single prism and has a special mounting designed to reduce flexure to a minimum. The firm has also made a slitless spectrograph for the Royal Observatory, Greenwich, following a design of Mr. C. R. Davidson. Messrs. Hilger now offer as standard productions a spectroscope for observing solar prominences designed by Mr. J. Evershed, and a direct-vision constant deviation monochromator recently designed by Prof. H. H. Plaskett.

Announcements

PROF. F. G. DONNAN, professor of chemistry in the University of London and director of the Chemical Laboratories, University College, London, has been elected a foreign member of the Division for Chemistry of the Royal Physiographical Society of Lund (Sweden).

DR. C. E. K. MEES, vice-president in charge of research and development in the Eastman Kodak Co., Rochester, U.S.A., will deliver six Christmas Lectures "adapted to a juvenile auditory" at the Royal Institution on Saturdays, Tuesdays and Thursdays, commencing on December 28. The subject of Dr. Mees's lectures will be "Photography". Further information can be obtained from the Secretary, Royal Institution, 21 Albemarle Street, London, W.1.

A DISCUSSION on "Ice Ages", arranged by the Royal Meteorological Society and the Royal Astronomical Society, will be held on January 31 at 4.30 in the rooms of the Royal Astronomical Society, Burlington House, London, W.1. The discussion will be opened by Sir George Simpson.

THE Empire's Airway Exhibition at the Science Museum, South Kensington, organised by Imperial Airways, Ltd., will be opened by the Secretary of State for Air in the lecture theatre of the Museum at 11 a.m. on Thursday, December 5. The chair will be taken by Sir Eric Geddes.

THE Exhibition of Kinematography at the Royal Photographic Society, 35 Russell Square, W.C.1, is to remain open to the public until Saturday, November 30. The exhibition is mainly devoted to 'stills' from films. Some very fine photography is shown. A certain amount of apparatus is shown, notably that for recording and reproducing sound with 16 mm. picture film.

THE National Trust has accepted from the Viscountess Rhondda and the Dowager Viscountess Rhondda some 2,130 acres of the Sugar Loaf, just north of Abergavenny. This magnificent hill, which is well known in South Wales and Monmouth, is at the south end of the Black Mountains and rises to a height of nearly 2,000 feet.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A technical officer, an assistant (grade II) and assistants (grade III) for work in wireless equipment at the Royal Aircraft Establishment, South Farnborough, Hants—The Chief Superintendent (Nov. 29).

A University lecturer and a University demonstrator in biochemistry in the University of Cambridge—Sir F. G. Hopkins, Sir William Dunn Institute of Biochemistry, Cambridge (Dec. 7).

A research assistant to the Animal Diseases Research Association—The Secretary, Moredun Institute, Gilmerton, Midlothian (Dec. 20).

A Jacksonian professor of natural philosophy in the University of Cambridge—The Vice-Chancellor (Dec. 31).

A head of the silk section of the British Cotton Industry Research Association—Dr. R. H. Pickard, Shirley Institute, Didsbury, Manchester.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 837.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Intensity Variations in the Channel of the Return Lightning Stroke

PHOTOGRAPHY of lightning strokes with the Boys camera has shown that each separate stroke is of a dual nature, consisting of a leader and a return portion. It has been shown that the return stroke travels from ground to cloud, passing outwards along the branches when it reaches branching points of the leader. The charge on the leader branches passes in this manner to ground. It has also been shown that there is a marked diminution in the intensity of the light emitted from the main channel after the return stroke has passed a prominent branch.

The photographs also permit of the study of the manner in which the intensity at any point in the channel varies with time. It is found that this intensity at the ground end of the channel fluctuates in such a manner as to indicate a series of component discharges, all apparently passing upwards. A maximum number of six such components in the return stroke has been observed, but the components of high order are weak and not always clearly seen.

The time intervals between successive component discharges are indicated in the following table :.

Component	1	2	3	4	5	6
Separation from first appearance of luminosity in return channel (microseconds)	0	7 to 75	37 to 370	110 to 580	510 to 2,100	815
Cases observed		25	21	7	3	1

The ratio of the intensities of the different components has been obtained by photometric analysis of photographs specially taken with this purpose in view. Component 2 is of the same order of intensity as component 1. In a few cases it is found that at a point above a prominent branch it is actually more intense than component 1. Between component 1 and 2 the luminosity of the channel falls to less than half its previous value. If the intensity of component 1 is taken as unity, that of component 3 is of the order of 1/10 and that of component 4 of the order of 1/200. The subsequent components are too feeble for a satisfactory determination of their intensities.

There is some evidence that the second, and sometimes also the third, component is related to the existence of the charge distributed along the branches. In a number of cases the time intervals between 1 and 2 is of the same order as that required for 1 to reach the start of a prominent branch. Component 2 thus starts at the moment that this branch charge is beginning to disappear, suggesting that it is associated with the induced charge bound on the surface of the earth beneath the branch.

Where prominent branches do not exist, as in the case of strokes after the first, the second component in the return portion does not start until the first has reached the cloud.

The influence of these components upon the wave-form of the atmospheric radiated from a lightning flash is being investigated.

Our thanks are due to the Lightning Research Committee of the South African Institute of Electrical Engineers for permission to publish this report.

Radioactivity of some Rare Earths induced by Neutron Bombardment*

WE have studied the radioactivity produced by bombardment with slow neutrons in those elements of the rare earth group where the results of other workers are not in agreement.

The results are summarised below.

Compound	Half-period	Quantity used	Initial activity
Neodymium oxide	35 min. ± 5 min.	2 gm.	8 impulses per min.
Gadolinium oxalate	6·4 hr. ±0·3 hr.	14 gm.	16 ,, ,,
Dysprosium oxalate	2·5 hr. ±0·1 hr.	1 gm.	strong ,, ,,
Erbium oxide	5·8 min. ±0·2 min.	25 gm.	6 impulses per min.
	2·7 hr. ±0·2 hr.	25 gm.	very strong
Holmium oxide	2·6 hr.	0·01 gm.	very weak
Lutecium oxalate	3·6 hr. ±0·4 hr.	1 gm.	35 impulses per min.

The source of neutrons consisted of 500 mgm. of radium intimately mixed with 2 gm. of beryllium. The irradiation was carried out inside a block of paraffin wax 30 cm. high and 30 cm. in diameter.

The half-period of dysprosium and the long period of erbium were determined by means of an ionisation chamber and quadrant electrometer; this is a convenient method where strong activities of fairly slow decay are concerned. The remaining half-periods were found by means of a Geiger-Müller β-ray counter, with aluminium walls 0·2 mm. thick.

It was not possible to compare accurately the relative intensities of excitation, on account of the differences in the quantities and geometrical arrangements of the specimens of the rare earths. Nevertheless, an idea of the relative intensities can be gained from the additional information given in the table.

The half-period of 6·4 hr. obtained for gadolinium is in fair agreement with the value 8 hr. reported by Hevesy and Hilde Levi[1]. The half-period, 3·6 hr., of lutecium is close to the value 4 hr. given by Marsh and Sugden[2]. The short period of erbium reported by the latter authors has been carefully investigated

* Sir John McLennan died on October 9, but the observations here recorded were made with the joint author, Mr. W. H. Rann.—Editor, NATURE.

and found to be 5·8 min. The 2·6-hr. period observed in the case of erbium is probably due to traces of the strongly active element holmium, as was suggested by Marsh and Sugden[2].

Our thanks are due to the Union Minière du Haut Katanga for the loan of the radium used, and also to Messrs. Adam Hilger, Ltd., for the loan of a specimen of neodymium oxide.

'Extra' Electron Diffraction Rings

Dr. G. I. Finch and A. G. Quarrell[1] have reported many 'extra' rings in electron diffraction patterns from thin metal foils containing preferentially oriented crystals. At first they attributed these to diffraction from two-dimensional gratings made up of the atoms in the crystallographic faces through which electrons might leave the foil. In a later comprehensive paper, Finch, Quarrell and Wilman[2] have stated that the extra rings do not appear unless the metal foil is contaminated; the earlier explanation has been abandoned. In this later paper are given, however, the results of the calculations concerning diffraction by atoms in exit faces. This note is concerned solely with the results of such calculations.

It is worth pointing out that the extra diffraction rings cannot be explained in the manner first proposed. The case is one of face-centred cubic crystals oriented with a (110) direction parallel to the primary beam and to the surface normal. It was first proposed[1] that atoms in (111) and (120) exit faces were responsible for the extra diffraction rings. In the later paper[2], the exit faces were described as (110) and (120). The previous designation of an exit plane as (111) was clearly an oversight or typographical error, as it can be shown that a (111) plane of atoms would give rise to all the Debye-Scherrer rings for the oriented crystals, and to no extra rings.

In regard to scattering by atoms in a (120) plane when the primary beam direction is (110), one can show that there will result diffraction cones about the primary beam direction, the semi-apex angles of which are approximately equal to:

$$\frac{\lambda}{a_0}\sqrt{\frac{1}{9}(11h_1^2 - 8h_1h_2 + 8h_2^2)}.$$

Here λ represents the wave-length, a_0 the length of the edge of the unit cube of the face-centred structure, and h_1 and h_2 are any positive or negative whole numbers. The radical has the following series of values: 0·94; 1·11; $\sqrt{3}$; 1·89; $\sqrt{4}$; etc. The integers 3 and 4 correspond, of course, to the first two Debye-Scherrer rings. The extra rings corresponding to the other values are not those calculated by Finch, Quarrell and Wilman[2], and they do not agree with the extra rings observed.

L. H. Germer.

Bell Telephone Laboratories,
New York, N.Y.
Sept. 12.

[1] NATURE, 135, 183; 1935.
[2] *Trans. Faraday Soc.*, 31, 1074; September 1935.

The observed ring radii are given in the table below, col. 1, and the ring radii we attributed to scattering from a (110) exit face [(111) is obviously an error] in col. 2. In cols. 3, 4 and 5 are set forth the values calculated by Finch, Quarrell and Wilman, and by Germer using his approximate and accurate expressions respectively.

Table

1	2	3	4	5
0·99	1·00	0·98	0·94	0·9407
1·10	—	1·11	1·11	1·105
—	—	1·12	—	1·107
1·40	1·41	—	—	—
1·65	—	—	—	—
1·73	1·73	1·73	1·73	1·727
—	—	—	—	1·729
1·76	—	1·76	—	—
1·78	—	1·78	—	—
—	—	—	1·89	1·877
—	—	1·95	—	—
2·00	2·00	2·00	2·00	2·001

Germer's results are the more accurate; we evidently placed too much reliance on four-figure tables in working out results involving small angles. We had, however, to consider more than one plane and so preferred the more direct method of calculation indicated in our paper.

I may add that, even before the experimental discovery of the real origin of 'extra' rings, the 'exit face' idea had lost much in attraction when it was realised that any and every 'extra' ring could be accounted for by postulating a suitable exit face.

Pigments of the Bull Frog Retina

The substances and processes found in the retina and pigment epithelium of the bull frog, *Rana catesbiana*, are identical with those in species of frogs

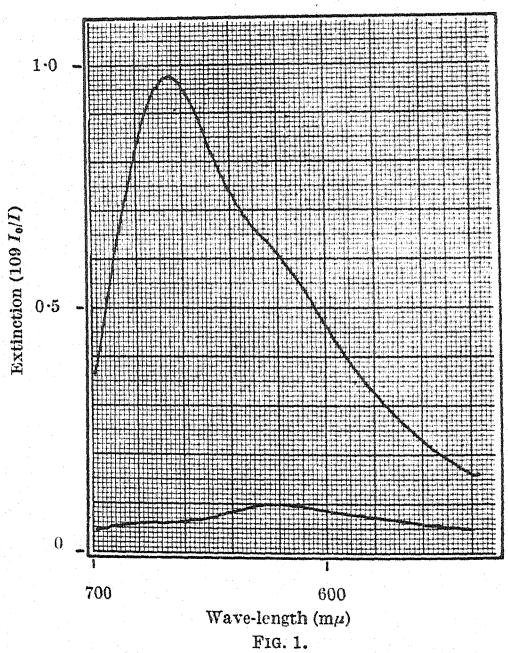

FIG. 1.

previously examined[1]. The retina contains varying amounts of the carotenoids retinene and vitamin A. Retinene is yellow, and when mixed with antimony trichloride reagent yields a sharp absorption band at

662–666 mμ. (In the hand spectroscope this band has invariably appeared to be at about 655 mμ, the position originally given.) Vitamin A is colourless in comparable concentrations, and in the antimony trichloride test yields a band at 612–615 mμ (crude extracts).

Dark-adapted retinas contain only a trace of vitamin A, which can be extracted in the dark with benzine without injury to the visual purple (Fig. 1, lower curve*). Afterwards, the same retinas may be re-extracted with benzine in bright light. Light bleaches visual purple to 'visual yellow', after which benzine readily extracts a large quantity of retinene (Fig. 1, upper curve). The destruction of visual purple in the dark with chloroform also liberates retinene (Fig. 2, upper series). Visual yellow appears

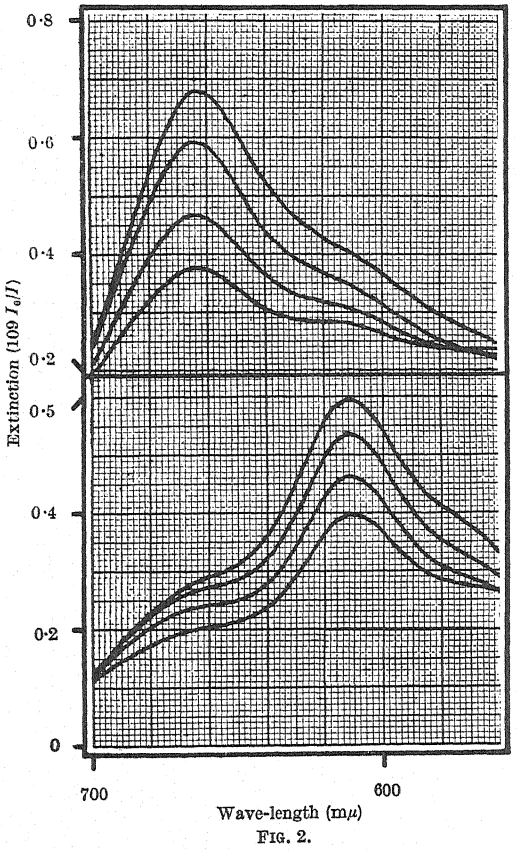

FIG. 2.

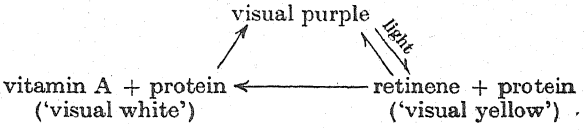
to be simply free retinene, liberated by light—or by chemical treatment—in the destruction of visual purple. (At the time of writing the previous report, I believed retinene to be bound complexly in visual yellow as it is in visual purple, a legitimate interpretation of the data then available.)

The retinene of bleached ('visual yellow') retinas is converted quantitatively to vitamin A by a thermal process which occupies about an hour in either light or darkness at 25° C. During this interval, the retinas fade from yellow to colourlessness. The lower curves of Fig. 2 show this change. They were obtained with retinas symmetrical with those which yielded the upper series, but had been bleached in bright light and allowed to fade for about an hour at 22° C. before being extracted.

In the isolated retina, vitamin A is the final product of the bleaching and fading reactions. In the intact eye, however, the vitamin is resynthesised to visual purple. This process completes the visual cycle, represented partly by the scheme:



Isolated bull frog retinas which have been bleached and wholly faded contain about 2·3 γ per eye of vitamin A. Retinas light-adapted *in vivo* contain only about 0·8 γ of the vitamin. This loss of vitamin A in the active retina probably accounts for the dependence of the visual purple system in some animals upon a continuous supply of vitamin A in the diet.

The combined pigment epithelium and choroid layer of the bull frog eye contain about 2 γ of xanthophyll and about 9 γ of vitamin A, at least 80 per cent of which are located in the pigment epithelium alone. An incomplete extract of these tissues also contained about 1·3 γ per eye of flavine, similar to that found by von Euler and Adler[2] in the eyes of several mammals and fishes.

Details of this work will appear in the *Journal of General Physiology*.

GEORGE WALD.

Biological Laboratories,
Harvard University,
Cambridge, Mass.

[1] G. Wald, NATURE, 134, 65; 1934. *J. Gen. Physiol.*, 19, 1935-36, in press.
[2] H. von Euler and E. Adler, *Z. physiol. Chem.*, 223, 105; 228, 1; 1934.

* Figs. 1 and 2 show spectra of antimony trichloride reactions with bull frog retinal extracts. They were measured at the Massachusetts Institute of Technology with a recording photoelectric spectrophotometer (Hardy, A. C., *J. Opt. Soc. Amer.*, 25, 306; 1935). The curves were drawn by the instrument, and have been merely mounted and photographed. The lower curve of Fig. 1 was drawn 5mμ too high in wave-length, due to a fault in calibration which was corrected before the upper curve was recorded. Each series of spectra in Fig. 2 presents successive measurements of a single antimony trichloride test, and ollows the fading of the blue colour produced in this reaction.

Statistical Tests

THE discussion in these columns which has followed Mr. Buchanan-Wollaston's letter in NATURE of August 3 tempts me, as yet a third member of University College, London, to try to express my views on an interesting, but evidently controversial, subject. Others besides myself have, I know, welcomed a reminder from the author of the "Grammar of Science" that, in the fullest sense of the terms, we are concerned not with the truth or falsehood of a hypothesis, but with the extent to which it graduates our observations of Nature. I fancy that if Mr. Buchanan-Wollaston were to consider specific examples he might find it a little difficult to substantiate the statement, made in his letter in NATURE of November 2, that hypothetical frequency distributions are of two radically different kinds. If I understand him correctly, he suggests, for example, that the Normal curve sometimes falls into one category, sometimes into the other. But can he really maintain that this distribution curve with its infinite limits for the variable is ever anything but a graduation formula?

Yet I agree that it is difficult to speak of all statistical analysis in terms of graduation. In

scientific research as well as in the affairs of every-day life, we are continually faced with situations where a decision must be made on incomplete data determining which of two alternative courses of action is to be followed. Since we may decide on course *A* when, with more complete information, we should have followed course *B*, and vice versa, two different faulty decisions may be made having very different consequences. A practical example is that of the large-scale purchaser of a certain mass-produced article, who has to decide after the inspection of a sample of limited size whether or not to accept a consignment of several hundreds of these articles.

In a very similar manner in scientific investigation a hypothesis is formulated and tested on observed phenomena. The scientific worker cannot tell whether the hypothesis is true or false, but if his investigation is to continue he must either accept the hypothesis provisionally as useful to him, or reject it as of no use and seek for an alternative hypothesis. Either decision may be one which he would not have made had much fuller information been available at the time, and in this sense may again be spoken of as liable to error.

The tools of statistical analysis have been fashioned to help the experimenter in this process of testing a hypothesis, and, as with all tools, their parts and uses must be described in a technical terminology. Further, as in other branches of applied mathematics, it is necessary to construct a precise but simplified model which we believe will represent the world that we observe with sufficient accuracy to provide us with useful results. Here there is freedom of choice.

Let me illustrate one method of approach by taking the case of a biochemist who is instructed to investigate, by experiments carried out on rabbits, whether there is any difference in regard to a certain reaction, between a new and cheaper form of insulin and an older standard form. Owing to the different response of individual rabbits even to the same treatment, it is the mean difference between effects that must be considered. Further, while no statistical test applied to a limited number of observations can be expected to detect very small differences, the test to be used should be one which is as sensitive as possible to the existence of a real difference, and yet will be unlikely to suggest a difference which is not there.

On the assumption that some decision, whether provisional or final, regarding the adoption of the cheaper insulin is to be based on the result of the experiment, the biochemist will probably report either that (*a*) there appears to be a difference, or that (*b*) he can detect no significant difference. In a purely formal sense, it is convenient to speak of these statements, leading to different decisions regarding further action, as (*a*) that of rejecting the statistical hypothesis that there is no difference in mean effect, and (*b*) that of accepting this hypothesis, and this is the sense in which these terms are used below. Further, it follows that statement (*a*) may have been made when more extensive experiments would show that the apparent difference was purely a chance sampling result, statement (*b*) when such experiments would establish a real difference. Thus again in formal language it is convenient to speak of a decision based on incomplete data as liable to two types of error.

In one case a cheaper form of insulin may be put on one side, at any rate temporarily, in the belief that it is of inferior quality, where fuller experiment would have shown that this was not the case. The statistical hypothesis tested has been rejected when it is true and an error of the first kind has been made. In the second case a cheaper insulin is advocated which in fact has not the properties of the older standard. The statistical hypothesis tested has been accepted when it is not true, and an error of the second kind has been made.

In any given problem it is impossible to say whether a hypothesis is true or false, but it is possible to assess the efficiency of statistical tests by the manner which, on repeated application, they control these two forms of error. Further, it does not alter the essential features of this approach if, as Mr. Buchanan-Wollaston points out in his second letter, it may often be desirable to allow for a third verdict, that of "not proven". I have stated the problem in its simplest form, yet it will be found that very frequently the immediate decision does lie between *two* courses of action. Thus while the purchaser of mass-produced articles might make one of three decisions after inspecting a sample, namely, (*a*) reject consignment, (*b*) accept consignment, (*c*) inspect a further sample, he does in fact often make his first decision between (*b*) and (*c*) and then, if he has followed course (*c*), decide between (*a*) and (*b*).

With Prof. Fisher's objections to our method of approach, Dr. J. Neyman and I have long been familiar, but it would, I am sure, be inappropriate to enter here into a discussion with him on the place of errors in statistical theory.

Crossing-Over and Chromosome Disjunction

BRIDGES, Anderson, Mather, Gershenson and many others have shown that there is a definite relation between crossing-over and the disjunction of chromosomes. Their work has made it evident that, during meiosis, crossover chromosomes are distributed between the daughter nuclei more regularly than non-crossover ones. However, the exact nature of this relation is still by no means clear. Darlington thinks that crossing-over is, in general, a necessary condition of regular chromosome disjunction. On the other hand, a number of general considerations as well as some recent facts obtained by Gershenson, Beadle and Sturtevant and Stone and Thomas, are opposed to such an interpretation in the case of *Drosophila*.

In order to decide the latter question, I undertook an experiment in collaboration with Miss Helene Pogossiants, in which, by using certain rearranged chromosomes, it seemed possible to obtain somewhat more conclusive results than in previous work. Crossing-over and non-disjunction were studied in females of *Drosophila melanogaster* carrying an *X*-chromosome with the *ClB* inversion and another *X*-chromosome (translocation X–IV or 'Bar-Stone'), most of the genetically active part of which was translocated to the fourth chromosome. Data on single crossing-over in the non-inverted region and the number of recovered double crossovers in the inverted region enabled us to conclude, with a high degree of certainty, that single crossing-over in the latter region (undetectable by direct methods) is very low. Possible undetected crossing-over in the

genetically inert parts of the *X*-chromosomes could influence only the disjunction of the *ClB* chromosome and the right (non-translocated) part of the other *X*-chromosome, as the left part, translocated to chromosome 4, does not carry any of the inert region of the *X*-chromosome. Non-disjunction of the left part of this *X*-chromosome and the *ClB* chromosome is much lower than would be expected if Darlington's hypothesis applies to *Drosophila*, and seems therefore to show that regular disjunction of chromosomes is not absolutely conditioned by crossing-over.

It seems clear that both crossing-over and chromosome disjunction are dependent on a third, more general factor, possibly on the intensity with which the conjugation of chromosomes takes place.

S. GERSHENSON.

Institute of Genetics,
Academy of Sciences,
Moscow.

DOBZHANSKY[1], Gershenson (above) and others have concluded that the disjunction of chromosomes does not depend directly on the occurrence of crossing-over between them, as I assume to be the case in all homozygous organisms[2]. They maintain that some "other factor" is concerned in their experiments. But these experiments have necessarily made use of hybridity, without which genetical tests are impossible; and the particular kind of hybridity (structural hybridity) they have used is bound to have a complicated effect on disjunction. It is itself the "other factor". Thus reciprocal crossing-over within two relatively inverted segments should give normal chromosomes with normal disjunction, other things being equal.

But when we consider the structure of the bivalent given by such crossing-over, we see that the disjunction expected in straightforward bivalents will not necessarily follow (Fig. 1). The pull which is to separate the paired chromatids is parallel to the plane of their association and not perpendicular to it. Resistance to separation is therefore not a certain constant minimum, but a function of the length between the two chiasmata. I have observed failure of disjunction in these circumstances in an inversion heterozygote in *Stenobothrus parallelus*. Other kinds of crossing-over in dislocated segments give rise to lagging, interlocking and irregular breakage. It is not therefore surprising that Grüneberg[3] finds the 'non-disjunction' that has previously been attributed to non-pairing and random segregation is often due to loss of both partners.

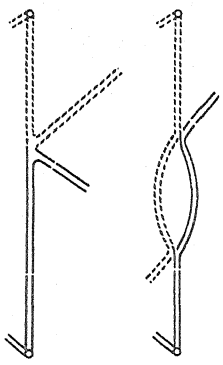

FIG. 1. The structure of bivalents with single (left) and double reciprocal crossing-over (right) between relatively inverted segments of homologous chromosomes.

This is merely one example of the special complications arising in structural hybrids. They have been described by Richardson for inversion hybrids and by myself for interchange hybrids in articles in the press[4]. They show the danger of arguing from the assumptions involved in an abstracted formal use of the terms "chromosome", "non-disjunction" and even "crossing-over" by the geneticist. They also show the difficulty the geneticist is faced with in dealing with the highly selected viable progeny of structural hybrids, a difficulty which can only be overcome by a close collaboration between those who are breeding the hybrids and those who are studying the structures found at meiosis in comparable material[2].

Induction of the Eye by a Specific Substance in the Amphibia

IT is known that in the axial mesoderm of the Amphibia, the capacity to induce individual organs varies from anterior to posterior, each organ having its 'induction field'[1]. After the discovery of inducing substances it is natural to consider whether the existence of these fields may be explained by the localised distribution of specific substances which determine their properties.

If this suggestion were found to be true in the case of any one organ, one could generalise and assume that it is true for other organs as well. The following investigation deals with the eye; if the development of this organ is determined by the presence of a specific substance, the diffusion of this substance from a dead eye must induce, in the ectoderm of an early gastrula, only eyes or eyes with the adjacent region of brain. Accordingly, optic vesicles were removed from *Axolotl* or *Triton taeniatus* in the tail-bud stage, killed by treatment with boiling water or alcohol, and implanted in the blastocœls of early gastrulæ of *T. taeniatus* or enveloped in flaps of presumptive ectoderm of that species. Eyes were induced in 100 per cent of the positive cases, either in whole embryos or in explants. In whole embryos induction was found to be independent of the level of the host. They were usually connected with a mass of brain tissue, which might be smaller than the eye; in some cases, several eyes were formed together. The eyes were normally shaped; and the retinal part of the eye was capable of inducing a lens from the host ectoderm, if it came in contact with it.

The conclusions which may be drawn from these facts are as follows: (1) The agent which induces the primary embryonic axis is not unspecific as regards the region of axis which is induced; possibly it includes a mixture of specific substances or entirely consists of such specific substances. (2) The regional differences within the primary embryonic axis are determined by the corresponding distribution of specific formative substances. (3) Polarity in the system of ectomesoderm[2] is possibly determined by a similar distribution of substances from pole to pole. The phenomenon of regulation must be accounted for by the assumption that these substances follow the principle of polar distribution, and that after a disturbance of the system the previous distribution of the substances is restored.

First Appearance of Red-eye in the wild *Gammarus chevreuxi*, Sexton

In a letter to NATURE[1], we were able to show that heterozygosity existed in the wild stock of this species —eggs from an outside mating, hatched some days later in the laboratory, gave 2 red-eyed recessives in a brood of 11 young.

Although dredging had been carried on at frequent intervals since 1912, and heterozygosity in the wild stock had been suspected for eleven years past, this was the first definite proof obtained, and it was again noted that no red-eyed had yet been found in the open. We have now to record its first appearance. In the dredging brought in on October 22 and examined for eye colour, one *red-eyed* was found amongst 2,000 black-eyed animals.

Hyperfine Structure and the Gross Structure Analysis of the Spectrum of Doubly Ionised Antimony

The hyperfine structure of two doublets of the spectrum Sb III has recently been investigated by me at the Reichsanstalt, Berlin. The structures were diffuse, but each line was resolved clearly as a doublet. The wave-lengths, classification[1] and the observed hyperfine structure separations in cm.$^{-1}$ are given below.

Wave-length	Classification	$\Delta\nu$
4265·09	$6s\ ^2S_{1/2} - 6p\ ^2P_{3/2}$	1·27
4591·89	$6s\ ^2S_{1/2} - 6p\ ^2P_{1/2}$	1·40
4352·16	$5s\,5p^2\ ^2S_{1/2} - 6p\ ^2P_{3/2}$	0·45
4692·91	$5s\,5p^2\ ^2S_{1/2} - 6p\ ^2P_{1/2}$	0·55

Taking the nuclear spin-moments of the two antimony isotopes as $5/2.h/2\pi$ and the ratio of their $g(I)$ factors as 1·37[2], and using the graphical method of Fisher and Goudsmit[3], the splitting factor of the $6s\ ^2S$ term for Sb^{121} could be estimated to about 0·53 ν. Applying the formulæ given by Goudsmit[4], the magnetic moment of the nucleus Sb^{121} could be calculated to be about 7·2 proton-magnetons. From my data[5] on the structure of the lines of the first spark spectrum, Goudsmit[4] has deduced a value 2·7 for the magnetic moment of Sb^{121}, compared with which the value obtained above is much too large. The reason for this is to be found in the incorrect analysis of the gross structure. If the $6s\ ^2S$ and the $5s\,5p^2\ ^2S$ terms are interchanged, the calculated value of the magnetic moment comes out to be 2·7, in quite good agreement with the value quoted above. Thus of the two ^2S terms, the deeper should arise from the configuration $5s\,5p^2$ and the higher from the configuration $5s^2\,6s$. This would assign to the $5s\,5p^2$ term a much larger splitting than that of the $6s$ term, which is not unexpected.

The two terms are very close together, their values differing only by 469 cm.$^{-1}$. The pair λλ 4352, 4693 is decidedly the stronger of the two, and it is more likely that the weaker pair should involve the double electron transition $5s\,5p^2 \leftarrow 5s^2\,6p$, and this is in accord with the suggested modification. A comparison of the values of the two terms in the iso-electronic spectra of In I, Sn II, Sb III and Se IV shows that the change suggested is quite consistent. In the corresponding case of As III, however, the pair of shorter wave-lengths is the stronger; it is therefore likely that the $5s\ ^2S$ term is deeper than $4s\,4p^2\ ^2S$. Here, too, the two terms are close together and a study of the structures of the lines in question would decide the correct configuration.

It is very interesting to note that the small energy changes in the radiation due to the interaction of the nuclear magnet with the extra-nuclear electrons helps to decide the electron configuration involved in a particular transition, and this is particularly useful when the terms are close together and it is otherwise difficult to assign the correct electronic configuration.

Details of the above investigation will be published elsewhere.

Occurrence of the Reversed Absorption Edges of the Long Wave-Lengths of X-Rays

In the region of the long wave-lengths of X-rays, there are difficulties in obtaining absorption edges, for the intensity of the continuous ground of the X-radiation is very small. A further difficulty is in the classification of some of these edges, as, for example, the M_V-edges. Also it is well known that the calculated energy values of the M_V-edges for higher elements do not agree with the measured values[1], and it is not possible to extrapolate or to say what differences can be expected in this region. We have found some reversed edges in this region[2], which must be classified as M-edges of silver and bromine. The classification of these edges requires a detailed discussion for which space cannot be afforded in NATURE. It may, however, be of interest to give the results and the difficulties in obtaining a L_{III}-reversed edge.

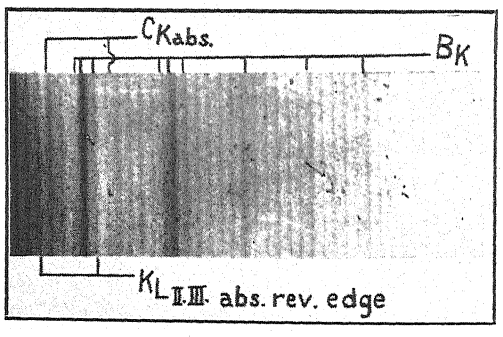

FIG. 1.

Two years ago, we obtained a reversed absorption edge of the wave-length $\lambda = 42{\cdot}1$ A., which corresponds to $\nu/R = 21{\cdot}6$. But on some plates, made with different anticathodes, this absorption has been either displaced, or appeared as a white absorption line or entirely disappeared. We have now found

that the above-mentioned phenomena were caused by occasional overlapping of emission lines, and the said overlapping could not be recognised on account of the lines in the region of long wave-lengths being broad and the dispersion small. It is now evident that this edge is only due to the emulsion of different photographic plates, and it belongs to the $L_{II, III}$-absorption edge of K (from potassium bromide), giving for L_{III} the calculated value $\nu/R = 21{\cdot}5$. One of the plates of this edge, made on Eastman-Kodak plate, shows (in the first and second orders) a clear potassium edge appearing as a broad white line. The appearance of this edge as a white line is caused through the simultaneous occurrence of the normal edge of carbon with the said reversed edge, as seen in Fig. 1. The value given above has been measured from other plates with greater dispersion, with copper and tungsten anticathodes, giving sharper reference lines.

With these results, obtained with the low tension ionic tube[3], the existence of the reversed absorption edges in this region is verified.

Reactions of Sulphuryl Diamide (Sulphamide)

APART from salt formation (for example, work by F. G. Mann in 1933) only two reactions of this substance have been recorded. Traube and Reubke (1923) obtained a 5 per cent yield of a condensation product with benzaldehyde, and in 1933 I showed (with Mr. A. E. Battye) that sulphamide readily condenses with formaldehyde to give a resin-like body from which a tetramethylol derivative may be isolated.

I have now found a third 'organic' reaction for this substance, which again exhibits its great similarity with urea. If xanthydrol in alcohol is added to a solution of sulphamide in acetic acid and water, after some time, beautiful lustrous crystals of dixanthyl sulphamide, m.p. 182°–4° C., are obtained. Condensation products have also been obtained with xanthydrol and

p-aminobenzene sulphonamide,	m.p. 209°
m-benzene disulphonamide,	m.p. 170°
p-toluene sulphonamide,	m.p. 198°.

Details will be published elsewhere of this general reaction for the sulphamides and sulphonamides, which in certain cases may be conveniently used for their estimation.

Points from Foregoing Letters

ULTRA-RAPID photography has shown that lightning strokes consist of a 'leader' from cloud to earth and a return stroke in the opposite direction. From fluctuations in the luminosity of the return stroke at the ground end, D. J. Malan, Dr. B. F. J. Schonland and H. Collens infer that the return stroke is made up of several component discharges, the intensity and time separation of which in micro-seconds they have measured. The authors are now investigating the influence of these components upon the wave-form of atmospherics radiated by the lightning flashes.

Some experiments by the late Sir John McLennan and Mr. W. H. Rann on the radioactivity produced by neutron bombardment of certain rare earths are described. They confirm earlier results of Hevesy and Levi and of Sugden and Marsh.

Finch and Quarrell suggested some time ago that the 'extra' rings obtained in electron diffraction experiments with metal foils (containing oriented crystals) were due to two-dimensional refractions at the exit crystal faces. Dr. L. H. Germer submits calculations showing that this cannot be the case. Dr. G. I. Finch agrees with Dr. Germer's findings and points out that they are consistent with the new interpretation put forward by Finch, Quarrell and Wilman, namely, that the 'extra' rings are due to surface contamination.

G. Wald finds in the light-adapted retina of the bull-frog, as in the case of other species of frogs, two substances chemically related to carotene, the yellow pigment of carrots: vitamin A (visual white), and retinene (visual yellow). In the dark, the yellow retinene changes to visual purple. Extracted retinene is transformed on standing into vitamin A. In the intact eye vitamin A is resynthesised to visual purple.

Prof. E. S. Pearson, continuing a discussion on statistical tests, contends that all hypothetical frequency distributions are merely graduation formulæ. We are never concerned with whether a hypothesis be true or false, but only with the extent to which it graduates our experience of Nature. But nevertheless, the efficiency of statistical tests can be assessed by the manner in which, on repeated application, they control certain errors of practice.

During the process of meiosis, the chromosomes carrying the inheritable characters from two parent nuclei join together, exchange certain portions, and then split (disjunction). Re-arrangement of certain portions (crossing-over) may occur. Darlington has stated that crossing-over is a necessary condition of regular chromosome splitting. Dr. S. Gershenson reports experiments with female fruit flies from which it appears that this is not the case. Dr. C. D. Darlington replies that this hypothesis applies to normal (homozygous) organisms and not to hybrids such as were necessarily used by Gershenson.

One or more eyes have been experimentally produced by G. Lopashov in *Triton tœniatus* by implanting into the blastocœls of early gastrula stage, dead optic vesicles from other specimens of *T. tœniatus* or of axolotl.

Using the known value of the magnetic moment of the nucleus Sb^{121}, a study by Dr. J. S. Badami of the hyperfine structure of the lines of the spectrum of the doubly ionised antimony atom has led to a modification of the gross-structure analysis of the spectrum Sb III.

Research Items

Pithecanthropus and the Gibbon

DR. EUGÈNE DUBOIS, having shown on the evidence of five thigh bones both the organic differentiation of *Pithecanthropuus erectus* and at the same time its close affinity with the gibbon, has now considered the trend of the evidence derived from the volume of its brain, much too large for an anthropomorphous ape, very small in comparison with the average of that of a man (*Proc. Akad. Wet. Amsterdam*, **38**, No. 6). Study of the laws regulating the size of the brain in mammals points to a relationship between its volume and the size of the body. In every case the functional degree can be expressed by the 'co-efficient of cephalisation' (or 'factor of animal organisation') which appears to arrange the mammal groups in a systematic order agreeing with what we know of their animal organisation. This has been found to hold good for birds, reptiles and fishes, and vertebrates generally. It was found that this law applied functionally to the psychencephalon, chiefly the cerebral hemispheres. Further, it has been found that in not a few cases of closely related mammals the co-efficient of cephalisation increases by doubling and redoubling, that is, in a geometric progression with a ratio of 2. This law of the autonomic phylogenetic progression of the psychencephalon is of direct significance for the taxonomy of *Pithecanthropus*. It is possible to arrange all the existing groups of mammals in a geometrical series with progressive 'co-efficients of cephalisation' in which there are no gaps, with one exception—that between man and the anthropomorphous apes. This marks the place of *Pithecanthropus erectus*. By a calculation on this basis, the probable weight of the body is shown to be 104 kgm. That probability is in favour of the accuracy of this figure is argued from the chief dimensions of the femur, on the analogy of similar organisms, for example, the gibbon. The gibbon resemblance also appears in the place of the gravitation centre of the head before the condyles, and also in the general form of the skull. The mandible resembles that of the gibbon and shows that *Pithecanthropus* was devoid of the power of human speech.

Rural Population in the United States

AN instructive series of investigations bearing on the character and movements of the rural population of New York State are being carried on by the Cornell University Agricultural Station, Ithaca, N.Y. A study of the activities and interest of the young women of the open country and villagers of Genesee County, N.Y., in 1934, has now been followed by a similar investigation among young men ("Interests, Activities and Problems of Rural Young Folk. (2) Men 15 to 29 Years of Age." By W. A. Anderson and Willis Kerns. *Bull.* 631. Cornell Univ. Agric. Station). Data were obtained from 307 young men, of whom 54 per cent were the sons of farmers and 33 per cent of skilled or unskilled labourers. Their interests were found to be mainly social-recreational and economic-vocational. The evidence collected pointed very definitely to the need for vocational guidance. For there was a very distinct urge towards a skilled trade as a life-work, but very little evidence of any definite plan to give it effect. A preponderating number expressed a preference for rural life and farm work. In this connexion it is significant that a previous inquiry ("Mobility of Rural Families" by W. A. Anderson. *Bull.* 623) showed that while agriculture in New York State is carried forward by the same type of population with only slight geographical shifting, giving the rural areas a stable social organisation, and while farming shows a greater tendency to be handed on from father to children than any other major occupation, it appears that this industry can employ only thirty per cent of the children reared in farm families, although previously the estimate had been placed so high as fifty per cent.

Breeding Habits of Common Catfish

A STUDY of the reproductive habits of the common catfish (*Ameiurus nebulosus*), by C. M. Breder, shows that they give the clue to some peculiarities developed in other nematognaths (*Zoologica*, **19**, No. 4; 1935). Thus the oral gestation of the Ariidae seems to be foreshadowed by the way in which the common catfish uses its mouth for churning the eggs about, taking them into its mouth and ejecting them violently; the adhesion of the eggs to the ventral surface of the Aspredinidae is suggested by the position of the catfish during incubation, when it lies upon the egg-cluster; and the special use of the ventral fins in working over the developing eggs initiates a habit which may have culminated in the use of the ventral fins as an inseminating basket, as in *Corydoras*. The common catfish may spawn twice in a season after a temperature of 21° C. has been reached, and the young fish, as well as the eggs, are guarded by the parents during their development.

Ecology of a Salt-Marsh

IN a paper on the ecology of a salt-marsh in Aberlady Bay on the Firth of Forth, fifteen miles east of Edinburgh, Edith A. T. Nicol (*J. Mar. Biol. Assoc.*, **20**, 1935) records that *Protohydra leuckarti* was common at certain times in some of the pools. It was present in May and June 1931 in large numbers in one pool and was still abundant in October, but died out during the winter and was not rediscovered until the summer of 1933, when it appeared in an adjacent pool. The uneven distribution and the difficulty of seeing this animal probably account for the few records of its occurrence in Britain. It has been previously recorded by Hickson from Southampton Water and from near Plymouth but, in addition to finding it in the Firth of Forth, Dr. Nicol found it in large numbers, in one pool only, in a small marsh at Torridon in Western Ross. She records that in one pool in Aberlady Bay, in June, there were 8,890 young *Nereis* in an area of one square foot of mud and in another pool 3,672 larvæ of *Chironomus aprilinus* were present in a square foot, and on the bare mud of the banks of the stream which runs through the marsh *Hydrobia ulvæ* was present to the number of 3,020 per square foot. Detailed observations were made on the conditions, salinity, oxygen-content, alkali-reserve, hydrogen ion concentration and temperature, under which the

animals in the pools were living, and the relationship of the conditions—of which the most difficult for the animals is that of changing salinity—to the life of the animals is discussed in connexion with recent work on the physiology of certain inhabitants of brackish water.

Vernalisation of Seeds

THE announcement by Lyssenko, a few years ago, of the process of vernalisation of seeds, raised very considerable hopes of enhanced yields and easier cultivation among the community of gardeners. Storage of the seed for certain periods at low temperatures was the main feature of the discovery. A short note in the *Gardeners' Chronicle* of October 19, by Mr. S. Burr and Miss D. M. Turner, throws further, but unfavourable, light upon the process. Tomato seed vernalised between 1° and 3° C. for periods ranging from 7 to 44 days was not equal, either in vigour of germination or in subsequent yield, to untreated seed. Normal seed germinated 97 per cent, whereas vernalisation for 44 days gave 20 per cent. Less extreme, though quite significant, were the yields—plants grown from seed vernalised 32 days yielded only 72 per cent of the untreated group. Cucumbers gave similar results.

New Virus Diseases of Tomato

THE number of virus diseases of plants increases at a really astonishing rate. Fifteen years ago, the well-authenticated virus diseases might have been enumerated without using two figures, but now they occur in hundreds. Dr. Kenneth Smith, of the Potato Virus Research Station, Cambridge, announces the discovery of three new virus diseases of the tomato (*J. Roy. Hort. Soc.*, **60**, 448–451, Oct. 1935). One malady causes cessation of growth, yellowing and purpling of the lower leaves, and malformation of the whole plant. The second is referred to as the 'distorting virus', and justifies its title by causing severe malformation of the leaves. Many fine leaflets appear instead of the usual well-favoured foliage, and the terminal leaflet frequently becomes a tendril. Symptoms of the mosaic type distinguish the third disease, which, however, differs slightly from the ordinary tomato mosaic by producing a greyness upon the leaf, with bandings of yellow and green. The two latter diseases may have been brought to Great Britain by the importation of smoking tobacco.

Transmutation by Deuterons

E. O. LAWRENCE, E. McMillan and R. L. Thornton (*Phys. Rev.*, Sept. 15) have studied the yield of induced radioactivity in a number of elements, activated by deuteron bombardment, as a function of the energy of the bombarding beam. Sodium, aluminium, silicon and copper all give β-radioactive products, probably by reactions typified by $Na^{23} + H^2 \rightarrow Na^{24} + H^1$. The yield increases with increasing deuteron energy (up to $3{\cdot}6 \times 10^6$ v.) less rapidly than would be expected on the Gamow theory of penetration of the particles through a potential barrier. Further, the activation of an element of atomic number as high as copper with deuterons of only 3×10^6 v. energy is much larger than would be expected on the Gamow theory. A theory is developed by J. R. Oppenheimer and M. Phillips (*Phys. Rev., ibid.*) along the following lines: The deuteron is built of a proton and a neutron linked with a certain binding energy. When the deuteron is projected against a nucleus, the proton is held back by the repulsive field, but a wave-mechanical calculation shows that the neutron has a relatively high probability of entering the nucleus. The actual shape of the function giving the variation of the neutron penetration with energy depends on the binding energy; and a good fit with experiment is obtained by taking this about $2{\cdot}0 \times 10^6$ v., which is consistent with the value obtained by other methods.

Industrial Applications of Electrolysis

THE field of electrochemistry as it is concerned in the industrial deposition of metals, the electrolysis of alkali and alkali chloride solutions and oxidations, has been summarised by H. J. T. Ellingham in an article (*Chemistry and Industry*, **54**, 895; 1935) which gives some useful general information. In recent years the electrolysis of fused sodium chloride for the production of sodium is tending to displace the earlier method of electrolysis of the hydroxide. The normal annual production of aluminium is 270,000 tons, while 20,000 tons of sodium and 2,500 tons of magnesium are produced per annum, with small quantities of calcium, cerium, beryllium, potassium and lithium. The principal countries producing aluminium are the United States, Germany, Canada, Norway, France, Italy and Great Britain, and during the last year the U.S.S.R. has become a major producer. For some years, the British Empire has produced about 20 per cent of the total output. The modern electrolytic zinc extraction process now competes with the retort process, and is operated on an increasing scale. The roasted zinc sulphide concentrates are extracted with dilute sulphuric acid and the rigorously purified solution is electrolysed between aluminium cathodes and insoluble lead anodes. Pure (exceeding 99·9 per cent) zinc is obtained, with cadmium as a by-product. Modern electrolytic plating and refining processes are also described.

Costing of Petroleum Refinery Operations

PROFIT and loss accounts are comparatively straightforward when cost and individual products can be assessed. With refineries, however, such assessment is not as a general rule practicable, since the main plants produce not one, but several, products. Allocation of operating costs to individual products is, therefore, an arbitrary matter. Mr. Gordon Kerr, who read a paper on "The Costing of Petroleum Refinery Operations" on October 8, before the Institution of Petroleum Technologists, suggests that, cost per product being inaccessible to refinery operators, process costs should be calculated. These being obtained, comparisons between the cost of operating plants from period to period, or for one refinery as opposed to another, are made possible. Moreover, in special circumstances, data are provided for comparison of alternative plants and methods of operation. In order to draw up a satisfactory process cost sheet, the processes to be costed must first be decided upon. Secondly, expenditure must be analysed and allocated to these various processes. Finally, distinction must be made between direct costs which automatically cease in the event of a particular process being discontinued, and indirect costs. These preliminary calculations having been made with the assistance of engineers, chemists and accountants, Mr. Kerr suggests that a perfectly satisfactory statement can be drawn up, and indicates the form it should take.

Symbols and Nomenclature in Physical Science

PROF. A. V. HILL'S recent letter[1] directing attention to the confusion arising out of the inconsistent use of symbols is a timely reminder of the need for greater uniformity. A certain amount of work in this direction has already been done. In 1914, committees of the Physical Society of London, and of the International Electro-Technical Commission reported upon this subject[2] and made certain suggestions as regards some of the more important physical symbols. The Smithsonian Physical Tables contains a table of symbols for electrical and magnetic quantities as adopted by the American Institute of Electrical Engineers, and the International Critical Tables gives a list of symbols based upon the recommendation of the International Association of Chemical Societies[3]. More recently, the S.U.N. Commission of the International Union of Pure and Applied Physics has recommended symbols for a limited number of physical quantities[4]. General agreement, however, upon anything like a sufficient number of symbols is not yet in sight.

Pending such agreement, as a step in the right direction and to prove its urgency, it would be instructive to have tables showing the variety of symbols employed by different authorities for the same physical quantity. A table giving symbols of some common thermodynamic quantities as found in a number of textbooks was compiled by the S.U.N. Commission in its report (mentioned above) and a similar table is appended here as an example; it will be seen how readily confusion can arise. Not only do the symbols differ, but also terms such as 'free energy' and 'thermodynamic potential' are used with different meanings by different authors.

With the exception of entropy, the various quantities given in the table are forms of (or have the dimensions of) energy, and the relation between them, using Gibbs's notation, is:

Quantity \ Author	Gibbs (1876)	Bryan (1903)	Goodenough (1912)	Planck (1922)	Planck (Eng. Trans. 1929)	Lewis and Randall (1923)	W. C. M. Lewis (1925)	S.U.N. Commission
Entropy	η	S	S	S	φ	S	S	S, P
Heat given to system	Q	Q	Q	Q	Q	Q	Q	—
Work given to system	−W	−W	W	A	W	−W	A	−W
'Free energy' (Helmholtz)	ψ	$\mathfrak{F}_v$	F	F	F	A	f	F
'Free energy' (Lewis and Randall)	ζ	$\mathfrak{F}_p$	φ	—	—	F	φ	G
Heat content	χ	$\mathfrak{F}_s$	I	W	H	H	—	H, I
Internal energy	ε	U	U	U	U	E	U	U, E

$$\overbrace{\underbrace{Q}_{\chi} + \underbrace{\zeta - W}_{\psi}}^{\varepsilon}$$

where Q, W and ζ stand for the energies obtained by multiplying the extensive quantities, entropy, volume and mass by their respective intensive factors (or potentials), temperature $(d\varepsilon/dS)_{v,m}$, pressure $(d\varepsilon/dv)_{s,m}$ and thermodynamic potential $(d\varepsilon/dm)_{s,v}$. It is unfortunate that many authors have used the term 'thermodynamic potential' in referring to energy quantities. Bryan[5] has used it to denote ψ, χ and ζ; Ogg, in the English translation of Planck's "Thermodynamics", refers to the energy equivalent of ζ as "thermodynamic potential at constant pressure", and the term is used in the same sense even in the International Critical Tables.

In its recent report the S.U.N. Commission states (p. 20): "As to the four quantities, U, $U - TS$, $U - TS + PV$, $U + PV$, it was pointed out that they are all cognate and should be regarded as on a parity in the sense that they are all potentials, so that by suitable differentiations of each, any of them can yield the complete state of a substance, entropy or temperature, pressure or volume, thermoelectric current or e.m.f. . . . The British Committee are also prepared to accept the name Thermal Potential for Gibbs' function." It may be pointed out, however, that Gibbs (*Scientific Papers*, 1, 92) used the term potential in a different sense; he defined his thermodynamic potential as "the differential coefficient of the energy taken with respect to the variable expressing the quantity of the substance", as we have done above.

Two other points may be here touched upon:

Owing to the relatively large number of physical concepts, authors have often recourse to Greek, German and other alphabets in order to find distinctive letters. An alternative way would be to use a combination of two or more letters as is done for chemical symbols. This would also have the advantage of allowing one to distinguish between, say, gas pressure *Pg* and osmotic pressure *Ps*, while at the same time indicating other generic similarity.

The addition of one or more letters could be resorted to in order to direct attention to the operational meaning attached to a given symbol: for example, *Psh* might stand for "osmotic pressure measured hydrostatically across a semi-permeable membrane", while *Psf* might indicate "osmotic pressure calculated from freezing point determinations". The need for some such device to express the operational meaning of concepts in order to prevent many unnecessary controversies and paradoxes has been discussed at length in a previous paper[6].

To summarise—there are three points worth consideration:

(1) The need for comparative tables giving the different symbols used for the same concept by various scientific workers.

(2) The advantages of symbols consisting of several letters.

(3) The advisability of using symbols which express the operational meaning of a concept.

Prof. Charles Flahault and the Scots College at Montpellier

PROPOSED MEMORIAL

MEN of science throughout the world will welcome the news that a movement is afoot to commemorate the work of the great geobotanist Charles Flahault. A committee of patronage has been founded to erect in L'Hort de Dieu, on Mont Aigoual, a commanding peak of 5,000 ft. in the Cevennes, a monument to the memory of this noted savant and essentially human figure. Flahault began life in modest circumstances. From being gardener of the Natural History Museum, Paris, he attained, through his undoubted ability, his application and hard work, the highest university degrees. At twenty-six years of age he found his place among the young savants of great promise. As professor in the Faculté des Sciences in 1883, he worked and taught for forty-four years in Montpellier, the University of which he never abandoned in spite of repeated calls of the Natural History Museum and of the Sorbonne.

Flahault was the founder in France of botanical geography, the aims, the methods and nomenclature of which he clearly defined. He organised the Botanical Institute of Montpellier, and by his learned words and guiding influence made Montpellier a noted centre for Mediterranean studies. His scientific activity aimed through all his life's work at an essentially human goal. He sought to discover and to teach the relationship of plant life to its environment and thereby to increase the yield of Nature for the benefit of man.

In retirement, Flahault turned his attention to the replanting of the *garrigues* and mountains, to the improvement of the cultural aspect of sand-dunes and to the uncultivated marshes which border the lagoons. The last seven years of his life were spent in this work, unceasingly giving practical advice, writing reports, articles and booklets into which he condensed the results of his researches and experiments. These included observations which he had made on the Aigoual in the Hort de Dieu, where he founded a botanical mountain garden and laboratory. Thus from the lagoons of the seashore to his hill-station on the edge of the Massif Central, Flahault revealed the unity of Mediterranean vegetation.

To students and men of science from Great Britain, the special significance of Montpellier and its region is its key-position at that point of the Mediterranean lands which is nearest to our own. This fact formed a fertile contact between Flahault and ecologists from our own shores. The unbroken friendship of the late Sir Patrick Geddes and Flahault, dating from the 'eighties, led to the founding of the Scots College (Le Collège des Ecossais) at Montpellier, and Geddes taking up residence there in 1924; the garden of the College with its wide variety of *garrigue* flora was planned by the two friends as an ecological museum of Mediterranean vegetation. Latterly, a co-worker of Flahault, M. Braun-Blanquet, has placed his Station Internationale geo-Botanique Mediterranéenne et Alpine (S.I.G.M.A.) in the College garden. Recently, at the College itself, the warden, M. Paul Reclus, has aided the supervision of ecological studies by British students. Thus the work of Flahault is continued, not only by his successor M. Pavillard at the University, but also at the College where so much of his time was spent. Students are ever welcome to this centre of study and research, and it is hoped that the College with such a beginning and tradition will receive the support of those interested in the allied sciences.

Progress in Road Research

THE first report of the Road Research Board, covering the two years ended on March 31, 1935, since the Department of Scientific and Industrial Research assumed responsibility for the researches on roads carried out at the Road Research Laboratory, Harmondsworth (H.M. Stationery Office. 3*s*. net), appears appropriately enough when an important discussion on science and the control of road traffic at the British Association meetings at Norwich has directed attention to the importance of road surface and similar factors in the prevention of accidents. A major group of problems with which the work of the Board is concerned is directly related to the reduction of accident ratios, the other main group of problems being concerned with economy in road construction and maintenance.

The report of the Board itself outlines the general policy pursued in its work and is followed by the report of the Director of Road Research. The first section of the latter report outlines a preliminary programme of research covering both materials and processes for road-making and providing for routine tests and *ad hoc* investigations by the highway authorities and the Ministry of Transport, which under the present scheme remains responsible for full-scale tests outside the Laboratory and is the channel of communication with highway authorities. This programme is designed to supply a real knowledge of all the fundamental factors involved in the processes and materials used by the industry, and the work falls into four main divisions: road construction, road usage, development of special testing apparatus, physiological and psychological effects.

The major part of the report is concerned with materials and processes for road construction. Investigations are outlined dealing with questions of the settlement, drainage and other characteristics of the sub-soil which are of importance with the use of large impervious surfaces in modern roads. The properties of the various road materials and their

mixtures with binders are being investigated to assess scientifically their suitability for use in road construction and to enable satisfactory specifications to be compiled. One of the first steps has been the designing of satisfactory workability tests for mixes. Bituminous binders are also receiving attention and co-operative research has been arranged with the British Road Tar Research Association. The report also stresses the importance of improving methods for the control of concrete during laying, and for the determination of the factors which influence the design and laying of road slabs and foundations.

In regard to road usage, special interest is attached to the studies of forces applied to roads by various types of vehicles, with the object of correlating these forces with the type of pavement, subsoil and vibration, as well as to attempts to determine the factors in vehicle design and usage which cause damage to the road. The value of scientific knowledge on these points needs no emphasis, while the importance of the attention being given to the problem of skidding is equally apparent. This work aims at determining the factors in vehicle design which induce skidding as well as those factors in road construction and road conditions which promote skidding. An apparatus for assessing the slipperiness of wet surfaces has been designed which has given numerical values for the slipperiness of surfaces in good accord with experience of actual usage of the roads tested. The work has shown, rather surprisingly, that in wet weather roads are in general more slippery in summer than in winter. Other work on road testing machines has been designed to provide some other means of judging durability than waiting for deterioration under normal usage, and it is hoped that the machines being built will form a link in the chain between the laboratory and the road, and ultimately establish a scale against which the probable performance of new forms of materials and construction can be estimated.

The report shows that a good beginning has been made on a programme of research not incommensurate with the expenditure of more than £50,000,000 involved in the making and upkeep of roads in Great Britain and in the problem of road safety.

Technical Features of the *Normandie*

AT a joint meeting of the Institution of Mechanical Engineers with the Société des Ingénieurs Civils de France (British Section) held at the Institution of Electrical Engineers on November 15, M. Jean Marie read a paper on the *Normandie*. He gave a very interesting description of the precautions taken against fire. The first precaution is the use so far as possible of fireproof materials for floor, ceiling and wall coverings. Where the use of materials such as plywood, linoleums, rubber carpets, etc., was unavoidable, these were made almost incombustible by the use of asbestos and fire-resisting paints. The only really combustible materials are the bedding, linen, clothes and the passengers' and crew's luggage. The outbreak of fire is limited by partitioning, six cabins being the maximum in the subdivisions. If a fire, however violent, breaks out in one of them, its extent is limited for more than thirty minutes by the insulating barrier, the temperature remaining normal during this period in the neighbourhood of the attacked cell.

There is a special fire patrol which has its headquarters in the central security post, with which 1,075 automatic devices are connected to give the alarm. If it happens to be a cabin, a red alarm light appears in the corridor. No bell system is installed in order to avoid the risk of a false alarm among the passengers should a bell ring accidentally. In the engine rooms, an outbreak is safeguarded against by means of a hose supplied with carbonic acid foam. In the lower parts of the ship, a plentiful introduction of carbonic gas can be arranged and in the upper parts there are numbers of fire extinguishers. Flying scaffolds are provided so that it is possible to introduce a hose, fed from an upper deck through a porthole, or shut the porthole should it allow a draught. The officers, staff and men who maintain this safety service are specially recruited for the purpose.

The electric lighting system is of low voltage (110 volts) and the power and lighting wires are everywhere kept separate. It is possible to cut off the electric supply from the single zone where a fire might originate. The fight against the outbreak and the normal life on board are thus not interfered with. In the main public rooms, marbles, onyx, plaster of Paris and glass (moulded or worked) have been used as much as possible. Furniture is either of metal or of a fire-resisting wood. Safety paints and varnishes are employed; all of them were tested to see that their burning point was not less than 400° C., and that their liability to spread fire was less than a certain fixed standard.

As the length of the *Normandie* is 1,029 ft. and the breadth at the overhang of the promenade deck is 120 ft., it is out of the question to use oil engines on account of the power that has to be developed, the weight and size of the engines and the risk of vibration resulting from the use of reciprocating moving parts. Water tube boilers and steam turbines were therefore chosen. Electrical transmission of the power generated to the propellers was chosen because of the absence of noise. It has, however, the disadvantage that it cannot be reversed, and so separate machinery has to be used for going astern. A double hull protects the two rooms where all the machinery is located.

The main power station has four 33,400 kilowatt turbo-alternators which run at 2,430 r.p.m., which is ten times faster than the propeller motors. On its first trip, the *Normandie* captured the coveted 'blue riband' of the Atlantic, going westward at an average speed of 29·98 knots and returning at 30·31 knots.

In all fast ships, vibration appears and is troublesome at definite speeds, and the *Normandie* is no exception. Alterations are being carried out during this winter to remedy this inconvenience, and the Compagnie Générale Transatlantique believes that they will be successful.

Educational Topics and Events

CAMBRIDGE.—The Vice-Chancellor gives notice that the Jacksonian professorship of natural philosophy is vacant. The professorship is assigned for this turn to experimental physics, and intending applicants should inquire of the Vice-Chancellor whether provision can be made for the researches that they wish to conduct. Applications must be sent to the Vice-Chancellor on or before December 31.

Sir Rowland Biffen has been appointed to act as head of the Department of Agriculture during the absence on leave of Prof. F. L. Engledow, Drapers' professor of agriculture, from November 15 until April 2, 1936.

Mr. G. E. Briggs has been appointed to act as director of the Sub-Department of Plant Physiology during the absence on leave of Dr. F. F. Blackman, reader in botany, in the present term and Lent term, 1936.

The absence of Prof. F. J. M. Stratton with the eclipse expedition during the Lent and Easter terms 1936 has necessitated the appointment of Dr. T. W. Wormell as acting head of the Department of Astrophysics and director of the Solar Physics Observatory during that period.

AT the time of going to press, the following representatives of university parliamentary constituencies in Great Britain and Northern Ireland were announced as elected or returned unopposed: Cambridge, Sir John Withers (Unionist) and Mr. K. Pickthorn (Unionist); Combined English Universities, Miss E. Rathbone (Independent) and Sir R. Craddock (Unionist); London, Sir Ernest Graham-Little (National); Oxford, Lord Hugh Cecil (Unionist), Mr. A. P. Herbert (Independent); Queen's University, Belfast, Colonel T. Sinclair (Unionist); Wales, Mr. E. Evans (Liberal).

THE School of Librarianship at University College, London, has published an account of its present courses. In the new syllabus for the diploma, stress is laid on languages, especially French and German, the latter being compulsory, and on practical work in cataloguing, classification and library administration. Candidates may specialise in palæography and archive work or in university or special library administration. Fees for the postgraduate diploma course amount to about £45 for tuition, registration and examination fees and books. The school was opened sixteen years ago, and received substantial assistance for a period of ten years from the Carnegie United Kingdom Trust. Its sphere of usefulness has expanded since then with the remarkable development of library services in the south of England, especially London and the home counties, where the number of registered municipal library users increased in five years by 56 per cent, and county library users and book stocks more than doubled. There is no indication in the prospectus of measures for giving effect to the resolutions passed at the recent International Congress at Madrid in favour of special courses for rural librarians and hospital librarians, but it is stated that a course may be arranged in the Easter or summer vacation.

Science News a Century Ago

Meeting of the Royal Society

AT a meeting of the Royal Society on November 26, 1835, Sir John Rennie being in the chair, two papers were read. The first of these was by E. J. Cooper and was communicated by Captain Beaufort. It was entitled "Observations on Halley's Comet made at Mackree, Sligo, in the months of August, September, October and November 1835". The observations, which were made with an equatorial telescope having a focal length of 25 ft. 3 in., "were communicated in the state in which they were taken, and without corrections for refraction and parallax, with a view to assist computors in the calculation of a new approximate orbit".

The second paper, "An Account of the great Earthquake experienced in Chili, on 20th February 1835", was by A. Caldcleugh. "The earthquake," the author said, "began at half-past eleven o'clock in the morning. The first oscillations of the earth were gentle and attended with little noise. They were succeeded by two extremely violent tremors, continuing for two minutes and a half. All the buildings of the town of Conception were thrown down during these undulations". Later on "an immense wave was seen slowly advancing towards the shore, and rolling majestically onwards, in ten minutes reached the city of Conception, which was soon overwhelmed in a flood of an altitude of 28 feet above high water mark. . . . Vessels navigating the Pacific Ocean within a hundred miles of the coast, experienced the shock with considerable force. Its influence was very perceptible in the island of Juan Fernandez, a basaltic mass 360 miles distant from the coast; as was shown by the sudden elevation and subsidence of the sea, which at one time rose 15 feet above the usual level carrying all before it."

British Railways and Steamships in 1835

THOUGH a century ago the mileage of railways completed in Great Britain was quite small, a large number of lines were either in hand or being planned, and the advertisement columns of *The Times* of November 1835 contained many notices of meetings, prospectuses, etc., of railway companies. From London alone there were plans for lines to Birmingham, Greenwich, Bristol, Cambridge and the north, the eastern counties, Dover and Folkestone, Shoreham and Brighton, Southampton and other places. Robert Stephenson was the engineer of the London and Birmingham Railway, Brunel of the Great Western Railway, Joseph Gibbs of the Great Northern Railway, Charles Vignoles and John Braithwaite of the Eastern Counties Railway, Rastrick of the Brighton line, while George Stephenson was the engineer of the London and Blackwall Railway and Sir John Rennie of the Commercial Railway to the East and West India Docks. There were projects also for lines from Birmingham to Bristol, from Bristol to Exeter, from Exeter to Plymouth and Devonport, while among the lines in the north was one from Newcastle-upon-Tyne to North Shields and Tynemouth.

In *The Times* of November 28, 1835, was also a notice of the formation of the British and American Steam Navigation Company with a capital of £500,000, which ultimately built the two pioneer trans-Atlantic vessels *British Queen* and *President*.

Societies and Academies

LONDON

Royal Society, November 14. G. L. BROWN and SIR HENRY DALE: The pharmacology of ergometrine. Ergometrine produces the central excitation, with general sympathetic stimulation, previously described as an initial phase of the action of the more complex alkaloids of the ergotoxine group. It has, however, no more than a trace of the specific paralysing action on motor sympathetic effects, characteristic of these other alkaloids. It causes cyanosis of the cock's comb, but the effect is evanescent and has not led to gangrene. It causes a rise of body temperature when given in toxic doses. It is in general less toxic than ergotoxine, and is much more readily absorbed with oral administration. The most characteristic action of ergometrine, and the only one produced by small doses, is the initiation of a long persistent rhythm of powerful contractions in a uterus normally quiescent, as in the early puerperium. On several organs, apart from the centrally excited sympathetic stimulation, ergometrine appears to have a peripheral action of sympathomimetic type. This, however, is much complicated by other types of action, and does not account for its specific action on the uterus. M. J. D. WHITE: The effects of X-rays on mitosis in the spermatogonial divisions of *Locusta migratoria*, L. X-rays produce both lethal and non-lethal effects in the spermatogonia of *Locusta migratoria*. Cells which are killed go into pycnosis. Those which are not killed show different kinds of chromosome abnormalities. The commonest of these is chromosome fragmentation. Fragmentation of the *X*-chromosome is much rarer than autosomal breakage. A new type of chromosome abnormality which leads to chromatid-tetraploidy with only a diploid number of spindle attachments is described. It is believed that this results from inhibition of the division of the spindle attachment following on irradiation. The whole of the work strongly supports the view that the spindle attachment is a constant cell-organ and that new spindle attachments only arise from pre-existing ones. The independence of the spindle attachment from the rest of the chromosome in regard to time of division is emphasised by the new abnormality of mitosis described above. Evidence is presented that the spindle attachments in the Acridiidae are not terminal, as hitherto believed, but sub-terminal. D. E. SLADDEN: Transference of induced food-habit from parent to offspring (2). Experiments with the stick-insect (*Carausius morosus*) in which the insects for several generations were forced to accept a new food-plant (in this instance ivy) and then reared to maturity on it, have shown that the offspring of each subsequent generation accepted the ivy more readily than did their parents and even showed an increased preference for it. The increasing ability of offspring of ivy-fed parents to eat ivy indicated in experiments previously recorded is still maintained, though the rate of increase is slowing down as is clearly shown by the presentation tests. The preference tests continue to show an increased preference for ivy.

PARIS

Academy of Sciences, October 21 (*C.R.*, 201, 693–748). HYACINTHE VINCENT: Remarks on streptococcæmia with accounts of some new results of serotherapy in this infection. Out of 310 cases of septicæmia due to streptococcus, 81 per cent were cured by the author's serum treatment. Stress is laid on the necessity of applying the serum treatment as early as possible. JEAN CABANNES and JEAN DUFAY: The spectrophotometric comparison of the zodiacal light and the light from the night sky. It results from these observations that the zodiacal light emits neither the line 5577 nor the bands 4838 and 4425. Allowing for the radiations from the night sky, the zodiacal light gives essentially a continuous spectrum with Fraunhofer lines. GEORGES BOULIGAND: The conditions of covariance of Meusnier's sphere. RAPHAËL SALEM: Certain continued functions and the properties of their Fourier's series. KARL MENGER: A general theorem of the calculus of variations. N. A. SLIOSKINE: Permanent capillary waves. HENRI MINEUR: The age of the Milky Way. LOUIS LEPRINCE-RINGUET: The sudden energy losses undergone by high energy electrons. LÉVI HERMAN and MME. RENÉE HERMAN: The absorption of oxygen in the ultra-violet. NY TSI-ZE and WENG WEN-PO: The influence of the electric field on the absorption spectrum of sodium. GEORGES BRUHAT and LOUIS WEIL: The construction and use of a quarter-wave plate made of quartz. MLLE. YVETTE CAUCHOIS: New measurements and observations relating to the non-diagram $L\alpha$ emissions of mercury, platinum and tungsten. PIERRE PREISWERK and HANS VON HALBAN, JR.: Some radio-elements produced by neutrons. Results obtained by irradiation with neutrons (radon + beryllium) of thallium, bismuth and phosphorus. The results of Sosnowski with bismuth were not confirmed; no activity was detected. J. CHÉDIN: The Raman effect in fuming sulphuric acid. Acids containing a high percentage of SO_3 give no line in common with H_2SO_4 and hence in fuming sulphuric acids containing up to 70 per cent of SO_3 the H_2SO_4 is entirely combined with SO_3. OCTAVE DONY-HÉNAULT and CLAUDE DECROLY: The direct determination of the concentrations of the zinc vapour in the thermal reduction of zinc oxide. MARCEL PRETTRE: The mechanism of the chain reaction of the hydrogen–oxygen mixture. The velocity of the reaction in glass coated with potassium chloride obeys the law of Arrhenius, it is sensibly proportional to $(H_2)^2$, to (O_2) and to p^4 (apparent order of reaction, about 4). The results are in agreement with the scheme suggested by Haber. GEORGES DARZENS and ANDRÉ LÉVY: The synthesis of octohydromethylphenanthrene carboxylic acid and of 4.methylphenanthrene. JOSEPH HOCH: A general method of synthesis and the chemical properties of the isocyanic α-ethylenic esters of the formula $R.CH=CR'.N=C=O$. The *N*-carboxethylketimines, for which the author has given a general method of preparation, are heated to 400° C. with a catalyst. MARC BASSIÈRE: The crystalline structure of silver nitride. The group N_3 is linear, the distance between the atoms being $1{\cdot}18 \pm 0{\cdot}04$ A., of the same order as those previously observed for other nitrides. GEORGES PETIT and PAUL BUDKER: The differentiation of cutaneous teeth, connected with the presence of sensorial crypts, in some Selacians. PAUL WINTREBERT: The explanatory value of physiological epigenesis. CHARLES JOYEUX and JEAN GEORGES BAER: Researches on the evolutive cycle of *Hymenolepis pistillum*. CONSTANTIN LEVADITI and MLLE. JEANNE VOET: A new classification of the neurotrope ectodermoses. FERNAND ARLOING, ALBERT MOREL and ANDRÉ JOSSERAND: The action on tumours, with intravenous injections, of new soluble complex ferrico-ascorbic salts.

EDINBURGH

Royal Society, November 4. A. D. PEACOCK: Some aspects of animal parthenogenesis. An address mainly surveying recent researches, namely, haploid parthenogenesis and the viability of haploids in the light of cytological work; Whiting's hypotheses of 'complementary factors' and 'selective fertilisation', educed from genetical experiments, whereby the diploid female hymenopteron appears to be heterozygous for sex, *XY*, while the haploid males, though phenotypically alike, are of two types, *X* and *Y*; Guhl and Dozorceva's cytological evidence for Whiting's thesis; Vandel's work on geographical parthenogenesis and his evidence that the rare triploid males of a triploid parthenogenetic race of *Trichoniscus* show 'change of valency of the sex genes'; sex control experiments in cyclic forms by Banta, Shull, Tauson, Luntz and others, with Berg's hypothesis that males appear as the result of 'physiological depression'.

BRUSSELS

Royal Academy of Sciences (*Bull. Classe Sci.*, 21, No. 8–9, Aug. 1935). A. DEMOULIN: Sphere congruences of which the curvature is equal to one. P. FOURMARIER: A new observation à propos schistous cleavage. G. BOULIGAND: Stability of mathematical propositions (2). J. L. DESTOUCHES: Abstract spaces in logic and the stability of propositions. P. BURNIAT: Birational quadratic transformations in hyperspace. M. DE HEMPTINNE and J. M. DELFOSSE: Contribution to the study of the Raman spectrum of heavy and light phosphoretted hydrogen. An experimental study of the Raman spectra of these substances and a comparison with the theory of the vibrations of a tetrahedral molecule. L. VERLAINE: The analytical character of perception in the macaque (2). A further attempt to educate the macaque to recognise various simple geometrical shapes and colours.

CRACOW

Polish Academy of Science and Letters, October 7. S. ROZENTAL: The analytical form of the approximate functions of state of the light atoms. W. SWIETOSŁAWSKI, M. WOJCIECHOWSKI and E. SAPIRO: Researches by the boiling point method on the amount of impurities in succinic acid, proposed as a secondary thermochemical standard. The sample of succinic acid used by L. Keffler in his thermochemical work was found to contain 0·002 per cent of water. The method was also applied to determine the amount of water produced by the decomposition of the acid on prolonged heating to various temperatures. M. CENTNERSZWER and M. BLUMENTHAL: The formation and dissociation of the peroxides of the metals of the alkaline earths. M. CENTNERSZWER and MLLE. M. SWIERCZEWSKA: The lowering of the boiling point of a ternary system by non-volatile substances. The influence of potassium chloride on the boiling point of aqueous solutions of calcium chloride. At a certain concentration of calcium chloride, the boiling point remains unchanged on the addition of the third component. The author terms this an 'indifferent' solution. K. DZIEWONSKI and J. KOWALCZYK: Study of α-methylnaphthalene. WL. SZAFER: The method of 'isopolles' applied to researches on the history of trees and forests. The 'isopolle' is a line corresponding to equal amounts of pollen of the trees at different periods of time. As an example, the method is applied to the post-glacial history of the beech and spruce in Poland. J. MADALSKI: The Pleistocene flora of Sciejowice, in the neighbourhood of Cracow. R. WILCZEK: Mosses with forest associations in the mountainous region of the Cieszyn district. J. BIBORSKI: The segmentary vessels and vessels of the unpaired fins of the plaice (*Pleuronectes platessa*). A. ZIELINSKI: Phosphorus and the embryonic development of the frog.

GENEVA

Society of Physics and Natural History, October 17. P. ROSSIER: The calculation of the initial radius of a new star. The author gives a new formula which takes into account the fact that the sensibility of the eye is extended over a wide range of wave-lengths. The calculation is very simple if use is made of a table of absolute colour index. F. CHODAT and A. MIRIMANOFF: Conservation and respiratory rate of yeasts in the presence of glucose. The authors show by means of manometric measurements that the presence of sugar is necessary for the maintenance of the respiratory coefficient of yeasts kept at a temperature of 60° C. G. TIERCY: Conservation of the polytropic character of thermodynamic equilibrium in the hypothesis of the θ variable or β variable. It is a question of finding under what conditions the total pressure keeps the characteristic form of polytropic equilibria. The general form of the algebraic condition is given.

LENINGRAD

Academy of Sciences (*C.R.*, 3, No. 2; 1935). N. MUSHELISHVILI: Solution of a mixed fundamental problem of elasticity in two dimensions. V. LUSTERNIK: The Brunn-Minkowski inequality in the case of any measurable quantities. W. TURKIN: A generalisation of a theorem of group theory by Landau. D. PANOV: A method of solution of limited problems in the case of differential equations with partial derivatives. B. NUMEROV: General formulæ for the development of perturbing forces in the calculation of absolute perturbations in polar co-ordinates. M. PODASHEVSKIJ: Influence of the photochemical coloration on the limits of stretching and of rigidity of rock-salt monocrystals. M. BRONSTEIN: Scattering of neutrons by protons. S. LEBEDEV and S. SERGJENKO: The dimerisation of butadiene-1, 3. B. RUBIN and L. NAUMOVA: Contribution to the methodology of the determination of ferments. B. DOSTOVALOV: Measurement of the dielectric constant and the specific resistance of rocks. L. BERG: Ecological parallels between lampreys and Salmonidæ. V. VOLOSCHUK: A new mite occurring in stored grain.

SYDNEY

Royal Society of New South Wales, October 2. A. R. PENFOLD and F. R. MORRISON: The essential oils of *Eucalyptus Australiana* and its physiological forms (1). *Eucalyptus Robertsoni* and *E. Phellandra* are simply physiological forms of *Eucalyptus Australiana* and they have now been described as varieties *A* and *B* respectively. These varieties, the essential oils of which are described, cannot be separated from the type, *Eucalyptus Australiana*, by morphological means, and are indistinguishable in the field. The chemical and physical constants of the various essential oils are given. G. F. K. NAYLOR: Palæozoic sediments near Bungonia: their field relations and graptolite fauna. The author discusses the evidence for assigning various geological ages to Palæozoic

sediments occurring east of Goulburn. He concludes that the following periods are represented: Upper Devonian, Upper Silurian (Ludlow stage), Lower Silurian (Llandovery stage), Upper Ordovician (Caradoc stage and Llandeilo stage). The Ordovician and Silurian series are overfolded in such a way that all the dips are westerly. The graptolites which have been collected from this area include several species of *Diplograptus* (*Orthograptus*) and *Monograptus*.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Sunday, November 24

BRITISH MUSEUM (NATURAL HISTORY), at 3 and 4.30.—Miss M. H. Smith: "Animal Communities".*

Monday, November 25

BRITISH MUSEUM (NATURAL HISTORY), at 11.30.—W. Campbell Smith: "Bible Minerals".*

ROYAL GEOGRAPHICAL SOCIETY, at 5.30.—A. M. Champion: "The Life of a Kenya Frontier Officer".

ROYAL AERONAUTICAL SOCIETY, at 6.—(at the Institution of Electrical Engineers, Savoy Place, W.C.2).—Dr. S. J. Zand: "Sound Proofing of Aircraft".

ROYAL SOCIETY OF MEDICINE (TROPICAL DISEASES AND PARASITOLOGY SECTION), at 8.30.—Dr. Magarino Torres: "Further Studies on the Pathology of Alastrim and their Significance in the Variola-Alastrim Problem" (Lloyd Roberts Lecture).

Tuesday, November 26

ROYAL SOCIETY OF ARTS (DOMINIONS AND COLONIES SECTION), at 4.30.—H. C. Sampson: "The Tana River Region of Kenya Colony".

ROYAL INSTITUTION, at 5.15.—Prof. Edward Mellanby: "A Survey of Modern Views on Nutrition" (succeeding lectures on December 3, 10 and 17).

Wednesday, November 27

ROYAL SOCIETY OF ARTS, at 8.—F. A. Secrett: "Modern Methods of Vegetable Production and Marketing".

Friday, November 29

QUEEN MARY COLLEGE (CHEMICAL COLLOQUIUM), at 5.—Prof. H. Freundlich: "Some Recent Developments in Colloid Science".*

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Prof. A. V. Hill: "Muscles and Nerves: Posture, Power and Communications in the Body" (Thomas Hawksley Lecture).

ROYAL INSTITUTION, at 9.—Sir James Jeans: "The Size and Age of the Universe".

Saturday, November 30

ROYAL SOCIETY, at 2.30.—Anniversary Meeting.
Sir Frederick Gowland Hopkins: Presidential Address.

Education and Leisure in Progressive Life

THE extent of unemployment in the world to-day in itself has forced attention on the problem of leisure. Plans have already been proposed for the wider distribution of leisure as a contribution towards the reduction of unemployment by raising the age of entry to industry at one end and lowering the age of exit at the other. Similarly, the reduction of working hours has been advocated as a means of distributing leisure and employment more equably.

Behind such proposals lies the fundamental belief that the increased powers of production which the advance of mechanical and physical science has placed within man's power, if rightly used, make possible a higher standard of living for all and also the attainment of that standard through less physical effort and with consequent greater leisure than ever before. Already this belief is challenging economic and political systems or dogma which prevent the realisation either of that higher standard of living or that fairer distribution. There is a widespread readiness to try new methods if the old prove inadequate.

The very linking of the problem of leisure with that of unemployment in such ways as these has, however, proved an obstacle to clear thinking on the fundamental issues with which the coming of leisure confronts us. Only slowly are we coming to see that education must be a preparation for leisure as much as for work.

Work and leisure cannot well be separated; one is complementary to the other. Life must be viewed as a whole, and, whether from the educational point of view or the wider social point of view, a society which does not provide the training or the facilities for the adequate enjoyment of leisure is in as dangerous a condition as a society in which training and opportunities for earning a livelihood are defective. The view of education as a preparation not merely for work but also for life, the conception that the provision of adequate facilities for recreation and the right use of leisure is a prime function of the State, are so revolutionary as to involve a radical change in our views on education and other questions.

The situation calls for much creative and fundamental thought, and it was with this conviction that in 1934 the New Education Fellowship commenced a comprehensive inquiry into the subject. The outcome of the first part of this inquiry is embodied in a report which has recently been issued under the title "The Coming of Leisure"*. This report outlines the problem as it exists in England to-day, and shows the directions in which solutions are being sought. It formed one basis of the discussions at a conference held at the University of St. Andrews on August 13–22.

The report naturally starts with the problem which leisure presents to education in its narrower sense. If education, whether at school or in adolescence or in adult life, is to be a preparation not merely for work but also for life, the fundamental policies in our system of national education require drastic modification. The belief that we have merely to teach a child a certain number of subjects with some relevance to the way in which he is to earn his living, and which will provide him with a modicum of knowledge and give him the facility for acquiring more, is hopelessly inadequate if we are to educate for leisure.

If therefore education is to help youth to master the means of making life worth while a new method of approach may be required if not an entirely new technique, and a complete change in

* The Coming of Leisure: the Problem in England. Edited by E. B. Castle, A. K. C. Ottaway and W. T. R. Rawson. Pp. 78. (London: New Education Fellowship, 1935.) 2s. 6d.

the attitude of both teachers and administrators. Notably is this true in the reorganised elementary school if the purpose of the Hadow report is to be realised, and unhappily all too rarely is there betrayed in discussions on the raising of the school leaving age any realisation of the possibilities of wider experiment and adventure in education which are bound up in the reorganisation outlined in that report.

The difficult problems which leisure and education present in adolescence are largely the result of defective education at an earlier stage. Even in adolescence, the question of idle hours due to unemployment can assume serious dimensions. Such idle hours must not be termed leisure. Neither education for leisure nor any other kind of education is possible for human beings living a precarious and hand-to-mouth existence. The essential basis for the education of the adult, whether regularly employed or not, is freedom from the grosser evils of poverty, helplessness and the sense of not being wanted. It is only in an atmosphere of freedom from these evils that the expression of personality is possible and the creative instinct finds full play.

This, in fact, is the centre of the problem—the securing of full play for human personality and the creative instinct within the ranks of an organised society. It involves, of course, much more than education. It involves the evolution of sociology into an organised science, as distinct from a mere body of organised knowledge, as well as the working out of ways and means by which the enormous increase in the productive powers placed in man's hands may be utilised to secure a wider and more equable distribution of leisure for all, together with the higher standard of living which is possible with the wise use of such powers.

These are tasks demanding no small measure of scientific investigation and creative thought as well as wise statesmanship, and it is only when they have been accomplished that the educationist can enter on his full opportunity. In the meantime he has much preparatory work to do. Apart altogether from his influence in the training of the right type of leader, his influence may easily be decisive in the formation of a society and a public mind which is capable of supporting and following great leadership. The statesman, it must be remembered, too often has to content himself with what he believes it to be possible to get accepted, not with what he believes to be the most altruistic and noblest solution of a problem.

Even in this work of developing a society with a capacity to accept change and advance to a finer social order, the educationist has much to do. What may be termed the educational climate of the country has completely changed. The extensive growth of social amenities, the cheap production of books, magazines and newspapers, the influence of the cinema, the wireless and gramophone have diminished the demand for formal education. The educational process has become more and more one of unconscious absorption and less and less the deliberate satisfaction of a conscious need.

This change has several consequences. It enforces close consideration of possibilities which both the cinema and broadcasting offer for cultural purposes, and the development of a new and appropriate technique both for schools and for adult education. It demands also the development of a new technique of art education which shall contribute to the enrichment of leisure hours, and encourage the expression of creative instincts and personality whether in speech or drama, in reading or in writing. Again, the advance of science and the gradual replacement of physical labour by mechanical power have enhanced the need for physical education, so that physical recreation represents one of the major problems in the right use of leisure. Scarcely anywhere is there more need of wise and skilful guidance to secure the full value from existing opportunities and to guard against unbalanced or untoward effects whether in games, in handicraft or in gardening and like activities.

Much the same applies to the opportunities for what may be described as social adventures provided by young people's clubs and societies whether of the indoor type or for camping and rambling or the like. Wise guidance is again needed if gifts for leadership are to be encouraged and developed and not repressed, and the full value of such activities realised.

Yet another consequence is even more fundamental. Progress may well depend finally on whether we are able to liberate the world from what Prof. William McClelland has rightly termed the degrading exploitation of mass suggestion. All the evidence suggests that we are in the midst of a new renaissance through which humanity is struggling to rise to a higher level of culture. We have to prepare youth for a world where everything is in a state of flux, and the fundamental need is to train up a strong flexible creative generation with

the spirit of adventure of the pioneer on the intellectual side. To do this, education must be continuously directed towards preparing youth to think for itself. Freedom of thought is an essential preliminary alike to the creative thought which is our supreme need or to that intelligent thought on vital issues in social and international relationship in which statesmanship can function.

More and more it becomes apparent that what is needed is not merely the capacity to deal with and evaluate facts, but also the capacity to deal with contingent truth. Far too little training is given in arriving at opinions, weighing evidence, sifting motives, discounting prejudices and resisting suggestions. The very advance of science itself depends upon the development of such capacity. Prof. Julian Huxley has recently indicated how sociology can only develop into a true science as it formulates its methods for dealing with multiple effect and multiple causation.

The coming of leisure thus sets before us not indeed the problem of education for leisure but of re-examining and re-orientating our whole system of education for life. Very largely indeed the survival of civilisation depends upon our capacity to plan and put into force an educational policy, wisely co-ordinated over the whole field, so as to produce citizens capable not merely of efficient workmanship but also physically and mentally equipped to enjoy the full resources of life at our disposal. These are the conditions in which independent and creative thought is possible and in which leadership will flourish. Our task, as Whitehead reminds us, is not the production of great leaders. A great society will always put up the great men for the occasion. It is the task of establishing a great society in which adventurous and creative thought and living flourish, and to that task the whole range of problems involved in the increase of leisure summon us anew.

Agricultural Production and National Nutrition

The Agricultural Dilemma:
a Report of an Enquiry organised by Viscount Astor and Mr. B. Seebohm Rowntree. Pp. xiii + 101. (London: P. S. King and Son, Ltd., 1935.) 2*s*. 6*d*. net.

IN the volume before us Lord Astor and Mr. B. Seebohm Rowntree present the results of an inquiry organised by them into the possibilities of increasing the agricultural population of Great Britain. The 'dilemma' which the authors postulate is the difficulty of reconciling increasing employment in the production of foodstuffs at home with increasing technical efficiency, falling population, the nationalistic policies of other countries, and Great Britain's relationship—in peace and in war—with the Empire overseas, and with friendly neutral countries. The conclusion is reached that the present conditions of over-production and unremunerative prices will prove in some degree a persistent rather than a transient phenomena: that imports of vegetables, poultry, fruit, etc., have already been reduced to the limit that is desirable: that any drastic reduction of our imports of such special foodstuffs as wheat, beef, mutton and bacon (which alone could allow of a specific increase in domestic production) would seriously aggravate the economic difficulties of the world, would entail a further loss of export trade and imperil the solidarity of the British Empire and our good relations with neutral food-producing countries.

If it were not for the element of truth in some of these arguments, our agricultural policy would be easy—no need for quotas, trade agreements or marketing boards. What a delightful life for the Minister of Agriculture. As it is, however, he has to build a structure within the main girders of a national policy, utilising as best he can those girders which are already in position, adjusting others, or persuading his colleagues that the main building will be the more secure if a few of his brand new ones take the place of theirs.

What this book in fact tells us is that we had better give up hopes of any material increase in agricultural production. Whereas the inquiry specifically set out to determine the possibilities of expanding land settlement, the conclusions must relate to increased production, whether from new or existing producers. Is it unfair to presume that the same conclusions would have been reached by the same authors four years ago? We think not, for the arguments applied then as now. Yet they have been entirely falsified. Production has increased, agriculture has received considerable benefit, and neither the cost of living nor our export trade has suffered.

Although the authors prove to their satisfaction that it is illusory to suppose agriculture offers a promising outlook for the absorption of large numbers of unemployed, this is not really the case at issue. It is true that there are some who dream of settling a million men on the land of Great Britain, but those with responsible knowledge know full well that such a policy is bound to remain a dream. It is quite unnecessary to argue that it is undesirable because of the increased food production that would result. Even this is not necessarily certain, and in any event land settlement is an experiment in men and management, not an experiment in farming or in increasing food production. It is equally unnecessary to condemn such endeavours as can be made to meet local demands and social needs for land settlement in carefully selected areas and with carefully selected men. The whole world situation may well have changed long before such a policy leads to any dilemma of over-production from this cause.

Again, many of us think that such a report, based on discussion of general principles and setting forth conclusions, the limited application of which may not be realised by the general reader, is doing definite harm to the cause of agriculture as a whole. Lord Astor has pursued a similar course before. When limited assistance to wheat-growing in Great Britain was introduced, he reviewed the position of wheat-growers as a whole in the world and this country and spared no pains to convince the general public that any assistance to British wheat-growers was unsound in principle and in practice. Even in the book now under review the old subject is introduced by the arbitrary statement, "Wheat is marked out by the peculiarities of the British climate as a commodity which is appropriate for us to import largely from abroad". It is a pity that the authors of such statements cannot review the intricacies of British agriculture as a whole. They might then well come to the conclusion that "Wheat is marked out by the peculiarities of British farming in certain districts as a commodity which it is not only appropriate but necessary to grow as the basis of arable cultivation until such times as some other crop of like nature appears to take its place". This habit of taking some agricultural measure in theoretical argument to its extreme and then condemning it, ignores the complexity of the agricultural structure and the urgent need to strengthen each separate section by suitable and often diverse means, each designed for its own specific purpose and often strictly limited in either its time or area of application.

Apart from all these general considerations, the whole 'agricultural dilemma', as set forth in this book, ceases to exist if consumption of foodstuffs in Great Britain can be increased. Such a possibility is somewhat lightly dismissed; for example, "There is a possibility that consumption might be increased by better marketing arrangements, but there is no indication that the reforms proposed would result in economy sufficiently large to stimulate consumption materially". Again, "The operations of the statutory marketing boards, which represent the existing experiments in the improved marketing of agricultural products, are not in the main of a character calculated to promote the growth of consumption . . . if, for example, the consumption of one-fifth of the population were increased by 20%, the aggregate consumption of food by the community would be increased by only 4%". On the other hand, it is admitted that "Measures that would increase the aggregate consumption of food would meet what is probably the chief need of the economic situation".

This last sentence, in our view, counteracts the whole argument of the book, and the previous quotation regarding marketing boards and the possibilities of increased home consumption by no means tells the whole story. We know that marketing boards during the first months of their existence have not been able to devote much time to the reduction of marketing costs and to increasing consumption, but that is because they have been primarily engaged in saving the livelihood of the industries which elected them. Their existence to-day provides the best opportunity of action being taken along the required lines, and evidence is daily accumulating that they are fully alive to these responsibilities. Then as regards the possibility of increased consumption the figures quoted are definitely misleading. The dietary of at least 20 million persons is markedly deficient from the point of view of health. To raise it to that consumed by families with total incomes of only 20*s*. a head a week involves an increased consumption of ten per cent; to raise it to the standard of those with 25*s*. a week income would involve an increase of twenty per cent, that is, at retail prices some £200,000,000 more would require to be spent on food. As Sir John Orr has pointed out, to bring consumption up to that of families with incomes of 35*s*. a head a week (£335 a family per annum) would call for an increased consumption of 42 per cent of milk, 27 per cent butter, 28 per cent eggs and 53 per cent fruit and vegetables. At present only the wealthiest ten per cent of the population approach the standard of one pint of milk a person each day which medical opinion holds is adequate, the national average being rather less than three pints a week. To bring the entire population up to the ideal would wipe out the whole surplus and create a very severe milk

famine, which could only be brought to an end by a fifty per cent increase in output.

These may be dreams of perfection, but is it correct when the authors of this report imply that the possibilities in this direction are limited? If we can correct malnutrition—this glaring mistake in our national life and national economy—then the agricultural dilemma vanishes: fears of over-production can be relegated to the distant future.

Few will quarrel with the conclusion that the settlement of vast numbers of unemployed on the land is impracticable. This book, however, bids us believe that any considerable increase in home production, from whatever source it arises, is impracticable. Such a statement we submit is unsound and definitely harmful to the cause of agriculture.

In saying this we wish particularly to add that no one could possibly imagine that Lord Astor and every one of his colleagues responsible for the inquiry do not sincerely and profoundly desire to see renewed prosperity reaching the English countryside. They themselves state that they arrived at their conclusions with very great disappointment. The reviewer, while feeling bound to attack these conclusions with all the force at his command, consoles himself with the thought that, if his view is correct, then the authors' disappointment can vanish with the dilemma which they have conjured up. The real problem before the country is to increase consumption of home foodstuffs to the mutual betterment of agriculture and of national health. W. GAVIN.

A New "Outline"

Science: a New Outline
By J. W. N. Sullivan. Pp. xii+286+4 plates. (London and Edinburgh: Thomas Nelson and Sons, Ltd., 1935.) 5*s*. net.

IT is perhaps insufficiently recognised that the writing of a good "Outline", of the kind which the public, or the publishers, seem to go on demanding, is a vastly more difficult task than the writing of a good monograph. The ratio of difficulty is that of Dürer or Cézanne to the village photographer. Dürers and Cézannes being scarce, it is a natural consequence that most "Outlines" are disappointing and few wholly satisfying. Mr. Sullivan has on previous occasions demonstrated his understanding of modern scientific thought and method, and his present "Outline" is an interesting and readable assemblage of usually accurate information from the physical and biological sciences. There is a gallant attempt to carry the pencil on without discontinuity from the physical to the biological, and the author may be congratulated on his general success in this difficult undertaking.

But whether Mr. Sullivan and his publishers are doing a service to 'science' in this new outline is very doubtful. Too frequently the reviewer sees in it a highly intelligent Jack Horner, pulling out of the scientific pie a number of attractive plums which are chosen merely "pour épater le bourgeois". It would be much better for the consumer to be told how and why the plums got there than to have them pulled out ready-cooked.

The plum-pulling encourages carelessness in the author. The most worthy of his chosen audience will stop at every third page to ask about the how and why, and will find no answer in this outline He will be repelled by the slovenliness of exposition in the introductory note, of "a certain very simple notation which is universally adopted by scientific men", in which one-millionth = 10^{-6}. He will wonder what is really meant when the polar diameter of the earth is stated to an accuracy of fifty feet. He will probably know enough to see that he is being misinformed when the aeroplane height record is implicitly put so low as seven miles; he will probably *not* know enough to see that he is being equally misinformed when he is told that "at something over sixty miles the atmosphere is almost entirely composed of hydrogen . . . while oxygen seems to disappear completely". He is not unlikely to be surprised by the author's neglect of the main factor in a simple problem in statics. Mr. Sullivan says, "Whenever we crook a finger all the hosts of heaven are affected", and goes on to use the inverse square law to mitigate the disturbance. An intelligent schoolboy will be able to tell him that a much more important reason why the hosts of heaven are substantially indifferent to one crooked finger or ten million extended right arms is that the earth side-slips to counter the crook.

These are small specimens from early pages, but they are representative of that culpable lack of care which is dangerously common in works of popularisation. It is culpable and dangerous because, in sum, the world will remain unfit for civilisation so long as the reader of "Outlines" is fed on the facts of science untempered by an education in its stringent honesty of aim and method. W.

F. H. Bradley's Psychological Principles

Collected Essays
By F. H. Bradley. Vol. 1. Pp. x+347. Vol. 2. Pp. v+349–708. (Oxford: Clarendon Press; London: Oxford University Press, 1935.) 36*s*. net.

THESE two imposing volumes are a very welcome addition to philosophical and psychological literature. It is true that with two exceptions all the essays here included have already seen the light. But each of the pamphlets containing the opening papers of the present collection —those on "The Presuppositions of Critical History" (the author's earliest production) and on "Sidgwick's Hedonism"—have long been out of print, and the other published articles have remained more or less buried in the back numbers of the periodicals in which they first appeared.

Bradley was the author of several epoch-making works in the fields of ethics, logic, metaphysics and epistemology; and some of the papers in the volumes before us deal with ethical questions. But, although he was a psychologist of rare independence and insight, he did not write any separate book on psychology; he was content to let his psychological contributions appear as articles in the pages of *Mind*. These occupy by far the larger, and I think it may be said the more important, part of the new volumes now under notice.

It was perhaps unfortunate that Bradley should have persisted in designating the point of view which seemed to him the right one in psychology as that of "phenomenalism", because he was using the term 'phenomenon' in a peculiar sense (familiar to readers of his work "Appearance and Reality"), whereas it usually carries with it implications which he would have repudiated. What, however, he meant was that the mere course of psychical events as such, happening and experienced within a single organism, and the laws of coexistence and sequence between these events, constitute the subject-matter of empirical psychology, while questions about the ultimate nature of mind or soul do not belong to its domain. He was trying, as he himself expressed it, to work in the spirit of the best English tradition (and, one may add, of the best Herbartian tradition), although rejecting absolutely the doctrine that had become associated with it of 'psychical atomism', and refusing to admit what had been so often taken for granted that *all* psychical facts can be treated as objects to be observed.

The association psychology went into bankruptcy, it has been said, when J. S. Mill felt himself compelled to suggest the hypothesis of 'mental chemistry'; and in the later decades of last century a new phase of psychological theory was taking its place. So far as stress was laid in the latter upon the primary importance of evolution or development in the mental life Bradley was in complete accord therewith. But he found in the writings of its two most prominent exponents, Wilhelm Wundt and James Ward, an underlying notion of the nature of mind which appeared to him not only unpsychological but also devoid otherwise of justification. Ward had laid it down, namely, that for psychology, as the science of individual experience, the duality of subject and object is fundamental and primordial. On one side, he maintained, is the active subject, with its one primitive capacity—that of feeling—and, on the other side, are the objects of its activity, the presentations attended to. And since the feeling agent, that is, the knower, and the known are antithetic and distinct, direct presentation or representation of feeling and activity must be alike impossible; we can know of these only mediately through their effects, through certain changes which they bring about in the character and succession of our presentations.

Whether one agrees with it or no, Bradley's criticism of the positions just indicated must be allowed to be searching and penetrating. He argued that to interpret the consciousness of force or energy as being itself a mode of exerting, or putting forth, force or energy is wholly illegitimate. He denied that this consciousness is in any sense a revelation of activity or energy, as an unanalysable element. It gives us, he urged, not a fact but an intellectual construction, and a thoroughly baseless intellectual construction. The notion of an arbitrary force proceeding from the self is, in truth, he contended, a notion to which no intelligible meaning can be attached. Not only so. It seemed to him that no valid reason whatsoever had been offered for assuming that the relation of subject and object is implied in all conscious experience. It is, he averred, inconceivable that experience at its poor and blurred beginning divides itself into two parts with a relation between them. Until the primitive whole of feeling becomes to some extent differentiated into feelings, and until within this whole a core had grown together, over against which different groups of presentations can come to appear as an 'other', it is, he

insisted, impossible to see how there can be any aspect of *self-feeling*, and still less how there can be anything like what is ordinarily meant by subject and object. In short, what I take Bradley's contention to be amounts to this, that the general terms "subject" and "object" have their meaning fixed only in and through the concrete experiences which enter into and serve to establish a recognised distinction between them.

Starting, then, with a conception of the beginnings of mental life such as he held we are warranted in framing, Bradley's constructive work in psychology consisted in endeavouring to trace the way in which the several so-called faculties of mind—attention, thought, will, and so on—gradually came to be. Thus, in dealing with attention, he shows, in the first place, how the process of involuntary attention may be regarded as having been initiated by differences in the intensity of feeling-tone accompanying certain presentations, the latter thereby attaining predominance in consciousness. And he tries, in the second place, to make manifest how from the undoubted facts of involuntary attention an intelligible account of the emergence of active or voluntary attention can be given without calling to our aid the idea of some mysterious "force" proceeding from the self. Briefly, it is with the rise into consciousness of a definitely recognised distinction between the self and the not-self that there become possible those experiences of strain or effort which characterise attention as we are familiar with it. Whilst recognising the influence of muscular and motor factors, Bradley conceived that the origin of the experiences in question lies in what he called a feeling of expansion consequent upon the enlargement of the self. When we get to know from repeated experience that changes ensue upon modes of our self, this expansion of our area, beginning from within, gives the feeling of activity.

The chief characteristic of conceptual thought, as regards its content, is, Bradley contended, objectivity; and, pursuing still the genetic method, he sought to render explicable the transition to thought from feeling or sentience by resort to the theory of Association, but that theory radically modified. Not only is atomism wholly banished, and with it likewise the "law of similarity"; but also the law of contiguity has to be so restated as to make it depend always on identity of content, not of existence. The law then becomes that of Redintegration, expressible in the form "every mental element when present tends to reinstate those elements with which it has been presented". Further, there is to be postulated what he called a law of Blending or Fusion—the law, namely, that "where different elements (or relations of elements) have any feature the same, they may unite wholly or partially". Lastly, underlying these two laws there is to be discerned, so he argued, one principle—the principle which may be described as that of Individuation, according to which "every mental element strives to make itself a whole or to lose itself in one"; or, in other words, "tends to give itself a context through identity of content". Such was the "machinery" which, working in all psychical processes, appeared to Bradley adequate to account for the fact that from a basis of mere feeling the development of thought, as the apprehension of something real by itself and independent of its connexion with a feeling-centre, emanates.

In a similar manner Bradley endeavoured to trace the genesis and development of volition or will. Obviously, will, involving as it does the consciousness of self, cannot be regarded as original or ultimate. It can be no other than a product or result from that which by itself is not volition. Its essence, on Bradley's view, consists in the passage of an idea into existence; and that passage depends on machinery—the machinery already alluded to. If an idea works itself out ideally and subject to identity, we have the process of thought. If, on the other hand, it produces fact, if it alters the existent object into accordance with its own character, the process is will; and unless the idea carries itself out into the changed existent there is no will.

My space is exhausted, but I may perhaps be allowed to indicate the sort of difficulty I feel in regard to the assertion just mentioned. If by 'idea' be meant, as I take it was meant, a content apprehended, then one may well ask whether an 'idea' ever does 'carry itself out'. The carrying out of what is willed, so far at least as that involves a change in the outer world, is surely a bodily affair, the details of which, as Lotze pointed out, entirely escape the consciousness of the willing subject. Indeed, I am possessed of an uneasy suspicion that having, as I think, rightly refused to picture consciousness as exerting force or energy, Bradley tended to transfer this notion to 'presentations' and 'ideas'; and to imply, after the manner of Herbart, that although a 'presentation' or 'idea' taken *per se* is not a force, yet a number of 'presentations' and 'ideas' when in conjunction do operate on one another as though they were forces.

Despite, however, the criticism they will certainly elicit, no competent judge will hesitate to acknowledge that these essays together form an extremely valuable contribution to psychological science. The volumes have been most carefully edited. They only lack one thing—an adequate index.

G. DAWES HICKS.

Gmelins Handbuch der anorganischen Chemie

Achte Auflage. Herausgegeben von der Deutschen Chemischen Gesellschaft. System-Nummer 35: Aluminium. Teil A, Lief. 2. Pp. 285–450. 26 gold marks. Teil B: Die Verbindungen des Aluminiums, Lief. 2. Pp. 309–613. 49 gold marks. (Berlin: Verlag Chemie G.m.b.H., 1934.)

THE well-known property possessed by aluminium of coating its surface with an invisible, firmly adhering and continuous skin of oxide has rendered the systematic investigation of its electrochemical behaviour extraordinarily difficult, while at the same time it has had most important practical results in the industrial application of the metal. Thus the properties of pure aluminium may be very different from those of the commercial metal. Accordingly, about one quarter of Part A, Section 2, of the volumes on aluminium is occupied with a discussion of electrochemical measurements. The remainder deals with the chemical action on aluminium of non-metals, water, acids and alkalis, including organic reagents.

Part B, Section 2, deals with a large variety of compounds of aluminium, including the silicates and the changes which kaolin undergoes when subjected to heat, natural and synthetic zeolites, the various alums and ultramarines. Historical accounts of the uses of alum and ultramarine are given. The latter has been in use as a dye since the eleventh century. Recent work upon its constitution has shown that in all ultramarines the ratio $SiO_2 : Al_2O_3$ remains practically constant in the silicate frame, and the colour depends not only upon the sulphur which is present but also upon the alkali. The latter can be partly or almost completely extracted from blue ultramarine by means of chlorine and certain organic solvents. The colour is thereby destroyed, but it can be restored by the addition of alkali. When chlorine was used it was found that the colourless product retained the original crystal lattice structure.

Chinese Art

Edited by Leigh Ashton. Introduction, by Laurence Binyon; Painting and Calligraphy, by Laurence Binyon; Sculpture and Lacquer, by Leigh Ashton; The Potter's Art, by R. L. Hobson; Bronzes, by A. J. Koop; Jades, by Una Pope-Hennessy; Textiles, by Leigh Ashton. Pp. xvi+111+23 plates. (London: Kegan Paul and Co., Ltd., 1935.) Paper, 2*s.* 6*d.* net; cloth, 3*s.* 6*d.* net.

THIS little book, which has been prepared in anticipation of the exhibition of Chinese art being held at the Royal Academy, Burlington House, does not call for extended comment, excellent though it is. It is intended for the uninitiated, and has been written by experts in the respective fields with which each deals, as indicated in the title-page. The essays are short, but have been skilfully adapted to their purpose of giving the Western visitor to the exhibition an idea of the Chinese artistic and technical achievement, as well as of the mentality and range of imagination of the Chinese artist. The dynastic and chronological relations of the exhibits—of the first importance in the appreciation of Chinese culture—receive due attention. The book is liberally illustrated.

Modern Production among Backward Peoples

By Dr. I. C. Greaves. (London School of Economics and Political Science: Studies in Economics and Commerce, No. 5.) Pp. 229. (London: George Allen and Unwin, Ltd., 1935.) 10*s.* 6*d.* net.

DR. GREAVES has broken new ground in her study of the economic activities and organisation found among backward peoples as the result of the introduction of European methods of exploitation of their resources. The data she has collected, as well as her conclusions, are of interest to economist, anthropologist and administrator alike. For the anthropologist they form an object lesson in culture contact, available equally for academic use and practical application; for the administrator, a message of guidance and warning; and for the economist, in the author's attitude to cultural differences, a new orientation in the assessment of comparative values.

Dr. Greaves passes under review the function of the State in administering backward territory in relation to imports, exports and the investments of capital from outside sources. She shows how, still keeping this triple aim in view, policy has changed direction from promoting the interests of the European, whether settler or ruling people, to a substantial, if not exclusive, support of indigenous activity. How far this is general depends upon local conditions, and all stages of development are to be found, going indeed so far in one direction as the complete segregation which is the ideal, not, however, realised in practice, in South Africa.

A wide variety of economic problems has been brought under review by the author, and her book is a store of information, as well as a well thought out and impartial survey of conditions and tendencies.

Low Temperature Physics

By Dr. L. C. Jackson. (Methuen's Monographs on Physical Subjects.) Pp. vii+122. (London: Methuen and Co., Ltd., 1934.) 3*s.* net.

UNTIL quite recently, the development of low temperature research has been carried on almost entirely abroad, and although the book has had to be restricted to a few sections of especial interest and, in particular, dealing largely with the range of temperature 1°–20° abs., a remarkably comprehensive survey is compressed into the six chapters on the production of low temperatures, their measurement, liquid and solid helium, specific heats, electrical conductivity and magnetism. The latest work on the region below 1° abs. is notable, and, in view of the interest and importance of electrical and magnetic phenomena at low temperatures in connexion with atomic and lattice structure, the last two chapters give a valuable summary of recent experimental and theoretical advances.

Although the book is mainly concerned with the description of experimental technique, given in many cases with illustrative curves and numerical data for a large number of substances, the mathematical theory and expression of the various aspects of the subject are not neglected. References to more than a hundred original papers are provided. N. M. B.

Hydrogenation of Coal

IN a country which had formed the habit of assessing power in terms of coal-burning in a furnace or under a boiler, the decline in the coal mining industry and the rapid expansion in the use of the internal combustion engine are two facts about which chemists and engineers have been thinking for a long time. Interest in the production of petrol from coal is now nation-wide; it has been stimulated by the hope—indeed by the conviction—that this branch of chemical industry will appreciably help British coal mining to surmount its financial difficulties, bringing work and wages into many homes that have long known neither; and it has been maintained by the success which Imperial Chemical Industries, Ltd., has already achieved in placing the operation on a commercially promising basis. For that reason alone, and apart from its obvious technical interest, Mr. Kenneth Gordon's lecture on November 21 to the Institute of Fuel, entitled "The Development of Coal Hydrogenation by Imperial Chemical Industries, Ltd.", deserves to be regarded as an event of more than passing significance.

Mr. Gordon reminded us that there are three types of reaction to be distinguished. First, there is the transformation of impure carbonaceous material into hydrocarbons, other elements being removed in the form of their compounds with hydrogen, that is, as water, ammonia and hydrogen sulphide. Then there is the saturation with hydrogen of unsaturated bonds between carbon atoms. Finally, there is the splitting up by heat of the saturated molecules so formed to give light hydrocarbons, although a certain amount of hydrocarbon gas, and even of coke, is also formed, particularly when the saturation has been inadequate. "The art of hydrogenation," Mr. Gordon said, "consists in choosing the proper conditions of temperature, pressure, time of reaction, and catalysis, so that the three desired reactions take place to the greatest extent, and the fourth reaction, the undesired formation of gas, to the minimum extent." In practice, pressures of at least 200 atmospheres, and temperatures of 300°–500° C. are employed, suitable means being used to dissipate the heat liberated during the chemical reaction; the catalyst may be mixed with a liquid, or vapours mixed with hydrogen may be passed over it. The choice of a catalyst is governed by its activity in promoting the hydrogenation reaction, the thermal decomposition ('cracking') reaction, or both, and its susceptibility to inactivation ('poisoning') by certain materials, for example, sulphur, often present in the original coal or oil.

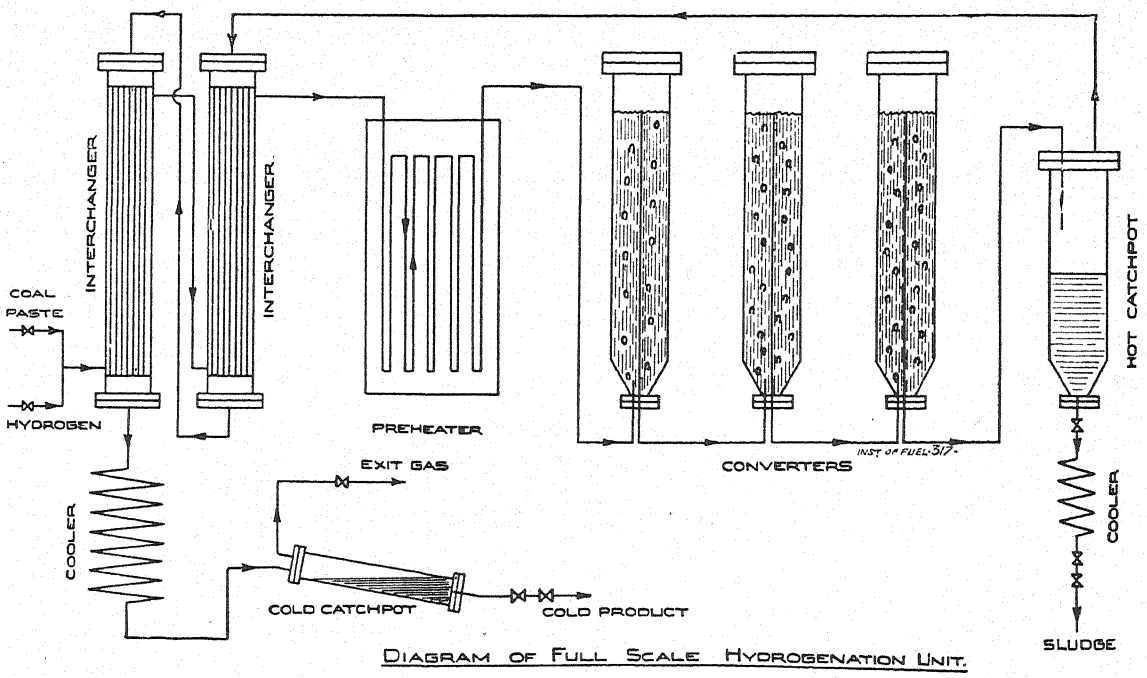

FIG. 1.

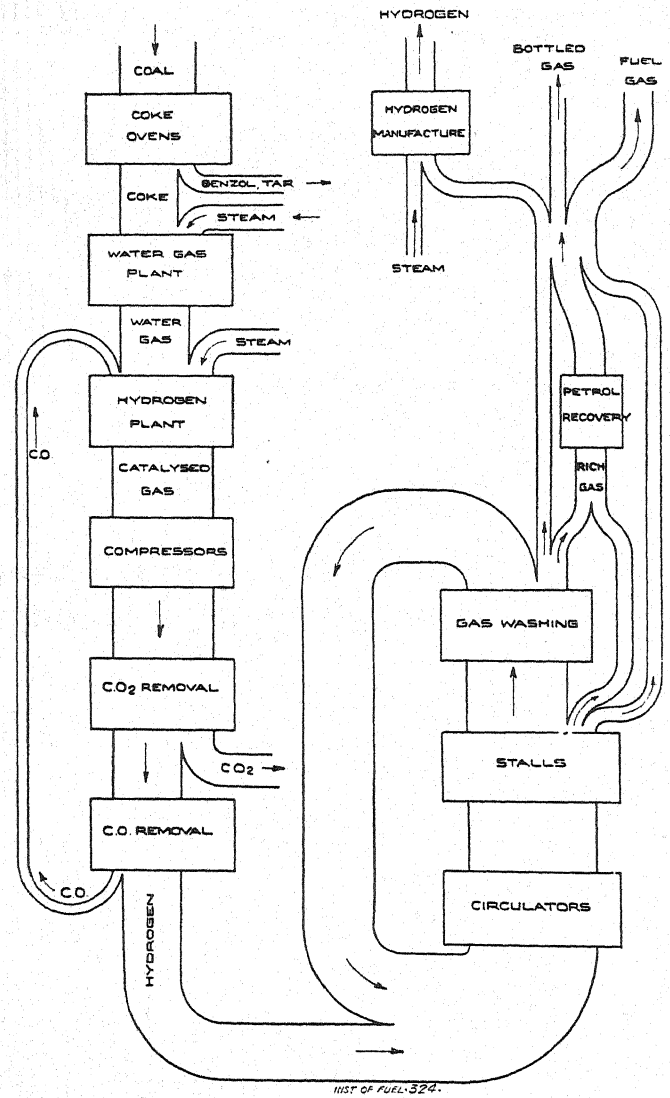
The solution of this important problem was an essential preliminary to any advance in the direction of commercial hydrogenation.

The original Bergius process, as developed by the German combine known as the Interessen Gemeinschaft für Farbenindustrie, or more briefly as the "I.G.", working at first independently and later in association with the Standard Oil Co. of New Jersey, afforded as products petrol, tar acids, heavy oil and pitch. Tests on British coals were carried out, but it was soon decided by Imperial Chemical Industries, Ltd. (equally well known as "I.C.I."), that modification in the direction of the production of petrol alone was desirable. Experiments were commenced at Billingham in 1927, and a plant treating 10 tons of coal a day was operated from 1929 until 1931. Following a demonstration in 1930 that 60 per cent by weight of petrol (a figure since exceeded) could be obtained from coal, the formation, in 1931, of the International Hydrogenation Patents Co. (a company formed by the "I.G.", "I.C.I.", the Standard Oil Co. of New Jersey, and the Royal Dutch-Shell Group) placed the interested companies in a very strong patent and technical position. During 1932 technical advances were being made, and schemes for operating on a large scale were maturing; so that when, in 1933, the British Government announced its intention to protect the new industry by guaranteeing the continuance of a preference for a term of years, Imperial Chemical Industries, Ltd., decided to proceed at once with the erection of a plant at Billingham.



FLOW DIAGRAM OF HYDROGEN PRODUCTION & TREATMENT OF HYDROGENATION PLANT GASES

FIG. 2.

Preliminary scientific work has, of course, been enormous in its extent; a million pounds were spent in this way between 1927 and 1933 by I.C.I. alone, but few details relating to it have appeared in the scientific literature by reason of arrangements made with the international company. It has been found possible on a large scale to dispense with mechanical stirring and external heating; tin, first used in the form of tinned iron plates, and later in the form of certain organic compounds, was found to be the most promising catalyst. The "Billingham" method of using two vessels, one inside the other, has been employed; thus one vessel withstands the temperature but not the pressure, whilst the other withstands the pressure and not the temperature.

The process affords petrol, middle oil and heavy oil; the heavy oil is recirculated with coal, but the middle oil has to be subjected to hydrogenation in the state of vapour. Cleaned coal is found to be much more satisfactory than raw coal, partly because it avoids the expense of processing mere ash, but partly also because the alkaline ash interferes with the catalytic reaction. The residual ash can be neutralised by the addition of hydrogen chloride now that its subsequent removal (in order to prevent corrosion) can be accomplished by scrubbing the hot vapours at 450° C. with a suspension of alkali in oil.

On the large scale, the hydrogenation of coal is at present associated with that of creosote oil, supplied by tar distillers, and of low-temperature tar; but if market conditions require, small adjustments to the plant will adapt it to the desired

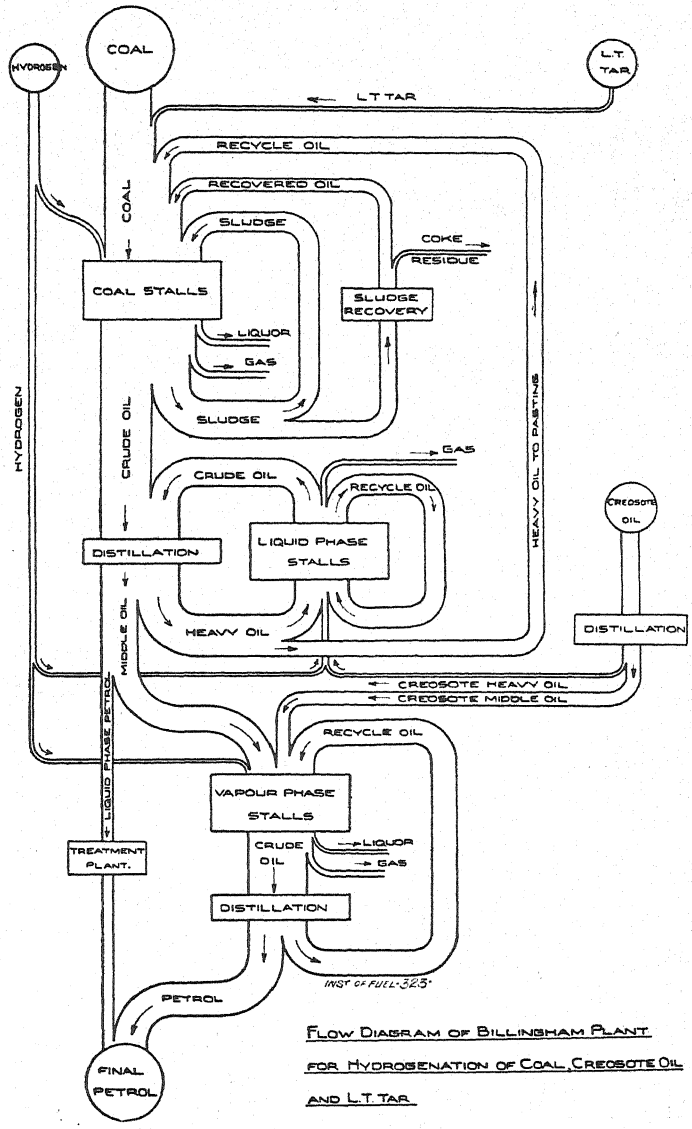
extent for the treatment of coal. In fact the Billingham plant is deliberately designed to provide for flexibility. The hydrogen comes from coal by way of coke and water-gas, but it is intended to manufacture hydrogen from waste hydrocarbon gases by catalytic treatment with steam instead of using these gases as fuel. Part of the waste gas is, however, already used commercially; liquefied butane is supplied for sale for domestic purposes where coal gas is not available.

The process is operated as follows: The coke, from coke ovens, is used for making water-gas, which is freed from sulphur, and then treated with steam in the presence of a catalyst to afford a mixture of hydrogen, carbon dioxide and a little carbon monoxide. This gas is compressed, freed from carbon dioxide by scrubbing with water at 50 atmospheres, and from carbon monoxide by scrubbing with a copper solution at 250 atmospheres pressure. The hydrogen circulating in the plant becomes contaminated with nitrogen and hydrocarbons; these are removed partly by dissolution in the products themselves (being recovered on release of pressure) and partly by scrubbing with oil under pressure.

Coal, first freed from dust by air and then cleaned by the Chance process (of floating the raw coal on a suspension of sand in water), is ground up, together with the right amounts of catalyst and oil, into a paste; the oil used for this purpose is the heavy fraction of creosote oil. This fluid paste, containing 50 per cent of coal, is injected against a pressure of 250 atmospheres, and becomes mixed with hydrogen, being brought to the reaction temperature first in heat exchangers and then in gas-fired pre-heaters. After passage through the converters the product is separated into gases and vapours on one hand and residual oil, ash and coal on the other.

The units, or 'stalls', comprise converters, heat exchangers and pre-heaters, which are arranged in one line and tended for maintenance by a Titan crane of 170 tons capacity; each pair of stalls has a control room containing the instruments and valves. The gas released from the crude products by the removal of pressure in stages is separated into 'lean' and 'rich' gas, the latter being further treated for recovery of the light fractions of petrol. All petrol is washed with caustic soda to remove hydrogen sulphide, and is stored under nitrogen; liquid phase petrol requires treatment with sulphuric acid as well.

It is estimated that the over-all consumption of raw coal would, on a new plant, be 3·5–4 tons per ton of petrol; the thermal efficiency is 40 per cent, whilst that for the generation of electric power is 25 per cent, and that for gasification is 55 per cent. In the Billingham plant, the over-all raw coal consumption is 5 tons per ton of petrol.



FLOW DIAGRAM OF BILLINGHAM PLANT FOR HYDROGENATION OF COAL, CREOSOTE OIL AND L.T. TAR

FIG. 3.

The petrol is of uniformly good quality, and has a high volatility. Concluding his paper, Mr. Gordon remarked that the company has not had much time to study the production of Diesel oil from coal, but that there is no insuperable difficulty in producing a satisfactory oil. Heavy oil obtained from coal is suitable for use as fuel oil without further treatment; whilst the problem of lubricating oil manufacture still awaits attention.

Some Geological Aspects of Recent Research on Coal*

By Prof. H. G. A. Hickling

Types of Coal Aggregate

In coal, as in other fragmental rocks, size is the great sorting factor. The dominating component, vitrinite, exists for the most part in fragments much larger than those of any other component except fusain. It follows that as the average size of the particles in any coal aggregate decreases, so the proportion of vitrinite usually becomes less, while that of spores, cuticles, resins, fragmented fusain and residuum becomes greater. This introduces an important element of order where there might have been almost complete chaos.

Complete gradation from the brightest coals, consisting entirely of large fragments of vitrinised tissue —that is, of vitrain lenticles only—through every stage of decreasing particle size, decreasing vitrinite content and decreasing lustre, to the most finely granular dull aggregate is to be expected and is easily found. But in most seams there is a small proportion of bands ('durain') which are unmistakably quite without lustre, and these are sharply separated from the 'bright' coal ('clarain' and 'vitrain'), even though the lustre of the bright bands may vary widely. The distinction of the two types of aggregate clearly corresponds to some difference in the mode of accumulation.

The really dull bands are usually (though not necessarily) characterised by a very much higher content of ash than the bright coal, and this excess always consists of a very fine clay which must have been water-borne. Both durain and clarain are of variable composition, and the one may shade into the other though they are commonly somewhat sharply separated. The clarain, however, with its dominating vitrinite constituent, tends to comparative uniformity of composition, while the durain may be far more varied. A rich content of spores, cuticles or resins may make the durain conspicuously rich in hydrogen; while a dominance of residuum, or a high content of fragmented fusain, may have the opposite result. It is the variable part of the coal.

Rank of Coals

From the geological point of view, the greatest contribution which is made by the microscope to the study of coal is, that it enables us to determine definitely whether the difference in quality of two coals can or cannot be attributed to original difference of composition. If they can be seen to consist of entirely similar plant materials in a similar state of preservation, then any considerable difference in quality must be attributed to some other factor. Conversely, we may compare the quality of coals which are visibly composed of different materials, and find what are the constant differences between them. The differences due to plant ingredients and mode of origin define the *type* of coal; those due to subsequent alteration denote the *rank*.

* *Continued from p.* 819.

Composition of Coal Components

In common with most vegetable substances, coals consist mainly of carbon, hydrogen and oxygen, and as the first step in the discussion of this problem we may inquire how the proportions of these constituents vary among the different plant materials which may be isolated from any single piece of coal. The vitrinite is of very uniform composition. The group of cuticles, spores and resins is notably high in hydrogen, but is not exceptional in the ratio of carbon and oxygen. Any fusain present will be very deficient in both hydrogen and oxygen. The chemical composition of the residuum needs further investigation; the indications are that it is usually a little deficient in hydrogen and oxygen, but not to such an extent as in the case of fusain. The outstanding fact is that the different components vary strikingly in their hydrogen content (from about 3·5 per cent in fusain to 8·0 per cent in some spores), while only in the case of fusain is there any notable variation in the oxygen.

Now, if we take a very large number of representative analyses of lignites and bituminous coals (but exclude for the moment anthracites and cannels) we shall find the limits of variation of the chief constituents to be approximately as follows: hydrogen, 4·5–6·0 per cent; carbon, 65–90 per cent; oxygen (varying in almost exactly complementary proportion to the carbon), 30–5 per cent. We see clearly that the whole variation of hydrogen content is well within the range observed among the different plant constituents in a single piece of coal. But the observed range of oxygen content in different coals is, on the contrary, many times greater than could be produced by any known variations of the plant constitution. It is this difference of oxygen content, in fact, which chiefly denotes the *rank* of the

coal, distinguishing the lignites, bituminous coals and anthracites.

A very significant feature of this variation in rank is the fact that it is *continuous* throughout its long range, and the significance of this continuity is emphasised in an interesting way by the work of Prof. Bone and his colleagues, who have shown that the proportions of the different types of organic compounds present in the coal vary progressively throughout the series.

Significance of Ranks

The thesis towards which all my remarks have been preparatory is that the rank of a coal is the measure of the alteration in composition which the deposit has suffered in consequence of the rise of temperature and increase of pressure resulting from its burial in the crust.

What do we know of the relation between the rank of coals and their distribution in the rocks ?

The fact which appears to me to establish most clearly that change of rank must be caused by some geological factors is its areal distribution. In every coalfield where substantial variation of rank has been noted and examined, the rank of any given seam is found to change *progressively* as it is followed across the field. If the variation be plotted on a map by means of lines representing volatile content, carbon content, or any suitable measure of rank, these lines are found to be arranged in an orderly pattern and—this is the important point—the same pattern is repeated by each seam within the area. Wherever the rank of one seam is increased, there also is that of the others. Whatever cause has affected one has affected all.

Valuable light is shed on this matter by the detailed information concerning the composition of many of our own coal seams and their variation which is being accumulated by the National Fuel Survey. Many of the seams examined, particularly in Northumberland and Durham, show large changes in rank as they are followed across the coalfields. Some of the seams are notably 'bright' coals, with a relatively high hydrogen content ; others contain a larger proportion of durain and (commonly) a lower percentage of hydrogen. A careful comparison of the analyses shows clearly that the seams which are high in hydrogen retain that peculiarity regardless of change in rank, while those which are low remain low. The chemical evidence supports that provided by the detailed examination of the physical peculiarities of the seams, and the cumulative evidence leaves no room for doubt that in these instances the change of rank is quite independent of the original constitution of the seams.

Hilt's Law

The simplest and most familiar evidence of a relation between rank and geological conditions is Hilt's law : that, in any single vertical section, the deeper seams are of higher rank than the upper seams. Apparent failure of the rule in some cases is doubtless due to the fact that original differences between seams may affect their present composition to a greater extent than small differences of depth. But when the differences of depth are substantial, exceptions are rare.

The value of Hilt's law lies, first, in the fact that it is unambiguous in its significance, and, secondly, in the fact that since we know something of the increments of temperature and pressure which correspond to given differences of depth, and can compare these with the changes of rank produced, it gives us the data necessary to reverse the process, and to consider the rank of coals as an indication of the temperatures and pressures to which they have been subjected. The temperature increments are clearly so small that most geologists have been inclined to attribute the effects mainly to pressure. It is impossible to discuss this matter within the limits of this address, so it must suffice merely to refer to the experimental work, which has shown how readily coal, even in its present condition, yields volatile products at very moderate temperatures, and to the fact that in the effects of igneous intrusions we have a series of beautiful natural experiments in the alteration of the rank of coals by heat alone. In some of these natural experiments the resultant effects on the coal appear to be in every respect analogous with the ordinary changes of rank ; in others they are obviously different. In the latter instances it is not difficult to see that the results are due to the rapid application of somewhat considerable increments of temperature. There appears to me to be quite good evidence to show, on the contrary, that in those cases, in which considerable changes of rank of the normal type have been produced, the total increments of temperature have been quite small.

If it be true that the rank of coals has been determined mainly by the depths to which they have been buried, then it is natural to look for some relation between the varying rank of any seam and its present depth below the surface, or to relate the variation to axes of folding. Much has been written on this subject, and completely contradictory conclusions reached. But this is to be expected. The coal can only indicate the *maximum* temperature or pressure to which it has been subjected, since change of rank is almost certainly an irreversible process ; decrease of temperature and pressure will not restore it to its former level. Now a little reflection will show that, after the completion of the coal-bearing series, the most

The chemical evidence supports that provided by the detailed examination of the physical peculiarities of the seams, and the cumulative evidence leaves no room for doubt that in these instances the change of rank is quite independent of the original constitution of the seams.

Hilt's Law

The simplest and most familiar evidence of a relation between rank and geological conditions is Hilt's law : that, in any single vertical section, the deeper seams are of higher rank than the upper seams. Apparent failure of the rule in some cases is doubtless due to the fact that original differences between seams may affect their present composition to a greater extent than small differences of depth. But when the differences of depth are substantial, exceptions are rare.

The value of Hilt's law lies, first, in the fact that it is unambiguous in its significance, and, secondly, in the fact that since we know something of the increments of temperature and pressure which correspond to given differences of depth, and can compare these with the changes of rank produced, it gives us the data necessary to reverse the process, and to consider the rank of coals as an indication of the temperatures and pressures to which they have been subjected. The temperature increments are clearly so small that most geologists have been inclined to attribute the effects mainly to pressure. It is impossible to discuss this matter within the limits of this address, so it must suffice merely to refer to the experimental work, which has shown how readily coal, even in its present condition, yields volatile products at very moderate temperatures, and to the fact that in the effects of igneous intrusions we have a series of beautiful natural experiments in the alteration of the rank of coals by heat alone. In some of these natural experiments the resultant effects on the coal appear to be in every respect analogous with the ordinary changes of rank ; in others they are obviously different. In the latter instances it is not difficult to see that the results are due to the rapid application of somewhat considerable increments of temperature. There appears to me to be quite good evidence to show, on the contrary, that in those cases, in which considerable changes of rank of the normal type have been produced, the total increments of temperature have been quite small.

If it be true that the rank of coals has been determined mainly by the depths to which they have been buried, then it is natural to look for some relation between the varying rank of any seam and its present depth below the surface, or to relate the variation to axes of folding. Much has been written on this subject, and completely contradictory conclusions reached. But this is to be expected. The coal can only indicate the *maximum* temperature or pressure to which it has been subjected, since change of rank is almost certainly an irreversible process ; decrease of temperature and pressure will not restore it to its former level. Now a little reflection will show that, after the completion of the coal-bearing series, the most

general result of subsequent folding will be elevation and denudation, leading to a decrease rather than an increase of load. In so far as this is true, the folding will not be reflected by any variation of rank; while, on the contrary, any circumstance which does lead to a further increment of temperature will leave its mark. Later burial of the whole series below an uncomformable cover may lead to a change of rank in the deeper parts of the seams, while leaving the upper portions untouched. The time factor, moreover, can by no means be left out of account. Geo-isotherms creep with exceeding slowness, even in terms of the rate of sedimentation and denudation. The duration of burial as well as its depth is therefore material. In fact, the whole sequence of events which have determined the maximum temperature and pressure reached at any point must have been much too complicated to be readily decipherable from the present disposition of the rocks.

In all these complications, however, one cardinal principle remains. At any given place, both temperature and pressure must always have increased downwards—apart, of course, from the influence of igneous intrusions. So, while the interpretation of the lateral variation of rank is involved in many complicating factors, Hilt's law remains as a simple and significant sign. Even in this case the significance is liable to be obscured by the variation of the original coal substance of the different seams; but the technique of the microscopic study of coal has now reached the point at which, I believe, the effect of this factor can be almost completely assessed and eliminated. If this be so, then we are in a position to use coal as a geological thermometer—or, perhaps, combined thermometer and barometer—and we may set about calibrating it by means of a thorough study of Hilt's law and of the effects of igneous intrusions. But we must never forget that the thermometer has one peculiarity—it is a maximum thermometer only.

Obituary

Prof. Sylvain Lévi

THE death is reported from Paris of Prof. Sylvain Lévi, France's most distinguished orientalist, which took place suddenly on October 30, at the age of seventy-two years.

Sylvain Lévi was born in Paris on March 28, 1863. From an early age he applied himself to the study of oriental languages, especially those of China and Tibet, and in 1886 he was appointed a lecturer in the Ecole des Hautes Etudes. He was a special lecturer in Sanskrit in the Faculty of Letters of the University of Paris from 1889 until 1894, when he was appointed to a chair in the Collège de France. At the time of his death, he was president of the Société Asiatique and of the section of religious studies in the Ecole des Hautes Etudes. Among other honours he was an officer of the Légion d'Honneur and an Hon. Litt.D. of the University of Calcutta.

Lévi had travelled frequently and far in the East to further his researches, applying himself deeply to the study of epigraphy, manuscripts and art, notably in China, Tonkin, India and Nepal, spending three years in the last-named country. On several occasions he held temporary appointments in Asia, at one time being a tutor in Sir Rabindranath Tagore's school at Santiniketan at Bolpur, Bengal, and later in charge of the Franco-Japanese Institute at Tokyo.

Although Lévi's approach to oriental studies had been through linguistics, his outlook and interests were never bounded by the limitations of the philologist or the purely literary scholar. His wide knowledge of eastern iconography, his sympathetic understanding of Eastern art, and his profound study of Buddhism, gave him an insight into the strength as well as the weaknesses of Indian culture, tradition and character, such as have been possessed by few European scholars. It was this quality, perhaps, more than any other, that gave Lévi his position of authority and influence among British orientalists, to whom, indeed, he was perhaps more closely akin than to the members of the German school of orientalists of his day. He was continuously in close touch with the Royal Asiatic Society and the India Society; and it is said that it was largely owing to his advice and his evidence before the committee, of which Lord Reay was chairman, that the School of Oriental Studies of the University of London was founded.

Among Lévi's more important works, apart from a large number of valuable contributions to the journal of the Société Asiatique and other specialist publications, are a study of the Indian theatre (1900), monographs on Nepal (1905–8), "Buddhachariya", an epic life of the Buddha by Asbaghosha, a dictionary of Buddhism from Chinese and Japanese sources, and two books on India, which appeared in 1925.

WE regret to announce the following deaths:

Prof. Jakob Schetelig, professor of mineralogy and geology in the University of Oslo.

Dr. Eugene W. Shaw, chief geologist of the Iraq Petroleum Co., formerly of the U.S. Geological Survey, on October 7, aged fifty-four years.

News and Views

Exploitation of Science in Company Promotion

CONSIDERABLE interest has been aroused in financial circles by a circular letter issued by the Chancellor of the Exchequer prior to the General Election to the clearing banks, issuing houses, and the various stock exchanges, relative to securing scientific and technical advice as to the value of processes which form the subject matter of new company prospectuses. The interest, probably, would have found wider expression, but for the turmoil of the elections. The text of the letter itself is as follows :

"The Chancellor of the Exchequer has been giving some thought to the question whether he could aid in strengthening existing means for checking the flotation of companies designed to exploit processes based on a scientific foundation which is intrinsically dubious or even unsound.

"Mr. Chamberlain is, of course, aware that when new projects are brought to the notice of Banks, Issuing Houses and Brokers they scrutinise them with great care before associating themselves with them. Nor does he fail to recognise the many contacts which exist to-day between industry and science.

"On the other hand, it would, no doubt, be generally recognised that within recent times a number of prospectuses have been issued containing claims for the scientific value of particular methods or substances which would not have been endorsed by the best scientific authority.

"Mr. Chamberlain has ascertained that the three research organisations of the Government (the Department of Scientific and Industrial Research, the Medical Research Council, and the Agricultural Research Council) would be willing, if asked to do so in any particular case, to suggest the names of scientists of the highest standing who could be invited by Banks, Issuing Houses or Brokers to furnish them with reports on the scientific merits of the methods or substances for the development of which it might be proposed to make a public issue.

"Any request of the kind above mentioned can be addressed to the Secretaries of the three Government Research organisations named above."

Safeguarding Interests of Investors

THE motive underlying the Chancellor's circular letter is excellent, indicating, as it does, a sense of governmental responsibility for the safeguarding of the interests of the investing public. The method suggested is plausibly sound ; but several aspects require to be considered. It is understood that if a request were made for advice to any of the three organisations mentioned, they would first consult with the particular learned institution whose field of activity was involved. Nevertheless, such a practice is calculated to occasion uneasiness to practising consultants in the fields of science and technology. The safeguard suggested by the Chancellor would not confer on an investor who had lost money the right to prosecute either of the Departments concerned ; and altogether it is rather a heavy responsibility to be shouldered by any Government department if it is to be effective. Consultants have suffered from the depression of recent years, and it would not be in the public interest if regulations were to be made limiting the prospects of the consulting field in science and technology. Just recently the question of scientific and technical advice has been exercising those connected with the mining industry in South Africa ; and a suggestion has been made that the Companies Acts should be so amended as to make it illegal for a mining company to be formed unless its board includes a scientific expert or technician of independent status. Provided that the experts so appointed are actually independent, there is a good deal to be said for such a suggestion ; but it would probably prove necessary to make such experts personally and financially responsible for their advice.

Prof. Henry Balfour and the Pitt-Rivers Museum, Oxford

IN conferring the title of 'professor' on Dr. Henry Balfour, curator of the Pitt-Rivers Museum since 1891, the University of Oxford has elected to honour one of her sons whose lifelong devotion to an idea, pursued with characteristic self-effacement and sanity of outlook, has built up from its modest beginnings an institution of world-wide repute and of unique standing among ethnographical collections. In the Pitt-Rivers Museum and in his many writings on technology in cultural development, Prof. Balfour has applied and extended the principle of evolution in material culture formulated by General Pitt-Rivers, whose collections provided the nucleus of the Museum, in such a manner that it has become one of the most powerful instruments of research in the hands of the student of artistic and technical achievement, as well as of the movements and contacts of peoples in the history of civilisation in the broadest sense. Since the death of Sir Edward Tylor in 1917—indeed from the time he relinquished his office in 1909—the chair of anthropology in the University of Oxford, for purely domestic reasons, has been vacant. The organisation of separate studies in the subject, which has obtained in the interval, no doubt has not been without its advantages, academic and other. Though anthropologists may entertain some feeling of regret that this group of studies at Oxford is still without its professor, they will admit that this circumstance enhances the signal character of the honour now conferred on the technological studies associated with the Pitt-Rivers Museum and of the personal tribute to its curator.

Presentation of the Petrie Medal to the Abbé H. Breuil

IN the proceedings of Foundation Day of the University of London on November 21, over which the Chancellor, Major-General the Earl of Athlone,

presided, the premier honours were accorded to the Abbé H. Breuil, who was present to receive the Petrie Medal awarded him in recognition of his services to archæology. The study of the origin and growth of civilisation from its earliest beginnings down to historic times is fortunate at the present day in having in its service a number of brilliant exponents in practice and in theory of archæological methods of investigation, whose authority receives world-wide recognition. Among these, the Abbé Breuil is a commanding figure. For a generation he has stood in the front rank of French archæologists. His investigations in the caves and occupation sites of palæolithic man in France, Spain and North Africa have added a mass of facts to the sum total of our knowledge of the history of man's early development, while his personal examination of all the more important archæological sites, and the archæological and palæontological material derived from them, throughout the world has given breadth and vision to that innate aptitude for the analysis of evidence and the logical classification of scientific data, which has won acceptance of his verdict in all questions relating to prehistoric archæology as a final court of appeal. The ovation given the Abbé Breuil at the close of the more formal proceedings of the assembly on Foundation Day was no more than an endorsement of an award, which in the fullest sense of the term was deserved.

Rudolph Fittig (1835–1910)

THE centenary of the birth of Rudolph Fittig, who made important contributions to the development of organic chemistry, falls on December 6. His early scientific work was carried out at Göttingen where he was assistant to Wöhler, and became *Privatdocent* in 1860 and professor in 1866. Whilst at Göttingen, Fittig was the late Sir William Ramsay's tutor (1871). From 1876 until his death, he was professor of organic chemistry at Strassburg. He is best remembered for his synthesis of the higher hydrocarbons, particularly the benzene homologues, by the action of sodium upon alkyl or aryl halides or on mixtures of both. It is not so generally realised that Fittig also studied the action of sodium on aldehydes and other series of organic compounds and carried out extensive researches on unsaturated acids. In the course of this work he prepared a number of sets of isomeric (active and inactive) acids and showed their relationships. He suggested a 'ketone' formula for benzoquinone in 1873 and this was afterwards adopted under the title of 'quinonoid structure' for this type of compound.

Johann Faulhaber (1580–1635)

AMONG the victims of the plague which ravaged Central Europe during the middle years of the Thirty Years' War was Johann Faulhaber. The exact date of his death, which occurred at Ulm in 1635, is unknown. Like Schickard (see NATURE of October 19, p. 636), Faulhaber was a mathematician of distinction. He dabbled in alchemy, announcing in 1621 that he would produce from one measure of gold two measures of the same metal of the finest quality. In spite of this unsubstantiated claim, he enjoyed a wide reputation as an able mathematician and as a constructor of ramparts and fortifications. He was visited in 1620 by Descartes, who was then serving in the French army in Germany.

A New Blue Pigment

THE introduction of a new insoluble blue pigment by Imperial Chemical Industries, Ltd., is of much more than passing interest. Monastral Fast Blue BS has none of the various drawbacks of the long-known Prussian blue and ultramarine or the more recently discovered blue lakes derived from coal tar colours, and will inevitably replace them in paints, distempers, varnishes, enamels, in textile printing and in the pigmentation of rubber, plastics and cements. As it is a very close approximation to a true 'minus red', the new pigment allows much brighter greens and purples to be obtained by admixture. The remarkable stability and inertness of the pigment are manifest in its exceptional fastness to light, heat, acid or alkali, and its complete insolubility in water, oil, spirit and nitrocellulose solvents. This new pigment belongs to a class of coloured substances to which the name 'phthalocyanine' was applied by Linstead, who first made clear their chemical nature (1934). The first phthalocyanine was obtained fortuitously as a by-product during the production of phthalimide at the Grangemouth Works of Scottish Dyes in 1928. It was a compound containing iron united with four molecules of phthalonitrile. Monastral Fast Blue BS is the corresponding copper derivative. Structurally, it is an aggregation of four *iso*indole units linked in a 16-membered ring of alternate carbon and nitrogen atoms around a central copper atom. The metal is held by two covalent and two co-ordinate bonds to four nitrogen atoms. The phthalocyanines are closely related to the porphyrins, which form the basis of some naturally-occurring colouring matters such as chlorophyll. Apart, therefore, from the value of the pigment in the arts, its chemical nature confers upon it a considerable scientific interest.

Darwiniana for Down House

THE British Association has recently received from Prof. Van Dyck a holograph letter of Charles Darwin's which must be one of the last from his pen, since it is dated April 2, 1882, only seventeen days before his death. The letter typifies the care and courtesy with which Darwin considered work sent to him by fellow-inquirers. He tells the young Dr. Van Dyck that "After much deliberation I have thought it best to send your very interesting paper to the Zoological Society in hope that it will be published in the Journal". He has preferred this journal to NATURE, which "has a wider circulation but is ephemeral". The journal, however, is "much addicted to more systematic work", so that if the paper be rejected by the Society it is to be offered to NATURE, as "I am very anxious that it should be published and perused". The Association has also

received from the Director of the Victoria and Albert Museum, with the generous consent of the Board of Education, a tall silk hat and a soft straw hat which were Darwin's: as a matter of history, the size is 7¼, possibly smaller than might have been supposed. Both the letter and the hats are now on exhibition at Down House.

Commemoration of Robert Hooke at Oxford

A REPRESENTATIVE Oxford gathering met in the Divinity School on November 20 to do honour to the memory of Robert Hooke of Christ Church, who was born three hundred years ago. Dr. R. T. Gunther, reader in the history of science, presided. The Warden of New College gave an address on the earliest 'Oxford Movement', that resulted in the formation of the Royal Society and, in particular, on the manifold activities in science and art of Hooke and Christopher Wren in London during the reign of Charles II. He pointed out why it was that the former, despite his many qualities, missed supreme greatness. Dr. Gunther spoke of Hooke's discoveries in mechanics, optics, biology and astronomy, and of his great inventive genius generally. Dr. Russell said what could be said of the work done in relating combustion and respiration to the gas afterwards named oxygen. Accounts were read of Hooke's activities in geology and other subjects. The Dean of Christ Church recalled in a witty speech some of the admirable qualities which Hooke showed as a man. He afterwards opened an exhibition devoted to Hooke's work, arranged by Dr. Gunther in one of the rooms of the Old Ashmolean Building. This contained early editions of the "Micrographia" including the beautiful original plates, books owned and annotated by Hooke, modern books about him, models of his microscope, of his mechanical inventions and of the apparatus he used in demonstrations. Particularly interesting was a photograph of the first foraminifer figured and described by Hooke in 1661. There was a nice collection of drawings and photographs of the buildings that Hooke had designed. Prof. F. Soddy had had prepared many models to illustrate different modern applications of Hooke's joint. He demonstrated their working to the visitors, and spoke of the applications of the joint made more than sixty years ago by Franz Reuleaux.

T. H. Huxley as Anthropologist

SIR GRAFTON ELLIOT-SMITH made an especially happy choice of subject for his Huxley Memorial Lecture to the Royal Anthropological Institute on November 26, when he spoke on "The Place of Thomas Henry Huxley in Anthropology"—a topic which, as he pointed out, has been neglected, curiously enough, in the many lectures delivered previously in memory of Huxley. Yet Huxley was not only mainly responsible for the amalgamation of the two rival societies concerned with anthropological studies, which led to the foundation of the Anthropological Institute in 1871, but he was also the real founder of the scientific study of man in Great Britain. By his insistence on the biological point of view in the study of man, he effectually disposed of the loose and facile argument on so-called evolutionary lines, which paraded in the 'sixties of the last century as scientific theory. In emphasising man's place in Nature, he provided the science of human biology with its chief instrument, the means of interpreting and applying to mankind the knowledge acquired by the investigation of man's nearest kindred and merging it in biology as a whole. In recalling the controversy, now almost forgotten, over the 'Hippocampus', in which Sir Richard Owen figured, Sir Grafton rightly stressed the importance of Huxley's identification and pioneer work on the calcarine region which made possible the definition of the characters that conferred its unique qualities on the human brain. Incidentally, he revealed that Huxley's work on this subject was the starting point of his own investigations of the brain and the comparative study of the development of its functions, especially in connexion with the acquisition of stereoscopic vision and its consequences for human evolution.

New Foreign Members and Correspondents of the Geological Society of London

AT the meeting of the Geological Society of London on November 20, Prof. C. P. Berkey and Prof. P. D. Quensel were elected foreign members, and Prof. F. Broili and Dr. E. P. de Oliveira foreign correspondents, of the Society. Prof. Charles P. Berkey, of Columbia University, is well known to geologists in Great Britain as the secretary of the Geological Society of America, a position he has held since 1922. His publications cover a wide field, but in recent years have been principally devoted to the geology of Mongolia, and have appeared as the reports of the Central Asiatic Expeditions of the American Museum of Natural History. Prof. Percy Quensel, of the University of Stockholm, has on several occasions lectured in Great Britain. His researches have been devoted principally to the elucidation of the problems of the petrology and structural features of the older rocks of Sweden; but he has also published papers on the geology and petrology of Patagonia. Prof. Ferdinand Broili, of the University of Munich, is noted for his studies on the fossil reptiles and Stegocephalians, and has also published papers on the Permian brachiopods and the Devonian trilobites. Dr. Euzebio Paulo de Oliveira is the director of the Serviço Geologico e Mineralogico do Brasil. His published works have been principally descriptive of the mineral resources of Brazil.

Air Transport Exhibition at the Science Museum

AN exhibition portraying the organisation and operation of the air services over Empire air-routes will be opened at the Science Museum, South Kensington, by the Secretary of State for Air on December 5, and will be on view to the public from December 6 until January 31. The exhibition, which is being organised and staged by Imperial Airways Ltd., is popular in character, both in scope and treatment, and will illustrate the development of air communications within the Empire by means of

models, charts, maps and photographs. It will include models of every type of air liner which has been owned by the Company since its inception, and sectional models of the new "Empire" flying-boat, the new Armstrong-Whitworth 4-engined land machine (A.W. 27) and the Short-Mayo "composite" marine aircraft, now under construction. The latter is of special interest as an entirely new project designed to meet the requirements of trans-Atlantic services. A part of the exhibition will be devoted to the design of air ports, and will include a large model of a modern combined land and air port, and dioramas of three famous Empire air ports. There will also be working models showing the part which wireless plays in the control of aircraft when flying in fog or above cloud. There will be sections devoted to the building of a flying-boat and a land machine and to aero engines. Operable models of a wind tunnel and a tank will enable the visitor to gain some idea of the part which these instruments play in the design of air liners. The exhibition should prove of considerable educational interest at the present time, and will serve to show the remarkable developments which have taken place in air transport during recent years; by way of comparison, the earlier historical development in aviation can be seen in the usual gallery of the National Aeronautical Collections in the Museum.

Alchemy and Music

THE audience for the Friday evening discourse delivered at the Royal Institution on November 22 had a double treat, for after listening to Prof. John Read's address entitled "A Musical Alchemist", some recently transcribed music by Count Michael Maier (1618) was sung by student members of the St. Andrews University Choir under the direction of Mr. F. H. Sawyer, lecturer in music in the University. Certain alchemical works published at or near Frankfort during the seventeenth century, largely under the name of Michael Maier, are rich in allegorical illustrations, which Prof. Read terms, for convenience, 'the Frankfort emblems'. The publishing firm of Lucas Jennis of Frankfort took a prominent part in issuing Maier's works. His emblems are often provided with a Latin epigram, together with a cryptic title and a discourse in the same language. "Atalanta Fugiens", or "Atalanta Fleeing", published by Maier at Oppenheim in 1618, contains fifty such epigrams, written in elegiac couplets and set to music by the versatile author. Maier's so-called 'fugues' are in reality rounds, or canons, for three voices. At the end of Prof. Read's discourse, Mr. F. H. Sawyer, who has made a close study of this interesting alchemical music, explained its construction and characteristics, after which examples were sung. It is to be presumed that these 'incantations' were intended to be sung at critical moments during the decoction of the Philosopher's Stone, such operations being directed also by prayer and astrological influences. To what extent Maier, or other alchemists, endeavoured to influence their laboratory operations by means of music is not clear. However, in view of the alchemical belief in the beneficent influence of music, it is likely that the processes of the 'Great Work' were sometimes performed to the accompaniment of musical chants or incantations.

Dangerous Reflexes of Car Drivers

"How Cars go out of Control: an Analysis of the Driver's Reflexes" is the title of a paper by Dr. Yandell Henderson, professor of applied physiology in Yale University, read before the National Academy of Sciences, Washington, on November 18. He attributes this situation to the 'self-righting' reaction which is instinctively and irresistibly excited by any sudden severe disturbance of equilibrium. The self-righting reaction is proverbial in the cat: no matter how the cat is dropped, it lands always on its feet. Into this neuro-muscular complex in man enters the 'extensor thrust' reflex of the lower limbs, owing to which a motor-car driver, often quite unawaredly, presses the accelerator pedal hard down, and continues to do, thus sending the car completely 'out of control'. Prof. Henderson realises that we cannot change the nature of so primitive a danger-response. His remedy consists in placing a pedal for the left foot "so low as scarcely to rise above the floor, but wide enough so that extension of the leg will always bring the foot to bear on it". The extensor thrust reflex involves both feet. The left pedal will be so connected that heavy pressure on it will either counteract the action of the right foot and so close the throttle, or will directly shut down the carburetter. From statistical studies, Prof. Henderson believes that at least ten per cent of fatal car accidents are attributable to the car being 'out of control' through the 'extensor thrust' of the driver's legs.

Rectifiers used on the London Underground Railways

WHEN an alternating current arc is established in a vacuum tube between a mercury and an iron or graphite electrode, the current only passes during half the time, namely, when the mercury pool is the negative electrode. The alternating current is thus converted into a pulsating direct current, the tube (rectifier) thus acting as a valve allowing the current to flow in one direction and not in the other. In a paper on the steel tank rectifiers operating on the underground railways of the London Passenger Transport Board, read by A. L. Lunn to the Institution of Electrical Engineers on November 7, a description of the rectifier substations is given and also much useful information of the working of these rectifiers for traction purposes. When the electric railways first started, they were supplied by three phase A.C. from the Lots Road generating station, the current being converted into direct current by means of rotary converters before reaching the trains. These machines were virtually A.C. motors on one side and D.C. dynamos on the other. For running machines, rotary converters are comparatively quiet, and there is little vibration; but in these respects the rectifier is much superior. The substation buildings for operating the traction system of the London

Underground are in very densely populated districts, and so the light weight and freedom from vibration of the rectifiers enable appreciable economies to be effected on the building costs. Mr. Lunn looks forward to the time when the continued development of the railway area may lead to the changing-over of a number of existing substations to new supply networks, probably involving a change of frequency. With the present system of rectifiers this would offer no difficulty.

Second-hand Electrical Plant

THE policy of the Central Electricity Board in closing down obsolescent electricity supply stations has had the effect of crowding the machinery and equipment market with plant at very low prices. In his presidential address to the Midland Centre of the Institution of Electrical Engineers, Colonel H. C. Fraser said that this plant is being bought by industrial users, and that this is detrimental to the supply industry. The user having very small capital charges is placed in a strong position to compete with the public supply. The recent sales of electrical plant and fittings from ocean liners, such as the *Mauretania* and the *Olympic*, have also decreased to a certain extent the capital charges of the purchasers. On the other hand, mill owners and others are very reluctant to dispose of existing moderately efficient plant at scrap values. The question is one of economics. When the user has capital at his disposal, he can estimate the cost of the renovation of plant and the increase in profits that will probably ensue; and if satisfied, he should not delay the change-over too long. We think that the gain to the community effected by scrapping plant at the proper economical time far more than counterbalances the loss to manufacturers due to the consequent diminished demand for machines and equipment.

Antarctic Discoveries

SOME of the more important discoveries made by Admiral R. E. Byrd's American Antarctic Expedition of 1934–35 are indicated in sketch maps accompanying an article by Admiral Byrd in the *National Geographic Magazine* of October. There seems now to be no probability of a sea-strait joining the Ross and Weddell Seas, a suggestion made some years ago on slender evidence. It appears that Marie Byrd Land, which lies south-east of King Edward Land, extends in a plateau of over a thousand feet, called the Rockefeller Plateau, to the base of the Queen Maud Range, which has been extended another two hundred miles eastward. At the south-eastern end of the Ross Sea a gulf extends into this plateau to about long. 140° W. Another discovery is that the Edsel Ford ranges which lie east of the Alexandra Mountains of King Edward Land extend east and west, and suggest possible extensions of the Andean foldings of Graham Land. A third striking discovery, made by sonic soundings, is that much of the Ross Ice Barrier is aground and not afloat. South of the Bay of Whales, Admiral Byrd has tentatively marked an area of the Barrier extending between lat. 78° 40′ S. and 80° 20′ S. and long. 160° W. and 164° W. as Roosevelt Island. This he believes to be underlaid by land. Several altitudes in this area are well above the general level of the Barrier.

Science and Social Needs

IN his Halley Stewart Trust Lecture delivered in the Memorial Hall, Farringdon Street, London, on November 21, Prof. Julian Huxley discussed "Science and Social Needs". The academic view of science is that it is "pure"—a disinterested explorer of the unknown, and thus an accumulator of organised knowledge. Opposed to this is the view that science is essentially practical, showering upon humanity gifts in the shape of inventions and technical improvements. A third view is that science, far from being beneficent, is actually an evil genius. Of course, the application of scientific methods in the mechanisation of industry may result in unemployment. But the blame does not lie with the scientific worker, but rather with the present economic system. Science is actually a tool, and is therefore ethically neutral. The tempo of scientific discovery may be too fast for modern society; but that is a matter for practical adjustment, not for moral condemnation. The true fact is that science embodies both the first and second views, in that it is both knowledge and control, pure and applied. Progress may flow either from theory to practice or vice versa.

SCIENCE is a function of society, influencing the social system and being influenced by it in return. To-day it is often frustrated—actual discoveries already made are not applied. In fact, science is prosecuted and applied much more from the angle of the producer and the State than from that of the consumer or the individual citizen. Research where an immediate profit can be discerned obtains far greater financial support than long-range research where the advantage is indirect. Prejudice too may often interfere with the use of scientific methods of analysis. This applies especially to social science, education, etc. Social forces could be scientifically analysed and controlled, and social machinery scientifically designed and planned in the same way as has been done for natural forces and industrial machinery. In order to prevent the present piecemeal or lop-sided development of science, we need a new discipline—the scientific study of science itself, in its capacity as a social function.

Journal of the Institution of Civil Engineers

WITH the opening of the 1935–36 session, there appears the new *Journal of the Institution of Civil Engineers*—an occasion which marks another stage in the development of the Institution's publications, and should increase the facilities for "the acquirements of knowledge in engineering", laid down by the founders as one of its objects. Portraits of the first president, Thomas Telford (1820–34), and of Mr. John D. Watson, who now occupies this office, appear in the first number, which opens with a foreword by Mr. Watson and an interesting account of the origin and progress of the Institution. Then follows the presidential address for the current

session, which dealt with the problems of water-supply, sewerage and sewage disposal during the last fifty years. Whilst maintaining continuity with previous publications, it is intended that the *Journal* shall enable the earlier publication of papers and the wide dissemination of the reports of the Research Committee and its sub-committees, one of the important activities of the Institution. Eight numbers of the *Journal* will appear each year, six in the session and two in recess. In the form in which the first number appears, the *Journal* is assured of a favourable reception from all who are interested in the work of the Institution.

THE present issue of the *Journal* contains details of the work of the Research Committee, four papers published by the Institution and a special lecture on "Surveying from Air Photographs" by Brevet-Major Martin Hotine, R.E. Among these, the most important contributions are Mr. E. H. Bateman's paper on "The Open Frame Girder" and J. P. R. N. Stroyer's on "Earth-Pressure on Flexible Walls". The former is an extended analysis, by the strain energy method, of uniform and non-uniform girders, and tables and diagrams are given to show the effect of variation in the stiffness-ratio, from which the effect of variation in the number of panels can be inferred. Mr. Stroyer's paper records the nature and results of an investigation by means of special apparatus on the pressures produced by several materials on wall panels flexing between supports, and sets out the several conclusions at which the author has arrived. Written communications on these papers have been invited by the Council.

Recent Acquisitions at the Natural History Museum

AMONG recent additions to the zoological collections at the British Museum (Natural History) are six skins of Malagasy mammals, including a rare insectivore (*Limnogale mergulus*) presented by Sir Frank Colyer. Acquisitions by the Department of Geology include a series of invertebrate fossils from the Permian of Durham, presented by Dr. C. T. Trechmann. These are arranged to show how the increasing salinity of the sea in which the animals lived led to progressive dwarfing and finally to the extinction of the forms. The Mineral Department has acquired by purchase a faceted cassiterite (tin-stone), weighing 13½ carats (2·713 gm.), together with a crystal of similar material, from Uganda. Cassiterite, known since classical times as the important ore of tin, has seldom provided transparent pieces of sufficient size for cutting for ornamental purposes, so that this specimen is an interesting addition to the collection of faceted stones. The purchases include a carefully collected and labelled set of Swiss rocks, together with the corresponding thin sections, which form a valuable addition to the collection of rocks. Thanks to the courtesy of the Director of the Royal Museum of Natural History at Brussels, the Museum has received part of five rock specimens which, though collected by the *Challenger* Expedition, were described by A. F. Renard and retained at Brussels.

Everyday Science in Civil Service Examinations

WE directed attention in our last issue (p. 825) to the withdrawal of "Everyday Science" from the list of obligatory subjects in the examination for admission to the Administrative Group of Civil Services—a step which appears to us regrettable. The policy of the Civil Service Commissioners in determining the type of the questions set in the examinations in science subjects is also called in question in an article by Dr. Herbert Dingle in *Time and Tide* of November 16. In discussing the part played by examinations in causing the ineffectiveness of scientific training in public life, Dr. Dingle relates his experience in the preparation of questions in astronomy. This confirms us in our opinion that the place of science in these examinations is not all that it should be.

British Institute of Radiology: Annual Congress

THE ninth Annual Congress of the British Institute of Radiology (incorporated with the Röntgen Society) will be held on December 4–6, in the Central Hall, Westminster, S.W.1. The Congress will be opened on December 4 at 3 p.m. by the Right Hon. Lord Nuffield. An exhibition of apparatus, organised by the British X-ray industry, will be held at the same time. On December 5, Dr. G. W. C. Kaye will deliver the eighteenth Silvanus Thompson Memorial Lecture entitled: "Forty Years of Radiology (1895–1935): a Review and Some Reminiscences". On the same day, several physical, technical and therapeutical papers will be read. On December 6, Dr. G. Harrison Orton will deliver the sixteenth Mackenzie Davidson Memorial Lecture entitled "Calcium Changes and their Importance in Diagnostic Radiology", and some papers on diagnostics will be read. Further information concerning the Congress can be obtained from the General Secretary, British Institute of Radiology, 82 Welbeck Street, W.1.

The Leonids

ATTENTION was first directed to this shower of meteors by Humboldt, who observed a great display at Cumana, Venezuela, on November 11, 1799. It was not, however, until the meteor 'storm' of 1833 that the shower was observed scientifically. The next return of the main swarm was observed in England in 1866 and in America in 1867. The period of about 33¼ years was now, by researches into records of past great 'storms', fully established. The next return, 1899, was eagerly awaited, but in the general excitement the work of Drs. Stoney and Downing was overlooked. They showed that planetary perturbations would probably deflect the richest portion of the stream so that it would escape encounter with the earth, and thus the recurrence of a great 'storm' was doubtful. The failure of the Leonids of 1899 has become historic, although good showers were seen in America in 1901 and in England in 1903. Observations have shown a steady increase of Leonid activity year by year in the few years up to 1931, giving hope of another 'storm' about 1933. The promise, however, was not fulfilled. Mr. A. King informs us that this year on November 15, about a day before

the probable maximum, the Leonids were again very scarce. It therefore seems unlikely that there was any extraordinary display at that epoch. British observers generally experienced cloudy skies at that time, so that a definite statement cannot be made until reports from more favoured localities come in. Dr. S. C. Blacktin, 20 Denton Avenue, Roundhay, Leeds 8, has sent a report of a meteor seen at Leeds at 5.30 p.m. on November 16. This could not have been a Leonid, since the radiant at that time was 13° below the north-north-west horizon.

Recent Shower of Meteors

A WIRELESS message from Mohd. A. R. Khan, of Begumpet, Deccan, India, presumably sent on November 22, reads as follows: "Splendid meteoric shower last night. Gamma Monocerotis radiant." Assuming the radiant to have been exactly at γ Monocerotis (R.A. 114·5°; $\delta - 9{\cdot}4°$), and taking the date as Greenwich midnight of November 21 (November 22, 0h. U.T.), Mr. A. King has computed the following parabolic orbit: ι, 115·0°; π, 135·4°; Ω, 58·8°; q, 0·608. The recently published "Index to Southern Meteor Showers" by Mr. R. A. McIntosh, of Auckland, N.Z., gives two radiants at 114½°–9°, November 15–16. Possibly Mr. Khan's shower represents a continuation of this stream, but more cannot be said until definitive details come to hand.

Announcements

THE Symons Gold Medal for 1936 of the Royal Meteorological Society has been awarded to Prof. Wilhelm Schmidt, director of the Central Institution for Meteorology and Geodynamics, Vienna. The medal is awarded biennially for distinguished work in connexion with meteorological science and will be presented at the annual general meeting of the Society on January 15, 1936.

THE Thomas Young Oration of the Physical Society will be given by Prof. Charles Fabry of the Institut d'Optique, Paris, on December 6 at 5 p.m. at the Imperial College of Science and Technology, South Kensington, S.W.7. The title of the lecture will be "Vision in Optical Instruments".

THE Right Hon. Lord Rutherford will open the new Research Laboratory of the London Midland and Scottish Railway Company at Derby on Tuesday, December 10 at 1.50 p.m.

THE opening of the next annual meeting of the Institution of Naval Architects will fall on April 1, 1936. A joint summer meeting will be held in the United States on September 14–19, 1936, at the invitation of the American Society of Naval Architects and Marine Engineers. Other British and foreign institutions will take part.

THE tenth Triennial Congress of the International Society of Surgery, of which 1,200 surgeons from 42 different countries are members, will be held at Cairo on December 30–January 4, under the presidency of Dr. Jan Schoemaker of The Hague. Further information can be obtained from the general secretary, Dr. L. Mayer, 72 rue de la Loi, Brussels.

ON the occasion of the seventy-fifth anniversary of its foundation, the Dr. C. Schleussner Company of Frankfort-on-Main offers a prize of 2,000 gold marks for the best scientific work on röntgenology. The president of the German Röntgen Society, in conjunction with the Dr. C. Schleussner Company, will decide the award. Purely technical and statistical works as well as those already published are excluded from the competition.

THE sixth assembly of the Spanish League of Mental Hygiene will be held in Madrid on December 2–6, when the following subjects will be discussed: suicide in Spain in its psychological and social aspects, the organisation of psychiatric assistance in families, and the intervention of the psychiatrist in tribunals for minors. The fee of five pesetas should be sent to the treasurer, Dr. A. Garma Cisne, 10, Madrid, from whom further information can be obtained.

ERRATUM.—In the last line of the letter "Records of Fatalities from Falling Meteorites", by Mohd. A. R. Khan, in NATURE of October 12, p. 607, for "Kawagam" read "Kawagaon".

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A principal of the Rochdale Municipal Technical School—The Secretary, Education Office, Townhead, Rochdale (Dec. 5).

The following appointments in the University of Cambridge: a University lecturer and a University demonstrator in biochemistry (Sir F. G. Hopkins, Dec. 7); two University demonstrators in chemistry (Dr. R. G. W. Norrish); University demonstrator in zoology (Prof. J. Stanley Gardiner, Dec. 31).

A principal of the North-Western Polytechnic, Prince of Wales Road, Kentish Town, London, N.W.5—The Clerk to the Governors (Dec. 12).

An assistant (Grade III) in metallurgy and a junior scientific officer in the Royal Aircraft Establishment, South Farnborough, Hants—The Chief Superintendent (Dec. 13).

A lecturer in organic chemistry in the Birmingham Central Technical College—The Principal (Dec. 14).

A lecturer in chemistry in the University of Capetown—The Secretary, Office of the High Commissioner for South Africa, Trafalgar Square, London (Dec. 31).

A professor of chemistry in the University of Otago—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (Jan. 6).

A lecturer (woman) in biology in the Darlington Training College—The Principal.

A lecturer in electrical engineering in the Burmah Oil Company's College of Mining and Engineering, University of Rangoon—The Secretary, Universities Bureau of the British Empire, 88A Gower Street, W.C.1.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 874.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Influence of Certain Polycyclic Hydrocarbons on the Growth of the Jensen Rat Sarcoma

As the outcome of considerations which will be discussed more fully in a forthcoming paper, experiments were performed to test the effect of certain polycyclic hydrocarbons on the growth-rate of the Jensen rat sarcoma. The present note is the first report on this investigation, and records the results obtained in experiments involving a total of 350 animals.

On account of the insolubility of these hydrocarbons in aqueous media, and in order to ensure a certain degree of absorption into the general circulation, the compounds to be tested were administered in the form of an aqueous colloidal suspension in 0·5 per cent gelatin, prepared by the method described by Boyland[1]. In most experiments the animals received daily intra-peritoneal injections of such preparations.

The effects of this treatment were studied by observing the behaviour of the Jensen transplantable sarcoma growing subcutaneously in the right flank, either by making daily measurements or by weighing the tumours after removal at the termination of each experiment. The significance to be attached to any given test was assessed by comparing such data with the corresponding results from simultaneous controls. The latter received similar daily injections of a gelatin solution treated exactly as in the preparation of colloid except for the addition of hydrocarbon.

In most experiments, treatment was started on the day of implantation and continued for 14–20 days, when the tumours were removed, weighed and photographed. Each test animal received a total dosage, varying in different experiments, of 15–40 mgm. of hydrocarbon. Although in certain experiments the treated animals appeared to grow less rapidly as compared with the controls, their general condition and activity remained good.

The data were studied by the application of Fisher's t method, and the accompanying table summarises the results in eleven experiments with six hydrocarbons. As a representative example, Fig. 1 shows the effect as seen in Experiment 7.

Expt.	Duration (days)	Hydrocarbon	Mean tumour weights (gm.)		n	t	P

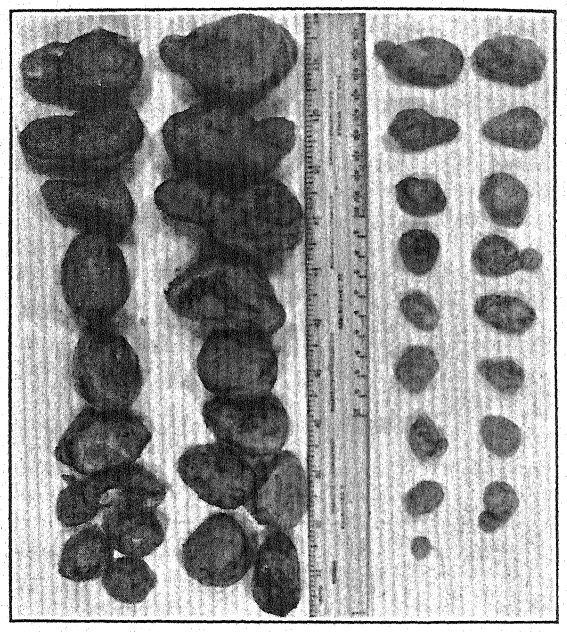
9	18	Anthracene	19·7	22·8	12	0·67	*c.* 0·5
10	15	Phenanthrene	10·6	12·0	20	0·64	0·6–0·5
11	15	„ „	11·2	11·5	15	0·13	0·9

It is clear that these experiments are sharply divided into two groups, and this has been indicated in the table. Under the conditions described, there



(*a*) (*b*) (*c*) (*d*)

FIG. 1. *Experiment 7*: Appearance of tumours after removal on eighteenth day following implantation: (*a*) from animals injected daily with 2·5 c.c. control material. (*b*) from control animals uninjected. (*c*) and (*d*) from experimental series (animals injected daily with 2·5 c.c. of a 0·03 per cent colloidal preparation of 5 : 6-*cyclo*penteno-1 : 2-benzanthracene).

can be no doubt that colloidal preparations of 1 : 2 : 5 : 6-dibenzanthracene, 1 : 2-benzpyrene, 5 : 6-*cyclo*penteno-1 : 2-benzanthracene and 1 : 2-benzanthracene produced a highly significant inhibition of the growth of the implanted tumour. On the other hand, anthracene and phenanthrene proved completely devoid of inhibitory power under the same conditions.

From other evidence (which will be reserved for future discussion), it seems possible that carcinogenic substances and agencies may act primarily by producing a certain type of inhibition in the activity of the normal cell, and it is of interest that the inhibitory effects described above are most obvious in the case of the substances 1 : 2 : 5 : 6-dibenzanthracene, 1 : 2-benzpyrene and

5 : 6-*cyclo*penteno-1 : 2-benzanthracene—the marked carcinogenic properties of which have been proved by the work of Kennaway and Cook and their collaborators[2, 3, 4]—less so in the case of 1 : 2-benzanthracene, the carcinogenic activity of which is feeble[4] and completely absent in the non-carcinogenic substances anthracene and phenanthrene.

Much further work is obviously required in order to test this hypothesis, but should a definite correlation be found to exist between carcinogenicity and inhibitory power, it is perhaps legitimate to point out that the paradox is only apparent, and is matched by the double action of X-radiation in inducing tumour formation or in controlling the growth of a tumour already established.

These experiments are accordingly being extended to determine (*a*) the effect on other tumours ; (*b*) the action of other hydrocarbons both carcinogenic and non-carcinogenic ; and (*c*) the effect of higher dosage. Full details of this and related work will be published in due course.

This investigation is being carried out with the aid of an expenses grant from the British Empire Cancer Campaign, and certain additional costs were defrayed by a payment from the Roughhead Fund of the University of Edinburgh.

My best thanks are due to Prof. J. W. Cook for his generosity in providing me with various pure samples (prepared in the Research Institute of the Cancer Hospital) of 5 : 6-*cyclo*penteno-1 : 2-benzanthracene and 1 : 2-benzanthracene, and for a supply of 1 : 2 : 5 : 6-dibenzanthracene. Without these the present work would have been impossible.

The tumour employed was originally obtained through the kindness of Dr. J. A. Murray. The majority of the animals were hooded rats of the Lister Institute strain, since previous experience had shown these to be particularly suitable for use with the Jensen sarcoma. For facilities in obtaining supplies of these animals I am indebted to Prof. J. C. G. Ledingham and Miss H. H. Smith. I wish also to express my gratitude to Col. A. G. McKendrick for his kind help in the statistical examination of results.

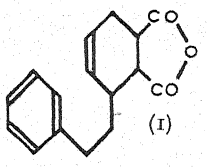
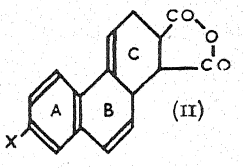
Synthesis in the Sex Hormone Group

INVESTIGATIONS into the application of the 'diene-synthesis' to the above problem have been continued in this laboratory since the completion of experiments described in an earlier communication[1]. The latter was chiefly concerned with the synthesis of 3-β-phenylethyltetrahydrophthalic anhydride (I), which, however, could not be cyclised to an octahydrophenanthrene derivative related to oxidative degradation products obtained from œstriol monomethyl ether by Doisy and his co-workers[2].

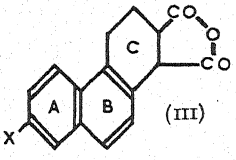
An obvious alternative route, which would obviate necessity for cyclisation, lay in employment, in the Diels-Alder reaction, of suitable naphthalene and hydronaphthalene derivatives containing an α-vinyl group. This has been carried out in a remarkably simple manner. 1-Vinyl-3 : 4-dihydronaphthalene could not be obtained through the Reformatsky reaction between α-tetralone and ethyl bromoacetate, a result by no means unexpected. But 1-vinylnaphthalene readily combines with maleic anhydride at ordinary temperature, affording the hydrophenanthrene-1 : 2-dicarboxylic anhydride (II or III ; X = H) m.p. 186°–189° (decomp.) (Found : C 75·9, H 5·1 per cent. $C_{16}H_{12}O_3$ requires C 76·15, H 4·8 per cent), which is dehydrogenated by platinum black at 300° to phenanthrene-1 : 2-dicarboxylic anhydride (IV ; X = H) (m.p. 310° corr.), recently described by Fieser and Herschberg[3].



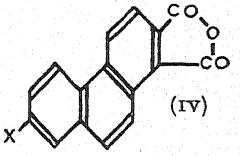
(I)



(II)



(III)



(IV)

[X = H or OCH_3]

After the completion of these experiments, there appeared a communication by Robinson and Walker[4], who had attempted to effect this type of synthesis. They were likewise unable to prepare 1-vinyl-3 : 4-dihydronaphthalene from α-tetralone, but stated that "no addition occurred" between 1-vinylnaphthalene and maleic anhydride.

In addition, dehydration of 6-methoxynaphthylethyl alcohol yields 1-vinyl-6-methoxynaphthalene, m.p. 41°–42°, which forms an orange-red picrate m.p. 114·5° (Found : C 54·7, H 3·7 per cent. $C_{19}H_{15}O_8N_3$ requires C 55·2, H 3·7 per cent) and combines with maleic anhydride, forming the methoxy-anhydride (II or III ; X = OMe) m.p. 171°–175° (decomp.) (Found : C 72·2, H 5·2 per cent. $C_{17}H_{14}O_4$ requires C 72·3, H 5·0 per cent). The latter is dehydrogenated by platinum black at 280°–300° to 7-methoxyphenanthrene-1 : 2-dicarboxylic anhydride (IV : X = OMe) m.p. 253° (260° corr.) which is identical with a specimen obtained by a synthesis to be described elsewhere in a communication to be made jointly with Prof. J. W. Cook and Dr. C. L. Hewett. (Found : C 73·2, H 3·7 per cent. $C_{17}H_{10}O_4$ requires C 73·35, H 3·6 per cent).

Formula (II) represents the structure of the primary addition products from vinylnaphthalenes and maleic anhydride, and, in agreement with this formulation, the two compounds isolated (X = H and OMe) rapidly reduce cold alkaline permanganate. However, isomerisation to the naphthalene structure (III) by migration of an ethylenic linking from ring *C* to ring *B*, is not excluded. Indeed, if (II) is correct, the possibility of effecting both isomerisation to the

equilenin type (III) and reduction to the œstrone type (one aromatic ring) is envisaged.

These experiments are being extended in several directions, and will be described in detail elsewhere.

Excitation of Nuclei by Neutrons

THOUGH many investigations have been made both of fast neutrons and those of thermal energy, much less is known about neutrons of medium velocity. The experiments described below have been devised to investigate such neutrons.

Wertenstein found that artificial radioactivity induced in various substances by neutrons is influenced by layers of gold or lead interposed between the neutron source and the test-piece. The activity was increased if the test-piece consisted of silver or iodine whereas it was decreased if silicon or aluminium were used. It is now known that silicon and aluminium can be activated by fast neutrons only, whereas silver and iodine are more sensitive to slow neutrons. This agrees with Wertenstein's interpretation of the increased activity as being due to a slowing down by the absorber of the fast neutrons from the source. The energy lost by the neutrons is taken up by gold or lead nuclei in the form of excitation energy, and is presumably re-emitted as gamma radiation.

Now neither gold nor lead is strongly activated by neutrons. We thought it interesting to extend Wertenstein's measurements[1] to silver since this is a substance which can be strongly activated. For this purpose we prepared a silver cylinder with walls 15 mm. thick and measured the activation produced in different test-pieces by a Rn–Be source with and without the silver cylinder surrounding the source. Table 1 shows the observed change in the activation as a fraction of that obtained without the silver cylinder.

Test-piece	Increase of activation
Silicon	− 23 ± 4 per cent
Aluminium	− 19 ± 3 ,,
Silver	+ 40 ± 5 ,,
Iodine	+ 19 ± 1·7 ,,
Rhodium	0 ± 2·5 ,,

From these results, the following conclusions can be drawn:

(1) The effect observed by Wertenstein is not restricted to the substances investigated by him.

(2) The decrease of activation of aluminium and silicon gives directly the cross section for the total absorption of fast neutrons by slowing down and possibly by capture. This cross section comes to 3×10^{-24} cm.^{2}.

(3) Collisions of neutrons with silver nuclei can lead either to an excitation of the nucleus without capture of the neutron, or to capture resulting in the formation of a radioactive element. This conclusion depends on the fact that both the existing isotopes of silver can be activated by capture and so no isotope is left that possibly could only be excited, but not activated.

(4) The activity induced in silver and rhodium is very differently affected by the absorber although these substances show almost the same increase when the neutrons are slowed down by paraffin. This proves that the neutrons slowed down by silver have different energies from those slowed down by paraffin. It further shows that the variation of the activation cross section with neutron energy is markedly different for different elements, at least in the energy range of the neutrons slowed down by silver.

Additional measurements gave the result that the increase of the activation of a silver test-piece is approximately proportional to the thickness of the retarding silver layer between 1 mm. and 15 mm. This result confirms Wertenstein's view that the slowing down of a fast neutron is effected by a single collision. It also shows that no appreciable part of the activity induced by neutrons in a thin silver test-piece is due to neutrons slowed down in the test-piece itself.

We have also studied the influence of a 3 mm. cadmium absorber interposed between the source and the test-piece. No decrease in activity was produced by the cadmium either with or without the silver cylinder surrounding the source. Provided cadmium does not retard neutrons to an extent comparable with silver, it follows from the margin of error in these measurements, that for the neutrons responsible for the activation by a bare source the cross section for absorption in cadmium is smaller than 10^{-23} sq. cm. In the case of the neutrons slowed down by silver the experimental error is larger; the lower limit for the cross section comes therefore to about 2×10^{-23} cm.^{2}.

According to Bethe's[2] theory of the variation of capture cross section with velocity, these limits indicate that the energies of both types of neutrons are of the order of 1,000 volts or higher.

To check directly the assumption that the neutrons are really slowed down by the silver we made the following experiments: A silver test-piece was placed at such a distance from the source that no measurable activity was produced. Then it was backed by a paraffin block in such a way that there was no paraffin between the source and the test-piece. With this arrangement the measured activity was enhanced by 25 per cent when the source was covered with the silver cylinder. Thus the elimination of primary neutrons in the silver block is more than compensated by the increased efficiency of those slowed down in the silver. This is to be expected as slower neutrons reach thermal velocity more quickly in paraffin since they need fewer collisions. As, on the other hand, slow neutrons are absorbed by paraffin, one should expect the effect to decrease if paraffin was interposed between the retarding cylinder and the test-piece. This was verified: When, in addition to the paraffin block behind the source, a block of paraffin 11 cm. thick was put in front of the test-piece the increase produced by the silver cylinder was only ten per cent.

Our thanks are due to Mr. Alton, of the Radium Institute, for supplying the radium emanation and for filling the sources.

Radioactivity of Ferro-Manganese Formations in Seas and Lakes of the U.S.S.R.

THE radioactivity of bottom sediments has been but little investigated. Data published by Joly, Pettersson, Piggot and Iimori refer to determinations of radium, contained mainly in oceanic deep-water sediments in red clays, radiolarian, globigerina oozes, blue muds and manganese concretions. The determinations have shown the manganese concretions to be richest as regards content of radium (up to 10^{-8} per cent); red clays and radiolarian ooze also possess a rather high content of radium. Other types of sediments are less rich in radium.

There are but very few determinations of radium in terrigenous sediments. The radioactivity of the bottom sediments of the U.S.S.R. is entirely unknown. I have therefore commenced a systematic investigation of these sediments. As a preliminary to the study of the radioactivity of the bottom sediments of each sea and lake separately, it seemed expedient to determine the radioactivity of a small number of the most characteristic types of bottom sediments from different seas and lakes. As the largest content of radium might be expected in deposits rich in iron and manganese, the ferro-manganese bottom deposits of different seas and lakes of the U.S.S.R. and two deep water concretions from the Pacific were used for the first investigations.

Besides radium, determinations have been made also of thorium X, the production of emanation and intensity of α-radiation. The results of radium determinations may be seen in the accompanying table.

Table 1.

No. of station	Depth in metres	Name of sea or lake	Radium content (per cent × 10^{-10})
1	512	Kara Sea	5·5
X	234	Barents Sea	1·8
425	181	White Sea	5·4
13	42	Lake Onega	9·2
3	10–12	Lake Konch	8·3
23	26	Bay of Finland	15·4
—	—	Black Sea	31·8
36	20	Caspian Sea	1·2
8,706	98	Lake Baikal	19·5
13	4,919	Pacific Ocean	146·6
285	4,343	Pacific Ocean	47·6

A more detailed table containing the co-ordinates and other data, as well as the characteristics of the samples, will be given in a special paper.

The results obtained make it possible to draw the following conclusions.

All the ferro-manganese formations of the seas and lakes of the U.S.S.R. investigated are to some degree radioactive.

Their radium content varies within wide limits—from $1{\cdot}2 \times 10^{-10}$ per cent (Caspian Sea) to $31{\cdot}8 \times 10^{-10}$ per cent (Black Sea); the mean for nine samples was $10{\cdot}9 \times 10^{-10}$ per cent. In comparison with the oceanic deep-water concretions ($47{\cdot}6 - 146{\cdot}6 \times 10^{-10}$ per cent) the radium content in these ferro-manganese formations is considerably lower.

The determinations of the thorium X have shown that its content is small—less than 1×10^{-3} per cent Th X equiv. Th. The relation of radium to thorium shows that in the ferro-manganese formations, in comparison to the rocks, there is a manifest lack of elements of the thorium group. This fact indicates the want of the thorium in the concretions, and the partial, or entire disintegration of the short-lived isotope of radium—the mesothorium I.

The observations made show small concretions to be more radioactive than large ones or crusts, and also the surface layer to be more active than the central part of the concretion.

The different contents of radium and mesothorium I – thorium X in separate layers of the concretions, and the different correlations of separate elements, enable an approach to be made to the solution of the problem of the rate of formation of the ferro-manganese concretions by radioactive methods. A thorough radiological investigation of several concretions is being made for this purpose.

The radioactive elements in the bottom deposits may be divided into two groups: elements contained in the fragmentary material forming deposits, and elements derived from the water, as the result of various chemical and biochemical processes. In the ferro-manganese concretions and muds rich in iron the chief mass—perhaps even the entire one—of the radioactive elements may be ascribed to the second group. In this case we have encroachment and concentration of radium and its isotopes by deposition of colloidal forms of iron from the water. In proportion to the disintegration of the short-lived isotopes of radium, and also of the radium itself, the radioactivity of the concretions must, in the course of time, decrease.

Determinations are now being made of some few score concretions and bottom soils of the Kara Sea, as well as of a series of bottom samples from other seas and lakes of the U.S.S.R.

The results of the investigations will be given for each sea separately.

In conclusion, I wish to express my gratitude to A. D. Archangealsky (member of the Academy), Prof. A. L. Bening, Prof. K. M. Derugin, Prof. M. V. Klenova, Prof. J. M. Shokalsky and G. F. Ul, for their courtesy in putting at my disposal the samples, and furnishing me with the necessary data.

A Simple Relay for Spark Counters of the Greinacher Type

H. GREINACHER[1] has described a valuable method for counting α- and β-particles by means of a spark-gap. A water-jet that is turned by the electrostatic forces between it and a pointed electrode allows an objective registration by opening and closing an electric contact. R. D. Summers[2] has pointed out that this arrangement can be used also as a relay.

I have found that it is possible to avoid the disadvantages connected with the use of a water-jet by constructing a mechanical relay. The electrostatic forces between a piece of spring steel and a copper sheet covered with a thin layer of mica are strong enough to attract the spring; this shuts the contact of a telephone counter circuit. The relay shunts the spark-gap. At the moment of ionisation of the air in the gap by a particle, a discharge occurs and the potential between the two electrodes of the gap breaks down. Therefore the relay is released for a moment and opens the circuit of the counter, which registers in this manner the presence of a particle.

The advantages of this mechanical relay are that it works without an auxiliary substance (water) and

it can be depended on for counts extending over a long period.

A detailed discussion will be published elsewhere (*Z. tech. Phys.*). The relay will be manufactured by E. Leybold, Köln a/Rh. I was enabled to construct the apparatus by a grant of the Deutsche Forschungsgemeinschaft.

Effect of Light on Diamagnetic Susceptibilities

THE effect of light on paramagnetic susceptibilities of the ions of the iron group has already been reported by Bose and Raha[1]. They have shown how the l-component of the magnetic moment, which is more or less quenched in these ions, is partially freed on exposure to light. We have since performed the corresponding experiment for some diamagnetics in a Curie-Chéneveau balance with a fine phosphor-bronze suspension.

The halogens in their $^1\Sigma_g$ states are all known to be diamagnetic. Experiments with halogen vapours (chlorine, bromine and iodine) indicate that on exposure to light from which the infra-red portion was cut out, the susceptibilities increase in all cases. The exaltation of diamagnetism is evanescent at the red end, and remains very small until the violet end is reached. It is too early to offer a definite explanation, as the halogen molecule by absorbing light of wave-length shorter than the convergence limit (4785 A., 5107 A., 4995 A. for chlorine, bromine, iodine respectively) is adiabatically dissociated into two atoms ($^2P_{3/2}$ and $^2P_{1/2}$), both of which ought to be paramagnetic. This should result in a decrease, rather than an increase, of the average diamagnetic susceptibility of the vapour as a whole. But we may tentatively assume that the stationary concentration of atomic halogen is extremely small, and as such its effect is more than offset by the excited molecules to which the exaltation is due. The last we suggest in view of the fact that the effect, although small, is detectable even in the banded region.

The phenomenon is of the nature of a temporary shift of equilibrium only, as we could reproduce the dark deflection almost immediately the light was off. A side experiment with an air tube gave identical deflections both in the dark and in light.

Archæology in South and East Africa

SOUTH AFRICANS interested in archæology are following the work in East Africa with keen interest in the hope that it may throw light on our problems, and that discoveries there may be interpreted with a due regard to our results. Mr. T. B. O'Brien's[1] views are therefore important to us.

He correlates (by implication, in time) the large-core phase of the Stellenbosch culture with the East African Early Acheulean, since the latter "marks the beginning of a large-core technique", and, further on, says that "Evidence is available in Uganda which suggests the presence here of a large-flake culture, separate from, but contemporary with the Chellean".

If Mr. O'Brien is correct in his correlation and van Riet Lowe[2] is correct in his classification of the Stellenbosch culture, according to which the Lower Stellenbosch uses "core and flake in almost equal proportions", then we must conclude that human history commenced at a very much later date in South than in East Africa.

Mr. O'Brien's correlation is, however, based purely on typology, deductions from which are vitiated by the inclusion of very serious assumptions in the line of reasoning, and Prof. Lowe's classification dates from a time when stratification of layers bearing various phases of the Stellenbosch culture, so far as natural deposits are concerned, were not known. Such a site is now known[3] and the successive, stratified phases are:

(1) Small Clacton flakes. (2) Very large Clacton flakes made into very rough *coups-de-poing* and cleavers. (3) Smaller Clacton flakes used for making the *coups-de-poing* described by Mr. Goodwin[4] from this area. A phase, apparently intermediate between (2) and (3), was found in a raised beach (about 20 feet) a few miles away; and on the surface of eroded sites there was also: (4) Still smaller Clacton flakes and small, beautifully made *coups-de-poing* of the Fauresmith type. (5) A very numerous association of still smaller flakes, not reddened like those of phases (3) and (4) but with surfaces such as could have been formed by the action of wind-blown sand. No *coups-de-poing* could be found among these and typical levallois cores are very common. The use of cores is very rare in phase II, but the core technique is used to an increasing extent in phases III and IV.

We have thus at Mossel Bay an evolutionary series demanding as large a slice of time as can be demanded for the evolution of any similar series in any other part of the world.

When I mentioned, in a previous letter[5], a Late Stellenbosch layer five or six feet above human remains in a shelter at Plettenberg Bay, I referred to a phase apparently intermediate between phases III and IV. I should perhaps have been more explicit than, for the sake of brevity, I was.

Inhibitory Effect of Phloridzin on an Enzymic Dismutation

RECENTLY it has been shown that phloridzin exerts an inhibitory effect on phosphorylations and dephosphorylations[1]. The action on enzymes other than diastase has not yet been investigated. On diastase no poisonous action of phloridzin was demonstrable[1,2]; however, phloridzin is not a specific inhibitor of phosphorylation and dephosphorylation. As the present communication shows, the dismutative conversion of triosephosphoric acid into phosphoglyceric acid and glycerophosphoric acid is also prevented or markedly inhibited by phloridzin in concentrations of about $N/100$.

Extract of rabbit muscles was used for the investigation. To the muscle extract, buffered at a *p*H of about 7·5, sodium fluoride phloridzin and finally the substrate hexosediphosphate were added. In the samples the decrease of P-compounds labile to acid hydrolysis and the increase of P-compounds resistant to acid hydrolysis were determined. Further, the hydrolysis of P-compounds in alkali at room temperature before and after oxidation with iodine was determined in order to estimate the accumulation of dihydroxyacetonphosphate and glyceraldehydphosphate[3,4]. In order to study the action of phloridzin on the formation of the last two substances, it is necessary to dilute the extract more than 100 times[3].

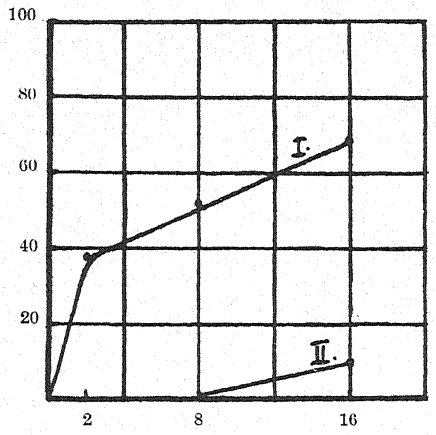

FIG. 1. Relation of percentage conversion into acid-resistant P-compounds (ordinates) to time in minutes (abscissæ). I: without phloridzin; II: with *N*/100 phloridzin.

The velocity of the conversion of hexosediphosphate into dihydroxyacetonphosphate and of this into glyceraldehydphosphate is not affected by phloridzin in concentrations of about *N*/100. On the other hand, the dismutative conversion of triosephosphate into phosphoglyceric acid and glycerophosphoric acid is inhibited 70–100 per cent by phloridzin in the same concentrations. In the same extract with starch as substrate, the well-known inhibition of the phosphorylation was observed. At the phloridzin concentration mentioned above, this inhibition was of the same order as the inhibition of the dismutation.

Further experiments must determine whether the inhibition of oxidation-reduction is an essential action of phloridzin.

A Toxic Emanation from Rubber

APPARATUS of several types for measuring and controlling the humidity of the air in entomological experiments was recently described by us[1]. We mentioned a convenient type of glass jar, which is now in rather common use among entomologists and botanists, for studying the effects of climatic factors on insects or plants. It is a commercial glass storage jar with a screw-on metal cap. The joint between the glass and metal is sealed by a thick rubber washer. The humidity inside the jar is controlled by means of a layer of a suitable solution (of potash, acid, etc.) and the insects are placed in the jar in a celluloid and gauze container.

Since describing this apparatus, and after using it frequently, one of us has discovered a potential source of error. If new rubber washers are used to seal the jars, they may, under certain conditions only, give out a toxic substance. This poisonous emanation is much more powerful when the humidity in the jar is high than when it is low. Thus sometimes moist air may appear to be more unfavourable to an insect than dry, when the difference is actually due to a fault of the apparatus. Certain conclusions obtained using this type of apparatus, for example with regard to the unfavourable effects of high humidities on tsetse fly[2], must therefore be accepted with caution.

After exposure to air for four months, the rubber washers which we have been using completely lose their toxic properties, and it is safe to use them even in saturated air. Different samples of rubber vary considerably, and any apparatus for investigating effects of humidity which contains rubber joints should be carefully tested.

Cytological Significance of the Nature of Sexual Fusion in Hymenomycetes

THE late Hans Kniep from 1915 onwards and Mlle. Bensaude in 1918 described the union of two mycelia of + and − strains as a necessary preliminary to the formation of the sporophore in heterothallic species of Hymenomycetes. In such cases, plasmogamy is usually separated from karyogamy in the basidium by several successive divisions of conjugate nuclei through clamp connexions. This is held as indicating a "degeneration of the sexual process", and as the principal point of distinction from the type of sexual fusion known in green plants, where there is *simultaneous* fusion of protoplasm and nuclei of two conjugating gametes. But a closer reflection would lessen this difference.

No doubt in the higher plants we have fusion of the two nuclei with the formation of the zygote and the initiation of the diplophase, but not the fusion of two sets of chromosomes (male and female), which simply lie together in the fusion nucleus; the actual fusion of chromosomes is delayed there by almost the same long steps until the prophase of the reduction division or meiosis in connexion with microsporogenesis or megasporogenesis. In the Hymenomycetes, on the other hand, the fusion of the two nuclei in the basidium is followed almost at once by the fusion of their chromosomes in connexion with meiosis. Thus, the only difference is that in the Hymenomycetes the two conjugate nuclei from two different strains (plus and minus) are not in actual contact with each other in the form of one fusion-nucleus as in the higher plants, though they lie very close together in each cell of the hyphæ.

The Schools and Pre-Medical Studies

THE writer of the article on "The Schools and Pre-Medical Studies", which appeared in NATURE of November 2, p. 706, very rightly stresses the need for a common syllabus for all First M.B. examinations. He refers to the differences between the London syllabus and the (new) Cambridge syllabus as regards biology. He does not, however, mention the fact that this new Cambridge syllabus is the fruit of the labours of the Joint First M.B. Committee of the Universities of Oxford, Cambridge and London. This Committee produced an agreed list of types to be included in the biology syllabus, "with a recommendation that each University should adopt a syllabus within the common outline". To this, not only Cambridge, but now also Oxford has subscribed. As a result, a schoolmaster will now require only a single course in biology to prepare a boy for the First M.B. at either Oxford or Cambridge; and if, as is very much hoped, the University of London sees its way to accept the report of the Joint First M.B. Committee, a great step will have been taken to secure that uniformity of syllabus which is so much desired. But it should be known that such uniformity is already in existence between Oxford and Cambridge.

It may perhaps be helpful to readers to remind them that the Joint First M.B. Committee of the Universities of Oxford, Cambridge and London is a body independent of the Conference of Representatives nominated by the Universities of Oxford, Cambridge and London, the Royal College of Physicians of London, the Royal College of Surgeons of England and the Society of Apothecaries of London, whose report on the Medical Curriculum forms the subject of the article in NATURE of November 2.

G. R. DE BEER.

Department of
Zoology and Comparative Anatomy,
University Museum, Oxford.

To justify the need for a common syllabus, I was more concerned with the differences between the syllabuses of the First M.B. examinations of Cambridge and London than with the uniformity already in existence between Oxford and Cambridge. The fact that the syllabus issued in September 1935 for the London First M.B. examinations during 1936 is the same as that of previous years appears to afford little hope of a common syllabus in the immediate future.

What is wanted is a common syllabus for *all* First M.B. examinations, and it is to be hoped that the achievement of this aim will not be hindered by the fact that the two distinct bodies referred to by Dr. de Beer have each decided independently what that syllabus should contain.

W. J. R. D.

Points from Foregoing Letters

A MARKED inhibition of the growth of implanted tumours in rats is found by A. Haddow when colloidal preparations of several benzanthracene compounds and of benzpyrene are injected intra-peritoneally. The same substances are known to produce cancer after prolonged application. The author points out that this behaviour is similar to that of X-radiation, which can both control and produce cancer.

Dr. A. Cohen describes the synthesis and structure of compounds of maleic anhydride and vinylnaphthalenes. These may prove useful in the synthesis of sex hormones of the equilenin and œstrone type.

Neutrons, apparently of medium velocity, from a radon-beryllium source surrounded by a 15 mm. silver shield, produced a greater activity in test pieces of silver and of iodine, and a smaller activity in silicon and aluminium, than that produced by the unshielded source. W. Ehrenberg concludes that collision of neutrons with silver nuclei may result either in capture of the neutrons with formation of a radioactive element, or in the transfer of energy to the nucleus (excitation) and consequent slowing down of the neutron. The reduced energy of the neutron is different from, and greater than that of, the neutrons slowed down by paraffin wax.

A table showing the radioactivity of ferro-manganese concretions and deposits obtained from seas and lakes of the U.S.S.R. is given by L. M. Kurbatov. The percentage and the relative proportions of radium, mesothorium I and thorium X in the separate layers of the concretions may give an estimate of the rate at which such concretions are formed.

A mechanical relay and spark counter (for counting alpha and beta particles) is described by Dr. H. Teichmann. It consists of a piece of spring steel and a copper sheet covered with a thin layer of mica, and it is claimed that it has certain advantages over the similar water-jet device devised by Greinacher.

H. C. Bhuyan reports that the diamagnetic susceptibilities of chlorine, bromine and iodine vapours are temporarily increased on exposure to visible light. Only a small increase is produced by the red end of the spectrum, but this becomes greater at the violet end.

Prof. T. F. Dreyer enumerates the stratification of layers at Mossel Bay, South Africa, bearing various phases of prehistoric implements of Stellenbosch culture. He disagrees with O'Brien's correlation of the Stellenbosch culture with the East African Early Acheulean, because it would indicate that human history commences at a very much later date in South than in East Africa.

Phloridzin, a bitter principle obtainable from the bark of apple and other trees, has been found to inhibit the reaction between the phosphate radicle and glycogen, the sugar-like substance in the muscle, the oxidation of which provides energy to the organism. H. Kalckar now points out that phloridzin also inhibits another reaction, namely, the oxidation-reduction ('dismutation') of triosephosphate into phosphoglyceric acid and glycerophosphoric acid.

Dr. K. Mellanby and Dr. P. A. Buxton direct attention to the occasional emanation, under the influence of moisture, of a poisonous gas from rubber washers used to seal the jars in which living insects are kept. This may vitiate experiments such as those on the influence of humidity upon the tsetse fly.

Research Items

Racial Origins of the American Aborigines

ARGUMENTS which have been advanced recently, based primarily on somatological evidence, in support of the view that Melanesian and Australian elements are to be found in the indigenous peoples of America, have induced Dr. Aleš Hrdlička of the Smithsonian Institution, Washington, D.C., to recapitulate the evidence and to examine the validity of the conclusion (*Smithsonian Misc. Collect.*, **94**, 11). The supporters of the theory rely mainly on the evidence of skeletal material from Lagoa Santa, Brazil, Lower California and Patagonia, but recently the evidence of linguistics and culture has been invoked. So far as the argument from physical characters and skeletal material is concerned, it was pointed out by de Quatrefages and Ten Kate that certain crania, recognised as of primitive type, presented close resemblance to Melanesian and Australian skulls; but they did not go on to deduce racial affinity therefrom as subsequent theorists have done. These theorists, and popular writers following them, have given the presence of the Melanesian and Australian elements more and more of a reality until the belief has assumed the semblance of a demonstrated fact. As the result of a study of 10,000 American crania, personal visits to more than a hundred tribes in America and the study of a larger number of Australian skulls than any other man, the author is unable to accept the theory. The basic foundations of the theory are built on sand. So far as the skulls from Lower California are concerned, these skulls do bear a resemblance to some of those of Melanesia; but this type is found also in not a few other widely separated regions of America, both among Indians and Eskimo. There it is contemporaneous with other types of these people, connects with them, and is only one of several.

Romano-British Gloucester

FURTHER evidence of the culture of Romano-British Gloucester is afforded by pottery from two sites in the city, which has been described by Mr. Charles Green (Public Museum, Gloucester, Occasional Papers No. 3, 1935; 2*d*.). The first group, of which part has recently been acquired by the Museum, was found in excavating the foundations of the girls' school at the corner of Denmark and Lansdown Roads. It has been ascribed to the period A.D. 250–300, but this dating is too late. The potter's mark *off. Calvi*, referring to the factory of Calvus at La Graufesenque, fixes the date of manufacture in the period A.D. 54–94. The evidence afforded by the collections in the Museum, mostly unpublished, points to the introduction of *terra sigillata* into Gloucester during the Flavian period. The coarse ware here described falls into well-known types, most of which are dateable and can be compared with dated pottery from other sites in the district. Most of it is late Flavian. The second group is from a double interment found in the garden of a house in Dean's Way. Iron nails, some showing traces of wood, were found, which possibly had belonged to a coffin. Other fragments of iron were with parts of a small bronze bowl, for which it is difficult to find a parallel, as unlike the bronze pans of the period, it has no traces of handles. The pottery is in a fair state of preservation. A bulbous beaker belongs to a type which did not appear earlier than the beginning of the fourth century, while a pseudo-Samian bowl is also late. The jars belong to a type which persisted throughout the whole Romano-British period.

Psychology and Nutrition

AN article by David Katz on "Some Problems of Feeding in relation to Industrial Psychology" appears in the *Human Factor* (**9**, No. 4). The writer stresses the difference between rational and irrational aspects of nutrition. Man manages, in normal circumstances, to obtain a sufficient quantity of the basic substances of his diet as protein, carbohydrates and fats together with nutritive salts and vitamins, but the way he gets them is entirely at the mercy of the particular taste or preference that has been developed by the nation, race or climate, in which religious taboos, tradition and subconscious factors play an important role. Mr. Katz refers to the international results of the Japanese food habits compared with those of the Europeans; to Germany's errors in food policy during the War; to the increasing 'democratisation' of food; sex differences; and changes of taste with age. If it should seem necessary to modify the acquired taste of a people, the administration should always keep in mind the important difference between rational and irrational ways of satisfying human appetite.

New Zealand Whitebait

IN the *Victorian Naturalist* (**52**, No. 3; 1935) Mr. Gilbert Whiteley gives an account of the Galaxiidae, a family which includes the whitebait of New Zealand and the mountain trout, minnow, jollytail, eel gudgeon or native trout of Australia. They are mostly found in fresh water, from sea-level to the tops of mountains, some, like the whitebait, migrating to and from salt-water, but probably not travelling very far out to sea. The New Zealand whitebait of commerce consists of the young of more than one species which ascend rivers in hordes towards the end of the year. The chief species is usually called *Galaxias attenuatus*, although strictly speaking it should be named *Austrocobites attenuatus*. The breeding habits are peculiar: in spring, countless numbers of these small adult fishes are seen in the lower reaches of the rivers within tidal limits where are mud flats and muddy creeks with salt rushes and stranded brushwood débris. There, ova in huge numbers are laid and cling to the rushes and water plants near the surface of the water. In order that the young may hatch, the ripe ova must be washed from the plants at high spring tides and the newly hatched fry driven out to sea, where they remain for a few weeks and then struggle up the rivers against the current. In the day an advance of a mile in three hours may be made. In the fresh water they remain for a few months and then descend again to breed.

Insects of the Kalahari Expedition

In the *Annals of the Transvaal Museum*, 7, Part 1, October 1935, are a series of reports on various groups of insects collected by the Vernay-Lang Kalahari Expedition (March–September 1930). Mr. Louis B. Prout deals with the moths of the family Geometridæ. Concerning this group, he remarks that, with the exception of a very few species, contained in the British Museum, from the N'Gami country, no specimens appear to have been previously obtained from the Kalahari Desert and its immediate vicinity. The number of Geometrid species collected was 51, distributed among 34 genera: six species and one subspecies are described as new. In the report of Mr. L. Gschwendtner, water beetles of the families Haliplidæ and Dytiscidæ are discussed. Altogether, 53 species are identified, three being described as being previously unknown, together with one new subspecies and one new variety. Beetles of the family Buprestidæ are reported upon by Dr. Jan Obenberger, who records 36 species, three being previously unknown. Dr. A. J. Hesse deals with the weevils (Curculionidæ). Out of 76 species, four are described as being new while the undetermined forms are represented either singly or belong to groups not sufficiently known at present. The last report, by Prof. T. D. A. Cockerell, is concerned with the bees. A very considerable proportion of these insects are described as new, namely, 29 forms out of a total of 62 species. The various reports make a substantial contribution to a knowledge of the fauna of a region of notable biological interest.

Role of Organic Matter in Plant Nutrition

Continuing the series of researches on the above subject, three further papers by Subrahmanyan and his associates have appeared (*Proc. Ind. Acad. Sci.*, 1, No. 12). These deal respectively with the economy of carbon during decomposition of cane molasses in swamp soil, the influence of fermentable organic matter on the transformation of iron, and the relation of the oxidation of organic matter in the soil to plant assimilation. Addition of molasses to water-logged soil was accompanied by much loss of carbon in gaseous forms, and still greater loss occurred after flooding. The distribution of total carbon was not appreciably affected by the concentration of molasses. Flooding removed the bulk of the organic matter in all cases. Fermentation and loss of carbon were increased by increase of temperature and access of oxygen. It is suggested that in the growing of rice it would be advantageous to convert the bulk of the added organic matter to insoluble forms before flooding. Addition of fermentable organic matter to swamp soils brought quantities of ferrous iron into solution, the amount varying with different soils, whilst insoluble ferrous iron in the soil sediment increased in all cases. Increasing concentration of organic matter increased the amount of ferrous iron brought into solution, and solution and subsequent precipitation were hastened by rise of temperature to 45° C. Evidence is presented to show that ferrous iron in solution is largely present in association with organic acids produced during fermentation, whilst insoluble ferrous iron is present as carbonate and sulphide. A survey of tropical soils showed most of them to be poor in organic carbon compared with soils from temperate regions. Addition of minerals may increase or depress the beneficial effect of organic manuring.

Fossil Fishes of Sokoto Province

Dr. E. T. White has described collections of fossil fishes collected by the officers of the Geological Survey during the course of water supply investigations in Sokoto Province (Geological Survey of Nigeria, Bull. No. 14, 1934). Two very distinct faunas are present, one from the Upper Cretacean, the other from the Lower Eocene. The material consists largely of isolated teeth and bones, but there are a number of skulls of bony fishes, chiefly cat-fishes (Siluroids) which still abound in this region and are a characteristic feature of the modern fauna. These fossil forms, however, cannot be referred to any living genera, therefore new genera have been established for them. The fishes from the Upper Cretaceous fauna include a Porbeagle shark (*Lamna*) of the same type as the living species, and a curious genus of saw-fishes (*Schizorhina*) of which no representatives have survived. Sokoto Province at the time when they lived was probably a tropical or sub-tropical sea. In the early Eocene period the deposits were coastal and the fishes were mainly sharks and rays and also cat-fishes. The cat-fishes very possibly did not actually inhabit the brackish waters in which the beds were formed, but are likely to have been carried down the rivers to the coast when dead or in a dying condition. Figures of the nearest living relatives of most of the fishes are given and there are several good text figures and photographic plates of the bones and teeth.

Origin of Copper Deposits

A group of copper-bearing pyrrhotite veins of the Ducktown type and genetically related ore-bodies are widely distributed in the southern Appalachian region. The origin of these is the subject of a contribution by C. S. Ross (U.S. Geol. Surv., Prof. Paper 179; 1935) which is of particular importance on account of the valuable discussion which it contains of replacement phenomena and the criteria by means of which mineral sequences can be determined. A magnificent series of forty-four plates illustrates the evidence most convincingly. The veins are thought to have been derived from a differentiating magma, but no parental igneous rock has been traced in the region. The first event in vein formation was the intrusion of a felspathic magma. This was followed by introduction of vein quartz, after which followed a stage characterised by a large group of ferromagnesian minerals. Replacement of quartz by hornblende and actinolite is of particular interest. In most of the veins, this stage was succeeded by one in which calcite was the dominant mineral, associated in some cases with later dolomite and ankerite. There is good evidence that the carbonates do not represent replaced limestone, but are hydrothermal deposits. A small group of silicates followed and replaced carbonates, and finally (with insignificant exceptions) sulphides were introduced and replaced carbonates, quartz, felspars, ferromagnesian minerals and schists. As regards the physical chemistry of the processes involved, our knowledge is woefully deficient, and after a lengthy discussion the author is obliged to confess that the character, concentration and reactions of the volatile substances that formed the solvents and the transporting agents for the vein materials are little understood. As a demonstration of replacement, however, the occurrences described are of fundamental petrological importance, since there is a steadily growing body of evidence that certain

igneous rocks, commonly thought to be crystallisation products from magmas, may actually be complex metasomatic replacements of pre-existing crustal materials.

The Asama-yama (Japan) Eruption of 1935

FOR more than two years since the explosions of 1932, the volcano Asama remained inactive. In October 1934, however, the floor of the crater began to rise at the rate of about 8 in. a day, and the surface of the ground at the Volcano Observatory, three miles east of the crater, showed a considerable tilting. These changes were the preludes of the series of eruptions, in April and May 1935, that are now described by Mr. T. Minakami (*Bull. Earthq. Res. Inst.*, 13, 629–643; 1935). The first and greatest eruption occurred on April 20, and was followed by forty others until May 28. During the explosions, the crater floor was broken up, and bombs, weighing altogether 4½ million tons—one of them 200 tons—were scattered over the surface of the cone. Ashes fell over a narrow zone entirely to the east of the volcano and including Tokyo and Tiba. In the same direction, there was no trace of a silent zone in the sound-area, but towards the north, west and south the zone was clearly developed, the boundary of the inner sound-area having a mean radius of 30 miles, while the boundaries of the outer area had mean radii of about 90 and 150 miles. During March, the ground of the Observatory tilted at the mean daily rate of 1·5″ towards the south-east. On April 17, the direction of tilting was reversed, and on April 20, the tilt was 2·5″. Another reversal occurred on May 2, and, after that, the daily rate of tilt began to decrease. It is interesting to notice that extraordinary tilts of the ground were invariably accompanied by violent explosions.

Physiology of Illumination

IN a paper read to the Illuminating Engineering Society on November 12, Dr. R. J. Lythgoe said that the eye can function over a range of illuminations between 0·00001 and 10,000 foot candles. It has been recently shown that even in occupations only requiring the crudest visual perception, the work is speeded up by an increase in illumination. Extremes of contrast are subjectively uncomfortable, and so it is advisable not to have a great difference in brightness between the task and the surrounding field of vision. It was stated that a single 'glaring' source of light hanging on a black wall near a visual test object may actually improve the perception. The general increase in the standards of artificial illumination is in keeping with the more generous economic outlook of to-day. Along with the rise of the level of living there has been an increase in the illumination of factories. Before the Great War, four foot candles was the minimum recommended; it is now ten foot candles. So far as evidence goes, the standard of illumination seems to be continually rising. The limit is governed by technical and economic reasons. Skill is necessary to make a little go a long way. Anyone can take a snapshot out of doors in 5,000 foot candles, but skill enables us to arrange lights indoors so that a good portrait can be obtained with 100 foot candles only.

Miniature Thermionic Valves

THE midget type of three-electrode valve referred to in NATURE of October 27, 1934, is now accompanied by a pentode of the same general form and construction. These 'acorn' tubes, as they are known in the United States, have been developed by the R.C.A. Manufacturing Company, and a brief, illustrated description of them and their characteristics is given in a paper by B. Salzberg and D. G. Burnside in the October issue of the *Proceedings of the Institute of Radio Engineers*. On account of the decreased impedances of the leads and the lower inter-electrode capacities and transit times, these valves permit of considerable improvement to be made in receiving equipment for ultra-short wave-lengths. The triode can be operated as an oscillator in a conventional circuit down to a wave-length of about 40 cm., while the pentode can be used as a radio-frequency amplifier at wave-lengths down to about 70 cm. It is claimed that, at a wave-length of three metres, these pentodes enable an amplification of 10–15 times to be obtained under conditions at which the ordinary valve would be quite useless. The small size of the valves and their novel structural arrangements permit the construction of compact and convenient receiving apparatus. Even at longer wave-lengths, the excellent characteristics of the valves make them applicable to purposes where their small size and low weight are of importance.

Reaction of Hydrogen with Oxygen

MANY investigations have been made of the reaction of hydrogen atoms with oxygen molecules, but it has remained uncertain whether the reaction $H + O_2$ occurs as a two-body or as a three-body process. G. A. Cook and J. R. Bates (*J. Amer. Chem. Soc.*, 57, 1775; 1935) have reinvestigated the reaction, the hydrogen atoms being obtained by the photo-dissociation of hydrogen iodide. A similar study was also made of the reaction between deuterium iodide and oxygen. It was found that, in parallel runs, more deuterium is oxidised than hydrogen, and that addition of nitrogen greatly increases the oxidation of hydrogen or deuterium. The results indicate that the reaction between hydrogen atoms and oxygen molecules is a three-body process. An analysis of two possible reaction mechanisms is made. It is also concluded that Steiner's value for the velocity coefficient k_{H+H+H_2} is to be preferred to the very different one given more recently by Smallwood.

Structure of Elliptical Nebulæ

THE true nature of the elliptical nebulæ is at present a problem of considerable difficulty, partly owing to the lack of sufficient observational data on which to found a satisfactory theory. With the object of remedying this deficiency, Sinclair Smith (*Astrophysical J.*, 82, 192) has recently made observations of polarisation, nuclear size and spectral character in Messier 32, a nebula which is regarded as typical of its class. He has found a definite nucleus of diameter approximately 0·8″, but no detectable polarisation within 75″ of this nucleus. The spectral type is *dG*3 and shows no variation along the major axis. Much work remains to be done on these lines; but at present the observations do not support Jeans's gas-sphere model, or ten Bruggencate's hypothesis of an assembly of small particles illuminated by the nucleus. It is suggested that a star cluster model accounts best for the facts, though the resulting central density of $8{\cdot}8 \times 10^5$ stars per cubic parsec is extraordinarily high.

International Exhibition of Chinese Art

THE exhibition of Chinese art, which opened at the Royal Academy of Art, Burlington House, Piccadilly, London, on November 28, is a unique opportunity for student and connoisseur alike. No such collection of objects from the Far East has ever been gathered together in Europe before; and it is an opportunity that is not likely to recur. Nearly four thousand objects are shown, of which every one is of interest, either for its æsthetic excellence, or for its historical significance.

The nucleus of the exhibition is drawn from the Chinese national collections and has been selected from the Imperial treasures which came from the Forbidden City. Not a few of these were made specially for palace use, and bear the emperor's commemorative inscription. In addition, exhibits have been contributed from public and private collections in Japan and the United States, and among European countries, Great Britain, France, Germany, Sweden, Russia, Turkey and the City of Danzig. Even Egypt has helped. In fact, every effort has been made to secure that the exhibits should be as fully representative as possible.

The range of the exhibits is almost as varied as the sources from which they have now been brought together. Every side of Chinese artistic achievement has been covered—in all instances adequately to meet the needs of the student, in many with abundance. Bronzes, carpets, enamels, embroideries, glass, ivories, lacquer, paintings, calligraphy, sculpture, textiles, and, needless to say, numerous examples of the most characteristic products of Chinese culture, jades and pottery and porcelain, all are shown at the highest point of attainment in technique and artistic development in the respective periods.

The exhibition has been arranged on a chronological basis, in dynastic periods. Some idea of the impressive character of Chinese civilisation will be gathered from the fact that the exhibits, of which the earliest in date may well stand comparison in artistic merit with later objects in their own class, cover a period of no less than thirty-five centuries, ending at A.D. 1800 and beginning with the Bronze Age at about the middle of the eighteenth century B.C. This is a record with which not even Egypt, with all its long history, can compete.

In an exhibition such as this, in which the principle of selection has been either purely æsthetic or relative to the history of artistic development, the objects shown are unfortunately but necessarily divorced from their cultural context—an association of the greatest importance, as all will admit, who have any acquaintance with Chinese culture. Of the purely æsthetic aspect of the exhibition, NATURE may well leave others to speak. It is far from being without significance for scientific studies.

The ethnologist, and still more the archæologist, will find much of supreme interest and no little importance here. This indeed is no more than might be expected when so long a period of development is covered. The ethnologist, for example, will note the early appearance in the bronzes of the Shang-Yin dynasty (? 1766– ? 1122 B.C.) of the characteristic feeling of China for form and ornament, as well as the delicacy of handling in technique. Nor will he overlook how, notwithstanding ethnic movement at various periods, after being influenced for a time, these qualities reassert themselves, except possibly in the last period under the Manchu dynasty, when the effect of influences making for an elaboration of form and colour seem to have been unusually prolonged. This persistence of the native stamp may perhaps be appreciated most readily in the sculptures and figures of the T'ang period (A.D. 618–819), when Chinese Buddhist art, purified from corrupting elements by fresh contacts with India through the Chinese pilgrims who journeyed to that country, rapidly reasserted its native qualities in the imported art forms. It is perhaps scarcely necessary to add that the objects belonging to the earlier dynasties, and especially the human figures, coming from burials, are of the greatest significance for Chinese religious belief, legend and domestic culture.

To the archæologist and student of prehistory, the interest of the exhibition, especially in the chronologically earlier sections, is even greater. Early Chinese history in its annals is obscured in the mists of time. The records of the emperors and of their achievements stretch well back into the third millennium B.C. Until recently it had been held—and even then with some doubt—that authentic history did not begin at the earliest before the Chou dynasty (? 1122–249 B.C.). Excavation, however, which began with a Japanese expedition in 1906, was continued by Dr. J. C. Andersson after the Great War, and recently has been prosecuted with vigour by the Chinese themselves, has revealed the existence in North and Central China of a chalcolithic civilisation, which followed on a neolithic culture ending about 2000 B.C. It would appear from recent research that this chalcolithic civilisation reached, or at least influenced, southern China about the beginning of the Chou dynasty, or slightly before (see NATURE of August 31, p. 346). Among the objects of this early culture there appears a painted pottery, apparently belonging to the groups of early painted pottery which have been found in eastern Europe, western Asia, Baluchistan and northern India. In China it appears to be an intrusion which dies out, a second type of unpainted ware being the characteristic form, persisting through the later period.

Interesting as this early civilisation undoubtedly is in view of its possible Western affinities, its connexion with the period which follows, on present evidence, is of no less moment. For it is to be noted that the early ceremonial bronzes and other objects of the Bronze Age from recent excavations, some of which are inscribed, appear to confirm the records of the emperors of the Shang-Yin dynasty in the annals previously regarded as legendary.

Unfortunately, it has not been possible to do more than refer in passing to the remarkable series of exhibits of the T'ang period, perhaps China's age of greatest expansion. Here the most noteworthy exhibits are the paintings recovered by Sir Aurel Stein from Tun-huang; but the whole exhibit of this period is of the greatest importance for the student of cultural contacts between East and West, notably in the sculpture, where Greek influence still lingers, permeating through India after many centuries.

Lenses Employed in the Technicolor Process of Cinematography

By H. W. Lee, Research Department of Taylor, Taylor and Hobson, Ltd.

IN colour photography it is necessary to analyse the light reflected by coloured objects into at least three spectral regions which, where there are three only, may be termed red, green and blue respectively. This is done by means of colour filters which transmit definite portions of the spectrum and absorb the rest; the three negatives are produced either successively or simultaneously. In cinematography the negatives must, of course, be made simultaneously unless the rate of movement of the film is increased threefold, to which there are grave objections. The three negatives may be made simultaneously by means of three lenses; this results in colour parallax, and the three images will never exactly superpose. Alternatively, the beam of light issuing from a single objective must be divided. This division may be made by means of superposed filters, the components of white light being successively subtracted and acting on sensitised films superposed. The objections to this are that the films and filters must be very thin if the composite 'tri-pack' and filter film is not to be too thick, and that each layer of emulsion produces a certain amount of scattering, so that the successive images are more and more diffused. Other methods of dividing the beam are by successive reflections from thin, partly-reflecting and partly-transmitting films, which may be either isolated films of collodion or films of silver on glass surfaces. The silver may be in the form of totally reflecting films partly covering the surfaces they are deposited on, a method not without objection since the areas of film must be small if there is not to be differentiation between different parts of the light beams; alternatively, the silver films may be so thin as both to reflect and transmit.

The Technicolor process is, optically speaking, a combination of two processes suggested above. *One* semi-reflecting metallic film on the diagonal plane of a glass cube is combined with a bi-pack, to which the objections of the tri-pack do not altogether apply, as the two sensitive films can be placed in contact.

The glass cube placed between the lens and the film has considerable thickness (being approximately equal to the size of field covered) and therefore produces considerable aberration. This fact was not sufficiently realised by early experimenters in colour photography, who tried to combine prism 'beam splitters' with normal lenses on the market, which of course had not been computed for use with considerable thicknesses of glass. The result was poor definition and images of unequal sizes. Technicolor, however, early realised the necessity for taking the prism into account in the design of the lens system, and in 1918, D. F. Comstock took out a patent (British patent 131,422) for several constructions, having apertures up to $f/3{\cdot}9$, for lens systems combined with prisms. In 1927, however, their prism system was simplified and the need felt for lenses of larger aperture, owing to the change in cinema technique from outdoor to studio photography. Technicolor approached Taylor, Taylor and Hobson, Ltd., who were making lenses having an aperture of $F/2$, and asked them to design a special lens for their needs. This was for two-colour work. With the change to three-colour work in 1931, a further change was needed, and, moreover, the matter of colour correction became more stringent.

It is possible to equalise the focusing position and the focal lengths for two parts of the spectrum which would, in practice, be the 'centres of gravity' of the spectrum bands passed by the two filters used, but when three colours are in question there is the difficulty that the third colour must necessarily be out of focus owing to the so-called secondary spectrum. This secondary spectrum can be reduced in certain optical systems such as telescopic objectives and photographic lenses of small aperture by the aid of special glasses; but the dispersive power of these glasses, the so-called 'telescope flints', which have partial dispersions more nearly proportional to those of crown glasses than the flints in ordinary use, is so low that, in photographic systems of large aperture and considerable field dependent entirely upon these glasses, the construction is prohibitively complicated. However, since, in the new Technicolor process, only two images are formed in a plane at right angles thereto, it is possible to allow for the slightly different focus for the green, if the foci for the red and blue coincide. These, then, were the conditions to be fulfilled; the red and blue foci must coincide, the tolerance being that the blue focus might be 0·0005 in. longer than the red as the blue negative is the rear one of the bi-pack. The green focus could be 0·003 in. shorter than the common focus for the blue and red. These conditions were for the 'standard' focal length of 50 mm. The aperture required was $F/1{\cdot}7$. As there is inevitably some loss of definition in colour processing, the definition of the lenses was to be better than that of lenses for non-colour work. Other lenses of focal length 70 mm., 100 mm. and 140 mm. were also required.

Now the 'secondary spectrum', which required an adjustment of 0·003 in. for the green on the 50 mm. lens, increases with focal length, so that it becomes 0·008 in. with the 140 mm. lens, while the 'adjustment', being made on the camera, is fixed. It thus became necessary to reduce the secondary spectrum with the longer focus lenses. Fortunately, the Parsons Optical Glass Co. (now Chance-Parsons) came to the rescue with a new glass; an experimental melting produced a glass having a reduced secondary spectrum and having the low V of 44·9 (as against 52·2 in the old 'telescopic flint'). By judicious incorporation of this glass in one or two components in the longer focus lenses, these were designed to give approximately the same difference between the green focus and the red-blue focus, as in the standard lens.

A further interesting problem arose when short focus lenses were required, because, with normal types, there is not sufficient clearance between the lens and the focal plane to accommodate the prism. Mr. J. A. Ball, of Technicolor, had tried placing a negative lens in front of an ordinary cinematograph-

taking lens, the distance between the two being greater than the focal length of the positive lens; thereby he decreased the focal length and at the same time displaced the nodal plane towards the focal plane, giving greater clearance.

A negative lens so placed, however, introduces considerable barrel distortion. Ball reduced this by using two negative components, each a cemented doublet, but when the problem was put to Taylor, Taylor and Hobson, Ltd. to provide a lens of aperture $F/2$ free from distortion, a complete solution was forthcoming with a negative consisting of only two simple elements. Fig. 1 shows the Taylor-Hobson lens. The same stringency as to colour correction, of course, applies to this lens.

The closeness of the limits for colour correction necessitates special precautions in manufacture. In a batch of lenses made to very close tolerances of radius and thickness and made from identical glass melts, it is rare to find the chromatic corrections identical to the Technicolor specification, owing to small variations in the composition of glass throughout the pot. The assembled lenses are first tested for focus throughout the spectrum on a collimator illuminated through a constant deviation prism. If necessary, alterations are then made, to bring the chromatic corrections right. Finally, a photographic check is made. An inclined object consisting of parallel lines is photographed through the actual colour filters used by Technicolor.

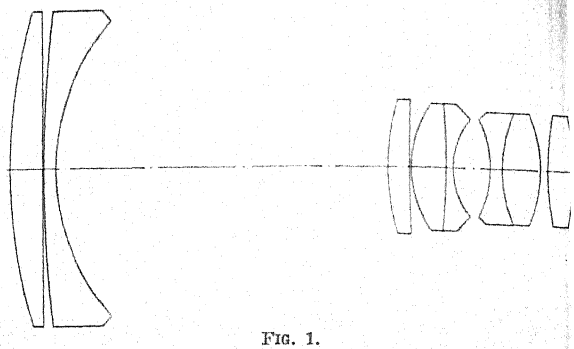

FIG. 1.

Bacteriology of the Atmosphere*

THE study of the bacteriology of the atmosphere dates back to the time of Ehrenberg, who published twenty-five papers dealing microscopically with dust and its biological concomitants in the air. The great impetus to the study was, however, the controversy over the question of spontaneous generation, with which the name of Pasteur is indelibly associated. He was not, however, the pioneer in this respect, for Gaulthier de Claubry in 1832 and Baudrimont in 1855 had already given definite experimental proof of the existence of living 'germs' in air, capable of provoking decomposition. It was the experimental genius of Pasteur which eventually settled the controversy beyond all doubt, and incidentally opened the eyes of scientific workers to the existence of a circumambient flora of unknown potentialities.

The epoch-making development of these discoveries lies in the antiseptic surgery of Lister. Researches on the sanitary quality of air multiplied exceedingly at this period, but, while much of scientific interest was revealed, the general result was to make clear that among the numerous organisms suspended in air and capable of growth, there were, as a rule, very few of pathogenic or of surgical importance. For this reason, there has been of late years a considerable waning of medical interest in the air-borne flora, to the point of positive neglect. Yet, while the above statement may be true of the surgical aspect, there is no doubt that from the physician's point of view, air-borne infection is, in certain cases, of primary importance. This is particularly true of pulmonary diseases.

Some excuse for this state of affairs may be found in the comparative dearth of knowledge about the conditions under which aerial organisms live and survive to convey infection. A few investigations have been carried out on the viability of organisms in sand or dust or suspended in water droplets; but it is still true to say, for example of the tubercle bacillus, that there is no exact knowledge of the conditions under which it can or cannot survive when floating freely in air.

If this is true of such special cases, of vital importance to man, how much more does it apply to the generality of air-borne organisms—the aeroplankton—not only of living rooms, etc., but also of the atmosphere as a whole. The biological side of oceanography has been impressively developed during this century, but the biological side of meteorology remains an unexhausted field for investigation. It has been too rashly assumed that the atmosphere cannot offer a permanent home to micro-organisms, and that those which are found there are strayed wanderers from their true homes and are either dead or in some dormant, spore form.

Investigation makes this much less certain. The number and variety of organisms found are sometimes very great, and they are in many cases not referable to types found elsewhere. Moreover, spore-bearing types are relatively rare, at least among the bacteria and the yeasts, though many fungal spores have been found. The latter have been investigated chiefly in Canada and the United States, in connexion with the spread of rust infections on crop plants, and their migrations have been traced, to some extent.

The distribution of organisms in the atmosphere is not a simple function of height, as earlier observers thought. Aeroplane surveys have made it clear that micro-organisms occur in sporadic clouds, like those of ocean plankton, which may be found at any height that has so far been investigated, that is, up to 20,000 ft. If it be true that the atmosphere does not provide permanence of vital conditions, yet it does provide undoubtedly continuity, so that there are at all times and places some portions of the atmosphere

* Substance of a Chadwick Public Lecture delivered by Prof. R. C. McLean on November 19 at the London School of Hygiene and Tropical Medicine.

in which organisms can live. Condensation of moisture takes place very readily on such small objects, and it is significant that the largest catches have been reported from just below the base of clouds, where saturation conditions obtain. In the like situations, multiplication of organisms may take place to such an extent as to give rise to a veritable cloud flora and perhaps to account for the many instances of rains of small organisms for which no terrestrial source has been reliably indicated. Even apart, however, from such favourable conditions, it is quite possible for micro-organisms to live, surrounded by condensation droplets, even at great heights. Many, if not most, are protected from the lethal action of ultra-violet rays by red or orange pigments which screen the living matter and also warm it by absorption of heat rays, so that they may survive anywhere below the ozone layer, even at air temperatures well below zero. All the elements necessary for nutrition may be obtained in the air in quantities sufficient for the exceedingly small weight of the aeroplankton. Formaldehyde and radioactive material are also present, and may play a part in stimulating growth.

When one considers the heavy contributions that air deposits make to the soil, even in country districts, there is seen to be no more reason for regarding the soil as the origin of the air flora than vice versa. Dust is in fact the mother substance of the soil.

Methods which will combine both qualitative and quantitative results still need to be worked out, and particular stress may be laid on the need for variety of growth-media and for prolonged incubation periods, since many aeroplankton organisms are of very delicate growth. Until we know why this is so and how such apparently delicate organisms can survive in the atmosphere, we are not likely to have a full understanding of the conditions of air-borne infection.

Educational Topics and Events

BIRMINGHAM.—Prof. Kenneth Neville Moss, professor of mining, has been elected to succeed Prof. Stiles as dean of the faculty of science.

Dr. E. L. Hirst has been appointed reader in the chemistry of natural products.

Work on the foundations of the new chemistry block has begun.

CAMBRIDGE.—At Clare College, J. D. Boyd, University demonstrator in anatomy, has been elected into a fellowship.

The governing body of Emmanuel College invites applications for a research studentship which will be awarded in July 1936. Applications must be sent to the Master, Emmanuel College, Cambridge, in time to reach him not later than June 30. Preference will be given to candidates who have already completed one, but not more than two, years of research. The studentship, which must be held at Emmanuel College, and has a maximum annual value of £150, is awarded and normally held for two years, but may be renewed for a third. The studentship is not tenable by a woman or by a graduate of the University of Cambridge.

LONDON.—Dr. Eric Boyland, since 1931 physiological chemist at the Research Institute of the Cancer Hospital, has been appointed University reader in biochemistry, and Dr. V. B. Wigglesworth, since 1926 assistant in the Department of Entomology at the London School of Hygiene and Tropical Medicine, has been appointed University reader in entomology.

OXFORD.—On November 23, Dr. R. T. Gunther in his lecture on the "Early Men of Science of Magdalen College" suggested that the natural amenities of the site may have attracted the attention of Edward Wotton and others to zoological studies, just as in the seventeenth century the foundation of the Botanic Garden on the College land stimulated an interesting group of botanists, among whom were William Browne, Stonehouse, Hooper and Drope. Cartwright, of power loom fame, Gowin Knight, maker of strong magnets, Charles Daubeny, vulcanologist, chemist and botanist, and Lord Rosse, were among the distinguished forerunners of the modern succession of eminent Waynflete professors now attached to the College.

The honorary degree of D.C.L. was conferred upon Sir Harry McGowan, chairman of Imperial Chemical Industries, Ltd., on November 23.

ST. ANDREWS.—Mr. R. C. Alexander has been appointed to the chair of surgery in the University, vacant through the death of Prof. John Anderson.

THE result of the parliamentary elections to the three seats for the Combined Scottish Universities was announced on November 25. The following were elected: Prof. J. Graham Kerr, formerly regius professor of zoology in the University of Glasgow (Unionist); Dr. G. A. Morrison, formerly headmaster of Robert Gordon's College, Aberdeen (National Liberal); and Mr. A. Noel Skelton (Unionist). The death of Mr. Skelton on November 22 will cause a by-election.

THE following scholarships, which are tenable for three or four years, will be offered by the Institution of Naval Architects for competition in 1936: *Naval Architecture: Martell*, £130 a year; *Trewent*, £125 a year; *Denny*, £75 a year. *Marine Engineering: Parsons*, £150 a year; *Yarrow*, £100 a year; *Denny*, £75 a year. The Denny scholarships are tenable for four years at the University of Glasgow only. Full particulars can be obtained from the Secretary of the Institution of Naval Architects, 2 Adam Street, Adelphi, London, W.C.2.

THE Association of University Teachers has written to the Rumanian Legation in London in reference to Prof. Pierre Constantinesco Iasi, professor of the history of art in the Faculty of Kichinev, who is stated to be undergoing trial on a charge of conspiracy against the State following his activities against war and fascism, activities which it is claimed have been carried out in a public and legal manner. The Association expresses the hope that the outcome of the trial will be such as to make it clear that the right of freedom of speech for university professors is upheld in Rumania, and quotes from a resolution adopted by its Council on December 14, 1934, in the course of which the Association affirms "the right of university teachers to the full exercise of their functions and privileges as citizens. It maintains that the public expression of opinion, within the limits of the law, on controversial matters is in no way incompatible with the position and responsibilities of a university teacher, it being understood that such expression of opinion is personal and does not commit the Institution to which he belongs."

Science News a Century Ago

Anniversary Meeting of the Royal Society

THE anniversary meeting of the Royal Society was held on November 30, 1835, J. W. Lubbock, vice-president and treasurer, being in the chair. The secretaries' report stated that the Copley Medal had been awarded to William Snow Harris for his "Experimental Investigations of the Forces of Electricity of high Intensity", while one of the Royal Medals had been awarded to Michael Faraday for his "Experimental Researches in Electricity" and the other to Sir William Rowan Hamilton for papers published by him in the *Transactions of the Royal Irish Academy*, vols. 16 and 17, entitled "Supplement to an Essay on the Theory of System of Rays". The report also announced the appointment of Mr. Robertson as assistant secretary "at a salary of £160 per annum with the use of a bed-room, sitting-room, coals and candles", and of Mr. Schuckard as librarian at a salary of £50 per annum. Mr. Schuckard was to attend from 12 to 4 o'clock on two days of the week. The Society consisted of 10 Royal personages, 48 foreign members and 735 home members, of whom 598 had compounded for life.

Culture of Grapes by Lord Tyrconnel

AT a meeting of the Horticultural Society on December 1, "a paper was read containing notes and observations on many kinds of grapes, cultivated at the seat of the Earl of Tyrconnel, near Catterick Bridge, in Yorkshire, the vineries at which place seem very rich in varieties of this fruit, placed under circumstances highly favourable for comparison; any remarks like these, have been the result of long experience by Mr. Whiting, Lord T's gardener, cannot fail to aid in clearing up the confusion which reigns over the nomenclature, etc. of nearly 200 supposed different sorts of grapes, and further the establishment of a standard of certainty among so much conflict of opinion". (*Athenæum*.)

The London Mechanics' Institution

ON Friday, December 4, *The Times* recorded that this Institution held its usual quarterly meeting on Wednesday evening, in its theatre, Southampton Buildings, Dr. Clutterbuck, vice-president, being in the chair. A report of the committee of managers said that the present number of members was 1,211, an increase of 180 on the preceding quarter. The funds of the Institution appeared to be in a prosperous condition, between £200 and £300 having been paid to lecturers during the preceding twelve months. The chairman congratulated the meeting on the Institution having arrived at its twelfth anniversary, and said he believed a more favourable report on its condition had not been presented before. Votes of thanks were given to Dr. Birkbeck, the president, for his exertions on behalf of the Institution, to lecturers and teachers of classes who had given their services free of charge and to the donors of books, etc.

Education in Italy

IN its column of Weekly Gossip on Literature and Art, the *Athenæum* of December 5 said, "In Italy, Silkworms, Wine-making and Education seem to occupy public attention. Silkworms, it appears, are subject to some sort of infection disease, the nature of which it is important to discover, that precautions may be taken to guard against it. . . . The attention to education we have before noticed; since then, we have seen announced in the periodicals, a 'Manual of Instruction for Infant Schools', a 'Course of Instruction for Girls', and more books for the use of young persons than we can recollect, besides sundry essays upon the subject of Education. We trust, therefore, that the rising generation of Italians will improve accordingly. . . . From Sicily we learn that not less than nine periodicals literary and scientific now flourish there. . ."

Electrostatics: Faraday Borrows a Copper

"HAVE borrowed a copper from Mr. Kipp. It is a new one, not quite finished, and having no cock fixed in it, so that its shape and condition is regular." Thus wrote Faraday on December 5, 1835, and with the borrowed copper proceeded to make the first of his electrostatic experiments. The vessel, a large one of 31 inches diameter, was set up on an insulating stool and charged by means of a frictional electrical machine. Then with a carrier ball—a small sphere covered with tinfoil and suspended by a silk thread—he examined the state of electrification at various points of the surface inside and outside the copper. The surface was touched and the charge taken by the ball transferred to a test electrometer. A series of trials soon showed him that projecting parts of the outside, for example, the edge or rim of the copper, were the most highly electrified. Very little electricity could be obtained from any point inside: the walls near the top were feebly charged, but the bottom showed no charge at all.

Societies and Academies

LONDON

Royal Society, November 21. A. R. UBBELOHDE, J. W. DRINKWATER and A. EGERTON: 'Pro-knocks' and hydrocarbon combustion. Former arrangements for sampling the gases from the engine cylinder have been so modified that the samples can be taken when ignition is made to occur every alternate cycle either in the firing or non-firing strokes. Aldehydes are formed at the end of the compression stroke in the non-fired cycle, but the concentration is much smaller than in the firing stroke. The quantities of formaldehyde and of total aldehydes have been measured when running on various fuels; the amounts produced are insufficient to account for 'knock'; for this, another source of peroxides is therefore needed. Experiments are described which suggest that most hydrocarbon fuels can be made to 'knock', provided molecules which can disrupt and give rise to a branched chain reaction are produced or made available. The main source of the nitrogen peroxide found in the previous experiments is probably the hot active surface of the exhaust valve, and is proved not to be the flame. D. T. A. TOWNEND and E. A. C. CHAMBERLAIN: The influence of pressure on the spontaneous ignition of inflammable gas-air mixtures. (4) Methane, ethane and propane-air mixtures. Whereas with the higher paraffins previously reported on, the ignition points were found to lie in two well-defined temperature ranges, location in the higher range occurring at low pressures, and in the lower

range at higher pressures, with methane or the intermediate products to which it gives rise, they were confined to an upper range even at pressures up to 30 atmospheres. The view previously put forward that ignition in the lower system occurs when temperature and pressure conditions favour the survival and further oxidation of aldehydes (mainly acetaldehydes) has found further support.

PARIS

Academy of Sciences, October 28 (*C.R.*, **201**, 749–800). FÉLIX MESNIL: The jubilee of the prevention of hydrophobia produced by a bite. Pasteur's first communication to the Academy was on October 26, 1885. Between July 6, 1885 and January 1, 1935, no less than 51,057 persons have been treated in Paris by the Pasteur method, and of these 151, or less than three per thousand, have died of hydrophobia. CHARLES ACHARD and MAURICE PIETTRE: Researches on the proteins of the cancer cell. The albumin isolated from cancerous tissue has the same composition as serum albumin, but has smaller molecules than the latter. PIERRE LEJAY: A new gravimetric linking of European stations of reference. The establishment of a base at the Pic du Midi Observatory. Details of measurements of the acceleration of gravity (g) at eleven European stations, with the same pair of pendulums. PIERRE LEJAY was elected *Correspondant* for the Section of Geography and Navigation. FRÉDÉRIC MARTY: The structure of the rational fractions and autoprojections of topological coverings. JEAN LE ROUX: The idea of distance. M. PAUL VINCENSINI: Convex bodies admitting a given vectorial domain. PAUL MENTRÉ: Developable inflectional surfaces of complexes of right lines. D. TOÏDZÉ: Integral functions. LUCIEN CHADENSON: The representation of a group of operators in Hilbert space. JEAN THOUVENIN: The application of photoelasticity to the study of shocks. An application of the Séguin-Labarthe ultra-cinematograph taking 4,000 photographs a second. Four of the films obtained are reproduced. E. BARRILLON and CH. CHARTIER: The flow in the mass of a fluid round an obstacle in the form of a house resting on the ground. An experimental study, the results of which are shown in three diagrams. F. ROCHEFORT and JEAN VILLEY: A new type of aviation motor. A method of pulverising fuels such as gas oil, giving homogeneous mixtures. The method has been applied successfully to a 200 horse-power six cylinder aviation motor. BERNARD KWAL: The difficulty concerning the existence of the infinite energy of radiation at the absolute zero in quantic electrodynamics. PIERRE JACQUINOT and TSAÏ BELLING: Measurements of the Paschen-Back effect with the Bellevue electromagnet fitted with supplementary coils. With the additional coils the magnetic field was raised to 65,800 gauss. The line 5789–90 showed a considerable Paschen-Back effect: the displacement of the central component was nearly 0·2 A. and the separation of the violet component reached 0·29 A. E. VELLINGER and J. D. HERRENSCHMIDT: The critical temperature of solution of mineral oils. An application of the method of Chavannes and Simon to the study of the changes brought about in mineral oils by refining. ANDRÉ KLING and MAURICE ROUILLY: Some derivatives given by the action of phosgene, methyl chloroformate, mono-, di- and trichlormethyl chloroformates on cholesterol. ANDRÉ DEMAY: The Carboniferous age of the Guéret granite and on the facies of contact metamorphism of the Dinantian grits and tufas of the Puy-de-Dôme and of Creuse. DANIEL BARBIER, DANIEL CHALONGE and ETIENNE VASSY: Measurement of the reduced thickness of atmospheric ozone during the polar winter. The authors have developed a spectroscopic method making use of stellar spectra for determining the ozone, and give the results obtained at Abisko (lat. 68° 20′ N.). PIERRE MARTENS: Direct fertilisation and cross-fertilisation in *Parnassia palustris*. PIERRE LESAGE: Acquired and inherited precocity at Rennes and Algiers in 1935. TONY BALLU: The determination of the resistance of a soil to the passage of agricultural tools. DAVID BROUN and H. SCHEINER: The physico-chemical state of the adrenaline hormone in the blood. MLLE. LAÏA OLSZYCKA: The quantitative study of the phenomena of synergy. The potentialisation of the hypnotic action in the mouse. ANATOLE ROGOZINSKI and BARUCH SAMUEL LEVIN: The action and hæmolytic dose of the X-rays.

LENINGRAD

Academy of Sciences (*C.R.*, 3, No. 3, 1935). I. VINOGRADOV: Fractional terms of polynomials and of other functions. N. SLIOZKIN: Streamlining a gas-filled envelope by a flat stream of ideal fluid. M. MARKOV: Permutations in a vector model of an atom. J. MENDELEJEV: The abnormal density of water in the depths of Lake Baikal. A. RABINOVITSCH, P. VASILJEV and T. GATOVSKAJA: The Donnan effect in ultra-filtration of colloidal solutions. A. PARSCHIN: Influence of paraphenyldiamine on the chemical processes in striped muscles. V. SILBERMINTZ: Occurrence of vanadium in fossil coals. E. KORIDALIN and S. MASARSKIJ: Seismographic prospecting by the method of reflected waves. I. KOROBKOV: The presence in southern Daghestan of strata analogous to the Priabona strata. A. KOLMOGOROV: Deviations from Hardy's formula in partial isolation. P. NIKITIN: The Miocene seed flora near the town of Tomsk, Siberia. A. SEVERCOV: Recapitulation: morphological and histological. A. BOIKO: Septicæmia of bees and its causative agent.

MELBOURNE

Royal Society of Victoria, October 10. B. J. GRIEVE: (1) The brown rot disease of potatoes in Victoria—the bacterial organism responsible for 'brown rot' or 'sore eye' of potatoes in Victoria is described and identified as a strain of *Bacterium solanacearum*, Smith. The reasons for regarding the organism isolated as a strain are as follows: (*a*) there is little or no production of a brown water-soluble pigment in colonies on agar plates; (*b*) there is a slight production of acid in glucose; (*c*) no infection can be obtained when the organism is cross inoculated to tobacco. Earlier reports on the occurrence of the disease and on the organism concerned in Australia are critically discussed. (2) Occurrence of *Bacillus carotovorus*, Jones, causing a soft rot of *Iris germanica* in Victoria. An organism was isolated and its pathogenicity established. Cultural and physiological characters of the organism were found to agree essentially with those of *Bacillus carotovorous*, Jones. The three differences recorded in physiological reactions, namely, non-liquefaction of gelatine, failure to produce indol and absence of definite diastatic reaction, are within the accepted variation of *Bacillus carotovorus*.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Monday, December 2

BRITISH MUSEUM (NATURAL HISTORY), at 11.30.—Dr. Ethelwynn Trewavas: "Oceanic Fishes".*

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—E. Shipton: "The Mount Everest Reconnaissance, 1935".

Tuesday, December 3

BEDFORD COLLEGE FOR WOMEN, at 5.15.—Prof. W. Wilson: "Indeterminacy in the Physical World".*

CHADWICK PUBLIC LECTURE, at 8.15.—(in Inner Temple Hall, E.C.4).—Dr. R. C. Maxwell: "Town Planning and the Housing Act".*

Wednesday, December 4

WARBURG INSTITUTE, at 5.30.—Dr. A. Mawer: "The Position of Place-names in Linguistic Studies" (succeeding lectures on December 11 and 13).*

ROYAL SOCIETY OF ARTS, at 8.—Prof. G. T. R. Hill: "Travel in the Stratosphere".

Thursday, December 5

QUEEN MARY COLLEGE, at 5.30.—Prof. H. H. Read: "The North-West Highlands of Scotland".*

Friday, December 6

PHYSICAL SOCIETY, at 5.—(at the Imperial College of Science and Technology).—Prof. Charles Fabry: "Vision in Optical Instruments" (Thomas Young Oration).

BROWN INSTITUTION (UNIVERSITY OF LONDON), at 5.30.—(at the London School of Hygiene and Tropical Medicine, W.C.1).—Prof. F. W. Twort: "Modern Views on the Bacteriolytic Agents and their Relation to Viruses" (succeeding lectures on December 9, 10, 11 and 12).*

BEDSON CLUB (ARMSTRONG COLLEGE, NEWCASTLE-UPON-TYNE), at 6.30.—Prof. J. E. Lennard-Jones: "Modern Theories of Valency". (Bedson Lecture.)

GEOLOGISTS' ASSOCIATION, at 7.30.—W. P. D. Stebbing: "From the Vaal to the Albert Nyanza: a Sketch of the Physiography and Geology along the Line of the Country Traversed".

Saturday, December 7

ROYAL INSTITUTION, at 3.—R. L. Hobson: "Chinese Porcelain".

GILBERT WHITE FELLOWSHIP, at 3.—(at the Art-Workers' Guild, 6 Queen Square, Southampton Row, W.C.).—Prof. F. E. Weiss: "A Visit to the Big Trees of Canada and California" (Presidential Address).

BRITISH INSTITUTE OF RADIOLOGY, December 5–6.—Annual Congress to be held in the Central Hall, Westminster, S.W.1.

December 5.—Dr. C. W. C. Kaye: "Forty Years of Radiology (1895–1935): A Review and Some Reminiscences" (Silvanus Thompson Memorial Lecture).

December 6.—Dr. G. Harrison Orton: "Calcium Changes and their Importance in Diagnostic Radiology" (Mackenzie Davidson Memorial Lecture).

Humanistic Science

IN recent years increasing recognition has been given to the contacts of science with social problems and public affairs. Many scientific workers, particularly those of the younger generation, are no longer content to be regarded as hewers of wood and drawers of water whose special knowledge is considered to disqualify them for administrative posts. They know how science enters into every department of national life or international undertaking, and they claim to be entrusted with a reasonable share of responsible control of the forces created by them. At present these new powers seem to be out of hand in their effects upon production and also their applications to destruction. Such disappointing results are not, however, essential consequences of scientific progress, but are due to the much slower rate of advance of man's ethical and spiritual nature.

During the past few years, several leading men of science have dealt with these aspects of modern life, and over and over again we have stressed in these columns the duty of scientific workers to assist in securing intelligent recognition of scientific values in civilised communities. During the five years of his presidency of the Royal Society, and particularly in his presidential address to the British Association in 1933, Sir Frederick Gowland Hopkins has on a number of occasions referred to this wider outlook of science, in which responsibilities as citizens are combined with the pursuit of natural knowledge. In his valedictory address to the Royal Society on November 30, extracts from which appear elsewhere in this issue, he deals with the subject again, and supplements the general theme by very appropriately describing the benefits to humanity of scientific investigations of nutrition and food production.

Sir Frederick Hopkins points out that "The current interest in the subject of the national food supply and in right feeding is doubtless largely due to the awakening of the public conscience to this and other kindred social responsibilities ; but it has also been stimulated, I think, by the nature of the results which scientific studies during the last twenty years have revealed". In this department of science, at any rate, and in the control and conquest of disease, the knowledge gained has been of unqualified benefit to humanity. Whatever may be thought of modern progress, and however much some people may look back with longing eyes to the days when disease, born in filth and ignorance, stalked through the land practically unchecked, they must acknowledge that science has provided the means of reducing suffering and death due to disease, and of improving our social heritage.

This mastery over the powers—mostly microscopic—which continually tend to destroy mankind, has been obtained by scientific inquiry, the spirit of which has had a greater influence than is commonly understood. As Sir Frederick Hopkins said in his address, "History itself shows that it is wrong to deny ethical influence, even if it be indirect, to the scientific spirit. While, for example, the earlier stages of the Renaissance enriched men's minds by restoring to them the literary and philosophical heritage of antiquity, we all know that not until later, when the awakening scientific spirit demanded a courageous inquiry into the actual facts of Nature, did human thought begin its release from the shackles of authority and traditional dogma."

The intellectual expansion brought about by the workings of this spirit, together with the sense of justice which resulted from knowledge of the existence and permanence of law in Nature, profoundly influenced human thought, and resulted in social changes which had the widest civilising effects. In spite of these ethical aspects, there are some who still regard the humanities as belonging essentially to polite scholarship or classical learning and having an antipathetic relation to science. When Greek was introduced into the curriculum of schools with the Renaissance movement of the fifteenth century, it was because the scholars of that period were eager for the new light which the language could reveal. Humanism then meant the substitution of new teaching for old, and its followers aimed at moulding the nature of man as a citizen and an active member of the State rather than at continuing the studies of doctrines relating to the next world upon which the attention of teachers had been concentrated for a thousand years.

The foundation of the Royal Society in the seventeenth century was a natural development of the revolt against scholasticism and theological authority which had for ages discouraged independent thought. The spirit of the new movement is represented by the Horatian motto, *Nullius in verba*, chosen by Evelyn for the Society and signifying "not bound by the words of any man"; and this intention, as the Earl of Athlone remarked at the anniversary dinner on November 30, was expressed by an even older motto: "Prove all things; hold fast that which is good". The object of the Society was the promotion of natural knowledge through observation and experiment as distinct from supernatural knowledge obtained through revelation. This new experimental philosophy was the method of inquiry which distinguished humanism of that epoch from medieval obscurantism, and its introduction was typical of progressive thought and action just as science is the humanism of to-day.

Science has not only emancipated human thought from the bondage of traditional authority, but also, through the concept of evolution onward and upward, has provided mankind with a new philosophy of life. It embodies, as Huxley pointed out long ago, the evolution of social ethics, and in this development through the right use of knowledge, scientific workers should take an effective part in shaping human destiny.

Culture and Peoples of Ireland

Prehistoric Man in Ireland

By Cecil P. Martin. Pp. xi+184+11 plates. (London: Macmillan and Co., Ltd., 1935.) 21*s*. net.

ALL who occupy themselves seriously with the baffling problems of prehistoric Ireland will welcome this book with open arms. It is just what they have been longing for, ever since science undertook to dispel the accumulated rubbish of charlatanism. It is not Dr. Martin's fault that the first reading of his work induces a slight sense of disappointment: it is because, with all the energy and industry which he has brought to bear upon his undertaking, the actual amount of material which he has found available is comparatively small. But he has made the best possible use of it, and has been enabled to lay a foundation which, with a little underpinning to be supplied by future discoveries, will bear the weight of years of research to come.

Ireland occupies a singular position among the countries of Europe. The Romans left her alone; they saw no advantage to be gained by occupying an island inhabited, as rightly or wrongly they believed, by cannibalistic savages. The country thus escaped Latinisation, and it afforded an extra-imperial refuge first for druids, and later for Christians, driven from their homes by persecution. The former introduced a literary tradition; the latter introduced a religion. But except for early invaders, tempted by the reputation of the auriferous gravels of the Wicklow rivers, and these refugees, the country stood aside, as the stream of culture flowed on elsewhere in the Continent. There is a biological 'lag' in the country, as is well known to biologists: these conditions produced a similar cultural lag, expressing itself in a self-centred absorption in domestic affairs, and an exaggerated appreciation of their importance. In the literature, developed first by druid refugees and afterwards by Christian scribes and teachers, there was enshrined a mass of contradictory legends, of very varying dates, about mysterious peoples called Nemedians, Fir Bolg, and so on, who had successively occupied the country:

notwithstanding which, these legends were overlaid with the boast that Ireland was the typical Celtic country, which had maintained Celtic blood, traditions and culture, undefiled and uncontaminated. This is the notion held by the layman even yet.

But archæologists are digging, palæobotanists are making an intensive study of peat-bog pollenation, 'higher critics' are riddling the documents which report these ancient fables, and Dr. Martin is applying his callipers to every ancient skull, recorded or unrecorded, that he can find in the country; and whether the layman likes it or not, he must awake, sooner or later, from his dreams, to a world of unpicturesque realities.

Preliminary chapters tell, clearly and succinctly, of chronological and craniological methods in modern research; and then the author gets to business. He begins with a few modern skulls, from five different districts in the country, which show, so far as they go, that the proportion of long-headedness increases as we proceed westward. Dr. Martin recognises environmental, as well as racial, causes as operating to produce this result. Next he gives us a brief résumé of early research in Irish ethnology, and of the endeavours made by Wilde and others to correlate the evidence of craniology, so far as it was understood in their time, with the invasion-traditions referred to above. Then comes a most valuable series of chapters, describing the craniological material from successive stages of Irish history—from the caves, the 25-ft. raised beach, the megalithic monuments, the later Bronze Age, the Iron Age, the Crannogs, the Early Christian period, and the time of the Norse invaders. In the first of these chapters, the author is not inclined to reject summarily, on the ground of more recent research, the authenticity of the Kilgreany man (or rather woman) as a true cave-dweller. The evidence from the raised beach and the later sandhill settlements is of the scantiest; but, such as it is, it points to a race "of low stature, with very long, narrow, and high skulls".

The Megalithic people seem to be variants of the same stock, but not necessarily direct descendants of their shore-dwelling predecessors; but the later Bronze Age introduces us to a definitely distinct race, thereby confirming the testimony which archæology has been voicing with a growing insistence, to the effect that there was an abrupt interruption in cultural development about the middle of the Bronze Age. Unfortunately, the critical problems relating to the introduction of the Iron culture are not yet illuminated by osteological material; but certainly the later evidence shows that in early Christian times races were as inextricably mixed in Ireland as they are to-day. One by one the shadows of the 'Celtic twilight' are vanishing, in the cold clear light of common day.

The book is well printed, and excellently illustrated. There are a number of misprints here and there in the text which it might be well to correct in a later edition; but these trifles apart, we have nothing but praise for the book and gratitude for its author.

Band-Spectra and Molecular Structure

The Optical Basis of the Theory of Valency By Dr. R. de L. Kronig. (Cambridge Series of Physical Chemistry.) Pp. x+246. (Cambridge: At the University Press, 1935.) 16*s*. net.

THIS book is highly recommended to those interested in the determination of molecular structure by physical methods. Here a wide range of material will be found presented in a simple but authoritative manner. A noticeable feature is that each chapter is practically complete in itself; and this makes the book very readable.

The first chapter is short, and serves as introduction. The second explains how the size and shape of molecules can be determined from experiments on the scattering of X-rays and electrons. It is unfortunate that the very recent work of Brockway and Sutton on the diffraction of electrons by the chloro-methanes appeared too late to be included in this chapter. Apparently only departures of the order of a degree or two can occur from the tetrahedral angle, in contrast with earlier conclusions based on X-ray evidence that they could be of the order ten degrees. The third chapter gives the usual account of the Periodic system, but has in addition a useful section on the charge, electron configuration and the size of ions. The fourth and fifth chapters are very good. They are the central portions of the book and represent the happy medium between an elaborate treatise on band-spectra and the few pages that are often considered sufficient for the subject. In them an account is given of the determination of molecular structure from band-spectra in the visible and infra-red regions of the spectrum. The significance of normal modes and force constants

is clearly explained and illustrated by numerous examples. The sixth and last chapter is also practically complete in itself, and deals with optical and thermal dissociation of molecules. This chapter is the lazy man's ideal, for it is so well illustrated with diagrams that there is scarcely any need to read the text.

Two minor criticisms may be levelled against the book, but of these perhaps the second is merely a prejudice on the part of the reviewer. The first concerns the title. One is not quite sure what to expect from "The Optical Basis of the Theory of Valency", but surely it is reasonable to hope for more than a very occasional reference to valency. The difficulty is of course appreciated. Obviously the best title is "Band-spectra and Molecular Structure", but unluckily this has already been used by Dr. Kronig for his earlier book. However, since more than half the book is covered by chapters beginning "Band-spectra and Chemical Binding", this itself would not have made a bad title. Our second criticism is that we consider a separate chapter should have been given to theories of valency based on quantum mechanics. Certainly, these are no appendages to normal modes and band-spectra of polyatomic molecules, as they would appear from the book. We would have liked a fuller explanation of the Slater-Pauling theory of directed valency, and to have heard something of Mulliken's bonding, anti-bonding and non-bonding electrons.

This is one of the easier books to read, but it contains a great deal of information that is not easily digested. The style is clear and very much to the point, and the reader is carried swiftly but safely over many waters and through many rapids. As one now expects in any book by Dr. Kronig, the bibliography is most complete and the index good. There are half a dozen excellent plates and numerous well-drawn figures. W. G. P.

Faith and Fact

Science and the Supernatural

A Correspondence between Arnold Lunn and Prof. J. B. S. Haldane. Pp. vii + 412. (London: Eyre and Spottiswoode, Ltd., 1935.) 10*s.* 6*d.* net.

THE method of controversy by correspondence has this advantage, when the correspondence is published in book form, that there is something very entertaining for the reader, who is in the happy position of a person watching a fencing bout or a game of billiards. But what such a book gains in entertainment value it may lose in other directions; it may, for example, be so discursive in method that it gets nowhere—or at least not nearly so far as the reader thinks he has a right to expect. Such indeed is the failing of the very interesting volume before us, wherein Mr. Arnold Lunn and Prof. J. B. S. Haldane engage in conflict for our edification.

The discursiveness, it is to be feared, is to be attributed very largely to the challenger—Mr. Lunn—who conveys the impression (like a bad chess-player) of not having laid his plans, with the result that the argument wanders like a lost child. For example, as early as p. 30, he makes the challenging and important statement that "We can prove that God exists by pure reason without entering a laboratory or consulting modern astronomers". In other words, he says (it is the beginning of all orthodox apologetic) that there are convincing metaphysical arguments for the existence of God. This is an important point if you are arguing about science and the supernatural. But having opened so well, Mr. Lunn does not proceed along these lines. On the contrary, he has to be urged repeatedly by his opponent to expound these metaphysical proofs. In the end, it is Prof. Haldane who, on p. 169, outlines the proofs and proceeds to examine them himself; and it is not until seven months and several other letters have passed that Mr. Lunn, now on p. 254, proceeds to answer Prof. Haldane's criticisms.

Turning towards the end of the book (p. 352), we find Mr. Lunn's explanation of this apparent reluctance to come to close quarters:

"You introduced St. Thomas's metaphysical arguments, but apart from this digression I have made no attempt to develop the traditional arguments in defence of Christian theism, for I do not think we have yet reached that stage in the debate in which it is profitable to pass from a discussion of the existence to a discussion of the nature of God."

This looks like a belated justification of the course which the argument has taken, composed after the event. Prof. Haldane's examination of Aquinas's arguments would scarcely have been introduced had not the question of the metaphysical proofs of God's existence been already raised by Mr. Lunn himself at the outset. To term it a "digression" seems strange.

In this same examination of the course of the argument, Mr. Lunn observes that the

correspondence started "by debating whether the Christian approach to truth was more scientific, or, as you think, less scientific than your own approach". This also was a very important question, but is best discussed not, as Mr. Lunn discusses it, by accusing scientific men of scepticism and intolerance, but by making a serious examination of scientific method, inquiring how its 'abstractness' hinders contact with reality, and whether it can deliver qualitative, as contrasted with quantitative, judgments. All this is legitimate material for discussion, and is really of much more importance than the alleged shortcomings of scientific workers, who do not claim to be any less human than theologians.

A great deal of attention is devoted by Mr. Lunn to what he terms the "physical" (as contrasted with the "metaphysical") proofs of the existence of God. This involves an attack on Darwinism, since this tends to make life self-explanatory, and also an examination of the 'miraculous' cures of Lourdes and the results of psychical research. The attack on Darwinism, based largely on the theories of Berg, elicits what appear to be some convincing rejoinders from Prof. Haldane, who asserts that we can no more go behind Darwin in biology than we can behind Dalton in physics and chemistry, or Harvey in physiology—though this, of course, does not involve the last word having been said in any of those spheres by any of the authorities named. As for Lourdes, Prof. Haldane is not satisfied of the miraculousness of any of the cures, real or alleged. There is the question of diagnosis, of the habit of skin diseases of clearing up rapidly, of the results of hypnosis, and so on. It is in fact impossible to say that a cause lies outside Nature until the whole of Nature has been explored.

After all, as Prof. Haldane points out, evolution is a minor question, and not worth the amount of space devoted to it here to the exclusion of more important topics such as "how a perfectly good and almighty creator could have made a world containing so much evil". It is a pity that Mr. Lunn definitely declined to tackle that question on the ground that there was now no space—the space having been squandered by himself on comparative trivialities and irrelevances.

"Our standards of intellectual valuation are so different", writes Prof. Haldane at the end, "that we found it hard to get to grips". The trouble is that the two disputants are not equally matched. Mr. Arnold Lunn, though a clever controversialist, is not in the religious sphere the equivalent of Prof. Haldane in the scientific sphere.

J. C. HARDWICK.

Natural Philosophy in the Ninth Century

Encyclopædia of Philosophical and Natural Sciences as taught in Baghdad about A.D. 817, or Book of Treasures

By Job of Edessa. Syriac Text edited and translated with a Critical Apparatus by A. Mingana. (Vol. 1 of Woodbrooke Scientific Publications.) Pp. xlviii+470. (Cambridge: W. Heffer and Sons, Ltd., 1935.) 42*s*. net.

JOB of Edessa, "Job the Spotted", or Ayyūb ar-Ruhāwī, was born in Edessa, possibly about A.D. 760, and seems to have survived until about A.D. 835. He was a member of the Nestorian church, and has achieved fame as one of the earliest and most prolific translators of Aristotle and Galen into an oriental language. Besides translations, he wrote many original works, of which only two are extant, namely, a treatise on canine hydrophobia, and the "Book of Treasures" which Dr. Mingana has here edited and translated from a manuscript—the sole copy in a European library—in his own collection. The "Book of Treasures", probably written about A.D. 817, is a kind of philosophical and scientific encyclopædia; it affords a clear perspective of the intellectual background of Bagdad under Hārūn ar-Rashīd and Al-Ma'mūn, and shows that, while Aristotle and other Greek writers were regarded as the great masters of secular knowledge, independence of thought was more prevalent than might be expected.

The scope of the book is wide; it includes metaphysics, theology, psychology, biology, anatomy, physiology, medicine, chemistry, physics, music, mathematics and astronomy. Among points of special interest are Job's rejection of astrology, his development of the idea of the elemental origin of the universe and of the different bodies comprising it, his denial of a material hell, and his explanation of the cipher—an arithmetical sign which reached Bagdad during his lifetime. The cipher, according to Job, is a circular link between number nine and number one, causing numbering in general to proceed in a succession of cycles between one and nine; the figure of the cipher is a circle made by linking the forefinger and the thumb together, and its

very shape represents the 'emptiness' of its unattached value.

In general, the book conveys the impression that its author was a man of vigorous and balanced mind, though, like the vast majority of his contemporaries, he shows astonishing credulity in many directions, and is anxious to leave nothing unexplained. Thus, he says that the functional ground for the non-existence of hair on the human forehead and cheek-bones "is to prevent dust, sand and other things which happen to fall on those places, from getting a footing there, and thus impeding vision"; further asserting that animals walk on all fours because, if their posture were upright, they could not be of much use as beasts of burden. On the other hand, he correctly explains the appearance of the Milky Way, and has a reasonable, even though incorrect, hypothesis to account for the salinity of sea-water.

Whether right or wrong, however, credulous or sceptical, Job is always interesting and lively, and his treatise is worth the attention of both the general reader and the historian of science. Dr. Mingana is to be thanked for having rendered it accessible, and for the valuable notes and commentaries which he has added. Unfortunately, there is no index, though the want is partly supplied by a fairly full table of contents.

E. J. HOLMYARD.

Experimental Botany

Botany as an Experimental Science in Laboratory and Garden

By Dr. Lilian J. Clarke. Pp. xvi+138+9 plates. (London: Oxford University Press, 1935.) 6s. net.

LILIAN J. CLARKE entered on her career as science mistress at James Allen's Girls' School, Dulwich, in 1896, at a time when science was still the Cinderella of the curriculum; long before her retirement in 1926 she had raised its status to such a degree that much of the renown of the school was based upon the results of its teaching of science. At the outset there was no laboratory, no apparatus, no available ground, no money. Within five years, however, a small general laboratory had been built, a few order beds established in the school gardens, while the pupils were already taking the highest places in botanical examinations in competition with other schools in London and elsewhere.

The earliest teaching was on more or less orthodox lines, and matriculation candidates spent much time on elaborate section cutting and work with the compound microscope. Gradually this was all changed, and individual experimental work became the objective for each pupil. Increasing stress was laid upon plant physiology, every step being elucidated by experimental work, usually of the most simple character. Plant nutrition was studied by means of water cultures, with such success that many generations of a single species were grown over periods of years, in spite of untold difficulties arising from the shortness of school terms.

Eventually more adequate accommodation was provided in the form of a science block with separate laboratories for botany and other branches of science. At the same time the development of the botany gardens proceeded steadily. For years no grant was forthcoming, all the plants being provided by the girls and mistresses and all the work done voluntarily by the girls in their spare time. At last, by dint of sheer enthusiasm and persistence on the part of Dr. Clarke, the value of the gardens for teaching purposes was recognised and an annual grant, which is still continued, was given by the Board of Education. The upkeep of the gardens is still by voluntary work, and the layout of the lawn, wood, ponds, sand dune, heath and other sections is such as to beautify the grounds as well as providing invaluable training in many aspects of botany.

The record of thirty years' struggle and progress has been written by Dr. Clarke, who completed the text, but did not live to see it through the press. She has given accounts of the many experiments with the details of technique which are apparently so insignificant, but which make or mar the success of the work. A great feature is made of the recording and comparison of results year after year, which has provided an accumulation of valuable data of which it has only been possible to give some indication. The book should prove a mine of information for teachers, and can equally well be used by the students themselves, as it is full of ideas and suggestions which stimulate the imagination and encourage independent investigation. As a textbook it is unique, and as a record of progress perhaps only those who were among Dr. Clarke's earliest pupils can appreciate fully the greatness of the achievement.

W. E. B.

A Text-Book of Organic Chemistry: Historical, Structural and Economic

By Prof. John Read. (Bell's Natural Science Series Second edition. Pp. xiv+703. (London: G. Bell and Sons, Ltd., 1935.) 12*s.* 6*d.* net.

PROF. READ'S textbook differs from many others on organic chemistry by its insistence on the importance of a knowledge of the early development of the subject, so that the student is enabled to follow the growth of the science from very ancient days to the present time. The theme has been presented in most attractive fashion by including in the text quotations of famous passages from documents of historical interest. Thus the problems, which were faced successively by Wöhler, Liebig, Kekulé, Pasteur, le Bel and van 't Hoff are set vividly before the reader. The rapidity with which chemical theory has been developed is most strikingly illustrated by a footnote on p. 276 from which we learn that Chevreul, who was born before the theory of phlogiston was abandoned, survived into the era of the asymmetric atom, the ionic hypothesis and synthetic indigo.

The historical aspect of the subject, however, has been by no means overstressed. The author has kept in mind not only the academic but also the industrial and economic interest, whilst biochemical discoveries have also received attention. Thus the chapter on carbohydrates includes an account of the economic aspect of sugar manufacture and a summary of the main features of interest in connexion with the various cellulose industries. The author does not discuss the actual structure of starch and cellulose, although a formula is given for the starch unit. It is rather surprising to find that the pyranose ring formulæ, which are so helpful to the student of stereochemistry, have not been adopted. Indeed, the chapter on stereochemistry might well have been expanded to include an account of some of the numerous types of molecular dissymmetry which are not associated with the asymmetric atom.

Turning to the polycyclic and heterocyclic compounds, we find useful summaries of the properties and composition of explosives, dyestuffs, drugs, perfumes, photographic chemicals and alkaloids, while a new chapter deals with the hormones and vitamins and another with the electronic theory of valency. The book provides a useful introduction to the subject, and should help the beginner to realise not only the practical value of certain organic products but also the important contribution which the organic chemist has made to the building up of chemical theory.

Paläohistologie der Pflanze:

Grundzüge einer Gewebelehre über fossile Pflanzen. Von Dr. Elise Hofmann. Pp. vii+308. (Wien und Berlin: Julius Springer, 1934.) 25.20 gold marks.

THE author presents a brief review of the anatomical structure of fossil plants, with a concluding section surveying the history of their various tissues and cell types. The descriptions are illustrated by numerous figures, some of which are original. Certain topics, such as the structure of fossil cuticles, receive fuller consideration than in any earlier book of the same character, but other subjects, such as the structure of the elements described by palæobotanists as phloem, receive a rather superficial treatment. In several sections the author seems to have taken all her information from recent papers, to the neglect of older work in which more complete descriptions are to be found; but she gives references to all the more important papers.

The value of the work is difficult to estimate. It will probably be of considerable use to Continental students, who have often underestimated the value of anatomical work in relation to morphology and taxonomy. When compared with the English works which deal with the structure of fossil plants, it often seems rather poor, but on the other hand it covers a wide field and gives an adequate introduction to some of the modern aspects of palæobotanical research. It is not entirely free from mistakes, both in the naming of the specimens figured and in the text.

Erdöl-Muttersubstanz:

Beiträge zu dieser Frage. Von Dr. F. E. Hecht, Prof. Dr. K. Krejci-Graf, Prof. Dr. R. Potonié, Prof. Dr. H. Steinbrecher, Dr. A. Treibs, Dr. E. Wasmund, Dr. Dora Wolansky. (Schriften aus dem Gebiet der Brennstoff-Geologie, herausgegeben von Prof. Dr. Otto Stutzer, Heft 10.) Pp. vi+181. (Stuttgart: Ferdinand Enke, 1935.) 17 gold marks.

A VALUABLE collection of essays on the vexed question of petroleum origin has recently been made available through the good offices of Prof. Otto Stutzer. The collection includes articles by well-known chemists, geologists and hydrologists. Dr. Erich Wasmund gives his opinion as to the origin of adipocere ('corpse wax') and also advances the theory that anærobic anabitumen bacteria can also originate in bitumen. Dr. Karl Krejci-Graf discusses the varied theories of origin of bituminous sediment, and projects interesting and novel conclusions for the attention of the reader. Dr. Hecht traces the chemical history of organic substance in the sea from the moment of death until final fossilisation and entombment. Dr. Treibs first reviews the works of J. E. Hackford and E. Berl on the transformation of plant substance, especially carbohydrates into oil, and then in his contentions that porphyrines are contained in petroleum derived from chlorophyll and hæmin, and that a higher formation temperature than 200°C. is out of the question for petroleum, shows that he differs from both. Prof. R. Potonié reports the results of geochemical investigations of sapropel from the Unterrücker Lake near Prenzlau and the Sakrower Lake near Potsdam. Prof. Steinbrecher emphasises the chemists' proved point of view that petroleum normally found in oilfields is not high temperature petroleum, since it contains constituents which would decompose at high temperatures. Finally, Dr. Dora Wolansky summarises such views as have appeared in Russian literature on petroleum origin, thereby giving a synopsis of valuable ideas which in their original form are incomprehensible or inaccessible to the majority of people.

Electricity in Poultry Farming

By C. A. Cameron Brown. Pp. 73+12 plates. (Oxford: Institute for Research in Agricultural Engineering, 1935.) 2*s*.

EVERYONE who is interested in poultry farming should read this book. It is written to help the average farm worked by its owner. The author has not in view the large 'luxury farm', worked sometimes altogether by electricity, the true economic value of which it is difficult to estimate. In this book the facts relating to the use of electricity on poultry farms in many different parts of the country are given, together with the work done by research institutes. Lancashire and Yorkshire are very favourably situated, since farmers can buy electricity at ½–1*d*. per unit. In districts where the cost is 1¼*d*. the user has to be economical in its use. All those consulted agree that there is a distinct saving in labour, a gain in cleanliness, safety from fire and exactness of operation by using electricity.

The economies that might be effected by relieving the hen from hatching eggs and brooding chicks and keeping it to its irreplaceable duty of laying eggs has been recognised from the earliest times, particularly by the Egyptians and Chinese. The author describes many types of incubators and gives the relative prices of hot-air machines when worked with oil and with electricity. He states that there is now no question about the technical success of electrical methods in poultry farming. Preston Corporation supplies 300 poultry farms with electricity, the average consumption of each being 7,000 units, and rapid developments are taking place in other areas.

Introduction to Electric Transients

By Prof. B. Kurtz and Prof. G. F. Corcoran. Pp. xv+335. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1935.) 22*s*. 6*d*. net.

As an introduction to the study of the curious effects produced initially when the switch is closed in an electric circuit due to its inductance and capacitance, we can recommend this book. Each type of transient phenomenon is considered from three angles. The student first analyses the problem by means of the principles and laws of physics. It is then discussed mathematically, and this usually involves solving a differential equation. Finally, the solution is illustrated by actual oscillograms. This experimental verification of sometimes quite unexpected mathematical results will greatly encourage the student and show him that theory is sometimes a great help in practical work.

In addition to showing voltage and current waves, power waves and sound waves obtained experimentally are given. The electrical records of three different tones obtained from the same instrument are very instructive. In this case the relatively pure tone has a fundamental frequency of 466 cycles a second, while the other two composite tones have frequencies of 173 and 87 cycles respectively. A useful chapter is given on Heaviside's operational calculus.

Elementary Textbook of Chemistry: with Laboratory Experiments

By John J. Guenther. Pp. xiv+274. (New York: The Macmillan Co., 1934.) 7*s*. 6*d*. net.

THE contents of this book are quite unlike anything a reader would be led to expect from the indication of the title, as ordinarily understood in Great Britain. The preface explains that the volume is designed mainly to meet the needs of schools of nursing, and the curriculum of these, as required in the United States, and to provide a course for presentation in "45 hours of time". The ground covered ranges from basic definitions in chemistry and physics, over elementary theory, formulæ, equations and calculations, and the general chemistry, chiefly of the non-metals, to complex organic substances such as higher fatty acid derivatives, aromatics, carbohydrates and foodstuffs, the organic chemistry occupying roughly one-third of the book. Sufficient attention is given to household, hygienic and everyday applications as to provide, virtually, a treatise on domestic science.

The course is intended to be followed rigidly, in the nature of a drill, and copious lecture and practical experiments are detailed. The amount of matter is remarkable, and might provide material for a year's study. Although the needs of the curriculum might be met, it is difficult to see in what respect the cause of scientific education would be furthered by covering the ground in forty-five hours, the distribution of which is left unspecified. An efficient index covers twenty-four pages. N. M. B.

The Calculus

By Prof. Hans H. Dalaker and Prof. Henry E. Hartig. Third edition. Pp. viii+276. (New York and London: McGraw-Hill Book Co., Inc., 1935.) 12*s*. 6*d*. net.

THE application of the calculus to the problems of engineering and physics has now become so extensive that writers on the subject no longer confine their treatment solely to the purely theoretical side. This is very encouraging, and, in the volume under review, the authors have made a very commendable attempt to combine theory and practice without sacrificing the fundamental principles of the calculus. The course covered is fairly comprehensive. Beginning with the ideas of functionality and limits, the student is led on to differentiation, with its manifold applications; integration up to double and triple integrals; infinite series and expansion; and finally, to a brief outline of differential equations. The principles developed are well illustrated by many fully worked-out problems drawn from mechanics, physics and engineering, and the accompanying diagrams are very clearly produced.

For the student, numerous carefully graded exercises, with answers, are provided both for purposes of drill and in illustration of practical problems. A complete and useful summary of formulæ, curves and integrals is given as a final chapter. The whole text is clearly printed and the book should prove very valuable to the advanced practical student.

Science in Modern Life*

By Sir Frederick Gowland Hopkins, O.M., F.R.S.

Social Responsibilities of Science

OWING to what would seem to be a confusion in thought, the supposed social harms created by science have been vaguely attributed in some not unprejudiced quarters to its own unethical character. General Smuts, on the other hand, holds that among the values gradually recognised by the developing human mind, science ranks with religion and art, and that while to-day religion, art and science are separate values, they may not always remain so. Indeed, he thinks that one of the greatest tasks before the human race will be to link up science with ethical values. It is perhaps not quite easy to follow closely his thought concerning the future extension of the scope of science, but his own assurance that its teaching can be linked up with ethical values is a corrective for some of the accusations from which science is apt to suffer.

Indeed, possible future developments apart, the gap between what science provides for humanity and what are usually spoken of as values in religion, literature and art, has been and is less wide than some assume. History itself shows that it is wrong to deny ethical influence, even if it be indirect, to the scientific spirit. While, for example, the earlier stages of the Renaissance enriched men's minds by restoring to them the literary and philosophical heritage of antiquity, we all know that not until later, when the awakening scientific spirit demanded a courageous inquiry into the actual facts of Nature, did human thought begin its release from the shackles of authority and traditional dogma. This release was surely ethical in its effects. In later times, throughout the years of the Royal Society's existence, the growth of intelligent interest in the material universe was slowly preparing the ground for that last great step in the progress of intellectual freedom which came in the middle years of the last century. The influence of Darwin and Lyell did more, of course, than establish a new outlook for science itself. It re-orientated all thought. It caused heart-searchings where there had been mere complacency in the acceptance of tradition, and its impacts subtly encouraged the growth of that intellectual honesty for which Huxley and others then so nobly fought. The history of those days is familiar enough, but we sometimes forget the debt we owe to them.

It was the influence of science which, more than any other influence, established the idea of progress, replacing as it did a static by an evolving universe, and incidentally a faith that man himself has an inherent capacity for advance. There are not a few to-day who profess to disbelieve in progress; but for the majority it is now a faith ingrained if sometimes only subconsciously held. Evolution, we know, may not at each step tend upwards, but we have reason to believe that in the long run it does, and that in spite of occasional disillusions we may believe in the upward tendencies of mankind. By this faith, hope is fed, human efforts towards betterment are encouraged, and ethical values emerge. The depressing belief that man and the social fabric he has contrived for himself, while so imperfect, are yet incapable of ultimate betterment, was the one excuse for that particular form of professed otherworldliness which from time to time has been an essential part of narrow religious ideals, but which was surely evil in its almost contemptuous indifference to social wrongs and to the urgent problems of this world.

The tendency of late, however, has been not so much to reiterate the theme of science's gifts to the powers of destruction, but rather to urge in a more general sense that scientific workers have not shown sufficient interest in the social implications of their work, or in the public responsibilities of their calling. We have only to look closely into this view as usually expressed to realise that, after all, its basis is vague, and, did it involve any charge against the individual worker, unreal. The individual investigator must realise that, *qua* scientist at least, he has little opportunity for effective action. Commonly he concludes that he will be most useful, even to society, by continuing his chosen work in its proper environment.

It is, I think, impossible not to sympathise with this view. The special endowments acquired by the scientific investigator are not those of a politician or of a missionary. Needless to say, it remains his duty to give his skilled services to the public whenever they are legitimately required and invited, and in so giving them he may do much to promote the interests of science itself.

What seems to be really desirable is some method of closing the gap between the mind and outlook of the publicist and those of the trained scientist. It is a just claim that in a civilisation so largely based on science as that of to-day, the scientist

* From the anniversary address to the Royal Society, delivered on November 30, 1935.

should have more influence on policy than he has hitherto been allowed. Not long ago the gap in question was wide; it is now, I think, lessening. Occasionally at least, modern statesmen do seek scientific guidance, and, I think, know better than they did how rightly to obtain it. But it is time, perhaps, that the building of a bridge should begin on the scientific side of the gap. This is a task for organised scientific effort and the pooling of knowledge.

Problems of Nutrition and a National Food Policy

There is a branch of scientific inquiry which can claim to yield knowledge of unqualified benefit to humanity, and one in which investigators, though inspired by the extreme scientific interest of the problems involved, have, I feel, always had the public importance of their solution in view, and have themselves done their best to encourage the practical applications of the knowledge they have won. I refer to the study of the nutritional needs of the body.

The last two decades have seen a quite remarkable activity in research upon nutritional problems, and it is now even increasing. Publications describing original work upon various aspects of these come from almost every country where science is pursued, and have amounted to many hundreds during the course of each single year. In Great Britain much research on nutrition has been generously endowed, organised and encouraged by our Medical Research Council, and it has received financial support from various other sources. We have begun to follow the example of the United States in founding chairs in dietetics, and emphasis is being placed upon the subject in physiological and biochemical teaching in the universities.

A desirable happening at the present moment is the international approach at Geneva for full discussion of the nutritional problems of the world; for, viewed broadly, the problems are undoubtedly international. On a demand from the representatives of twelve nations including Great Britain and Australia (which has played a leading part in the movement), the health organisations of the League have set machinery in motion for securing full and intimate discussion. Policies concerned respectively with the production, transport, distribution and consumption of foods will all, we may hope, be discussed. They seem to be the very proper business of the League, and if discussion goes deep enough and is frank enough, it may well do no small service to the interests of peace itself.

Many are concerned just now to know the truth concerning the degree and extent of malnutrition as it exists among the less fortunate sections of the community at the present time. They have seen certain desirable steps taken to mitigate whatever may exist, as, for example, the diversion of surplus milk to the schools; but they yet ask how far is an extension of such measures an urgent need of the moment. That underfeeding and ill-feeding exist is sure, but to measure their extent is, for reasons to which I will allude, a task of some difficulty.

We have only to read the successive annual reports from numerous medical officers of health to believe that, in the case of children at least, nutrition, inadequate for one reason or another, exists in various districts to an extent which is far indeed from being negligible. Nevertheless, we have to realise that the numerical data supplied from different centres are based upon varying standards, and the opinions expressed depend to no small degree on the temperament and perhaps on the acuity of individual officers. The difficulty before all concerned is that there is no clear definition of the term 'malnutrition', and no satisfactory objective methods for measuring its degrees. Sir George Newman, formerly Chief Medical Officer to the Ministry of Health, always felt justified in taking an optimistic view concerning the available food supply for children in Great Britain, and he was wont to insist upon the circumstance that though under-nourishment may be due in part to an insufficient quantity of food, it depends also on other factors. "The principal cause," he wrote, "is a body unable to assimilate the food supplied to it." In certain cases this must, of course, be true, but we are entitled to ask whether in many such cases the disability of the body when observed has not followed upon malnutrition at an earlier period. What we know to-day justifies this view.

In any event, the essential question is whether food adequate in quantity and quality is within the reach of all. In the annual report for 1934 issued by the present Chief Medical Officer of the Ministry, it is made clear in a section devoted to the effect of unemployment on national health and dealing with evidence based upon a conjoint investigation by officers of the Ministry and the Board of Education into conditions in certain depressed areas in Durham, that the statistics of actual diseases there do not indicate unfavourable effects of present economic conditions. We may conclude from this, and take comfort from the fact, that malnutrition even in such areas has not been at its severest, but it may be highly deleterious in its ultimate effects when not such as to affect the current statistics of disease. Moreover, full normal nutrition was only claimed for some 70–80 per cent of the children, varying between these figures in different areas, and though, as I have

said, criteria for establishing the existence of subnormal nutrition are not satisfactory, it is difficult to be content with such figures. The Ministry's investigators admit further that in the areas studied the condition of adolescent youths, especially those aged 14–15 years, was found unsatisfactory. These are years when good nutrition is quite especially desirable.

As a measure of the state of health of younger adults at the present time, the results of medical examinations for recruiting are not without importance. The War Office report on the health of the Army for 1933 shows that in that year nearly 38 per cent of the prospective recruits were rejected as unfit. Although, as the report points out, many of these rejections were on account of disabilities which unfitted them for military service in particular, and therefore did not reflect on their general health, yet a glance at the stated reasons for rejection shows that a large proportion of the men suffered from defects which might well be due to faulty nutrition in childhood or adolescence, and a considerable proportion in which it almost certainly contributed to their unfitness.

The current interest in the subject of the national food supply and in right feeding is doubtless largely due to the awakening of the public conscience to this and other kindred social responsibilities; but it has also been stimulated, I think, by the nature of the results which scientific studies during the last twenty years have revealed. They have shown that our nutritional needs are so much more numerous, subtle and specific than was earlier thought, and they have shown how extraordinarily potent and how entirely indispensable material may be, even though consumed in infinitesimal amounts. We know now that a fault in quality may be as deleterious as a failure in quantity. This fact the general public is now rapidly assimilating, though not always to its profit. Indeed, a certain vocal section of the public is (as it has always been) so perverse in its views concerning food that it is almost necessary to remind it that, after all, quantity still counts. We cannot live on vitamins alone! A more intelligent section of the public seems, I notice, to assume with impatience that so much scientific talk about food may lead to individuals being dragooned with respect to what they shall or shall not eat. A self-constituted committee whose propaganda against malnutrition I respect for its wisdom and fairness has appreciated this attitude, and in a recent memorandum made the following wise statement: "certain diet habits must be classed as cultural, and of personal and psychological necessity, and to upset these in the service of protein or vitamin content is to provoke a natural reaction against [the advice that science can legitimately give]". It is, of course, unthinkable that there should be any such dragooning. The intelligent public will learn to apply the newer knowledge of nutrition without discomfort to itself.

The same memorandum says—again wisely—"to a working class housewife with restricted purchasing power, education in food values alone can only add one further problem to an already insoluble series of anxieties and worries". This of course is true, and so long as we see that foods of the right variety are all within her purchasing power, elementary instruction in terms of the foods themselves and not in technical food values will set the housewife on the right path. I am tempted to add that what the English housewife in the poorer classes needs most to be taught is the art of simple but good cooking! It is not beneath the dignity of nutritional science or of administrative policy to take note of the circumstance that in Great Britain, more than in perhaps any other country, is good food ruined, and its nutritional value impaired, by unintelligent treatment in the home.

One last consideration. Is the time yet ripe for the initiation of a comprehensive national food policy: one that will endeavour to adjust production, in a qualitative as well as a quantitative sense, to right consumption, and at the same time organise all the details of distribution on national lines?

I note that those responsible for the contents of that very impressive book entitled "The Next Five Years", which has appeared under the ægis of many influential names, hold that no administrative action less comprehensive than a national policy of the kind in question could deal adequately with existing problems. They suggest that it should now be taken in hand. Others have urged that, apart from the almost prohibitive magnitude of effort the policy would require, it is one which should await the arrival of more knowledge. The latter suggestion has, I think, but little point. There is doubtless much more scientific knowledge to be gained about nutrition and food production, but we know enough to guide administration on to the right lines.

More to be thought of perhaps is the fact that if we take a long range view, any policy concerned with food production must ultimately, if it is to be ideal, become part of a world policy. At Geneva, Mr. Bennett, speaking of such a world policy, said that its aim would be to "marry agriculture to health". Such a marriage, if ever properly consummated, would greatly profit the world. The interests of both partners must be equally guarded, however, in the marriage contract. In Great Britain, one may venture to say, the first mentioned is at present receiving preferential treatment.

The Advance of Herring Research

ON April 21, 1881, Prof. T. H. Huxley delivered a striking lecture at Norwich on the herring, during the National Fishery Exhibition held there. Reference to the text of that lecture (published in full in the issue of NATURE of April 28, 1881) shows that Huxley made the following statement: ". . . And all kinds of real knowledge and insight into the facts of nature do so bear upon one another and turn out in strange ways practically helpful, that I propose to pour out my scientific budget, in the hope that something more may come of it than the gratification of intelligent curiosity". Fifty-four years later, in the same city of Norwich, during the recent meeting of the British Association, the members of Section D (Zoology) listened to a symposium on the herring problem which demonstrated beyond any doubt the truth of Huxley's assertion, and realised his hope. Indeed, the symposium can best be described as an account of current investigations for the express purpose of rendering direct assistance to the commercial herring industry, not only by predicting the quantity and quality of the fish likely to be available during an impending season, but also by stating where and when nets should be set in order to secure the best possible catches. That is to say, the 'problem' with which the symposium really dealt was the entirely practical one of how to aid industry by scientific research.

The four papers of the symposium were read by Mr. E. Ford, Dr. W. C. Hodgson, Prof. A. C. Hardy and Mr. R. S. Wimpenny, in the order named. The first paper confirmed and extended Huxley's view that practised eyes distinguish local breeds of herring, dealing in particular with the study of vertebral variation as evidence in this connexion. It was shown that although the simple count of the total number of vertebræ in a herring falls far short of the ideal specification of so important an organ of the body as the backbone, its use as a statistical character in population studies has proved of very material assistance in acquiring knowledge of the life and movements of the different local forms of herring within their own limited territories of the sea. Using the average number of vertebræ for a sample of herrings as a statistical estimate of the average for the population from which the sample was drawn, real population differences have been demonstrated by comparing sample with sample: and by considering the results in conjunction with corresponding differences in other characters, the 'ground-plan', as it were, of the complex of local forms by which the species *Clupea harengus* is represented has gradually revealed itself. The reliability of this work remains unaffected by the fact that scientific opinion is at present divided as to the precise nature of a local form of herring, and the parts played by heredity and environment in preserving its continuity from generation to generation.

Having learned the essential facts in the life-history of the particular local form with which he is concerned, an investigator may then inquire into the factors which determine the success or failure of the commercial fisheries based on that local form. Important researches of this kind in connexion with the great East Anglian drift-net fishery in the Southern North Sea formed the subject of the second paper in the symposium. The sharp and irregular fluctuation in the annual yield of the fishery is partly accounted for by the natural waxing and waning in numerical strength of the fishable stock. This, in its turn, is a sequel to the unequal production of young from year to year. Reliable evidence, direct or indirect, as to the brood production of to-day is therefore a portent for good or ill in the fishery of to-morrow. Hence, the announcement that there is indication of a positive correlation between brood production and the January temperatures of the sea, in the vicinity of the Varne lightship, is one of much interest and promise.

Inequality of brood production, however, does not entirely account for good and bad fishing yield. Whether the fishable stock be rich or poor, the best possible catches will only be made when fishing is conducted at the right time in the right place. It is important to know that the yield is best at the time of full moon, and that the most favourable conditions for a productive season is when the October full moon occurs during the second week. The conditions of wind blowing over the fishing grounds must also be taken into account, for it is held that herrings tend to swim into the wind; and it is easy to understand that persistent winds from an unusual quarter may cause the shoals to move away from places which they normally visit and where fishermen expect to find them.

It is not only in connexion with the great East Anglian exploitation of shoals making their way to the spawning grounds that scientific investigation is proving its worth. We know that, in the intervening months between annual spawning migrations, the shoals are ranging the sea in

search of food. Information as to the places in which such shoals are likely or unlikely to be found is thus of real value to fishermen wishing to intercept them. Work in this direction was described in the third and fourth papers of the Norwich symposium. Ingenious instruments and methods have been used in a comprehensive and continuous survey of the floating animal and plant plankton of the North Sea with relation to the movements of herring. Positive correlations between the number of herring caught and their food *Calanus*, and negative correlations with phytoplankton, have already been demonstrated. The practical outcome of this is that fishermen can be assured of a greater return for a season's labour if they will regularly use a plankton indicator in deciding where to set their nets. It has also been shown that the phytoplankton at times forms dense patches which interfere with the movements and shoaling of herring, with serious consequences to the dependent fisheries. The study of the origin, disposition and fate of these patches, therefore, is in itself of major interest to the industry. We must also know whether the observed tendency for the autumn herring shoals of both 1933 and 1934 to mass against the edge of a diatom patch is a regular phenomenon.

A word or two must suffice to deal with a line of investigation about which the symposium was silent. Nothing was said regarding the urgent necessity of a greatly improved market for herrings, to prevent the complete collapse of the British industry. For of what use to the fishermen is scientific aid in his fishing if he cannot sell the catches he is already making without such aid?

E. FORD.

Erosion Surfaces

SINCE Ramsay recognised in 1878 that the even skyline of South Wales represented a plain of marine denudation, uplifted and dissected, upland surfaces of low relief have been recognised in all parts of the world, and their probable relation to the great unconformities of the stratified rock succession has been discussed. Some, following W. M. Davis, have preferred to regard them as sub-aerial peneplains rather than marine features, but few certain criteria exist for distinguishing sub-aerial from submarine surfaces, after uplift and dissection, and each case must be judged on its merits. Recent years have witnessed a concentration of interest upon such features, commonly known as 'platforms'. In America, the work of the late Joseph Barrell, and of D. W. Johnson, has emphasised the importance of this line of study. A committee of the International Geographical Congress, on which Prof. A. G. Ogilvie is the British representative, is at present seeking to organise the work of mapping erosion surfaces in Europe, using an agreed, though tentative, scheme of symbols. Interest has also been fostered by the publication of Prof. Baulig's recent monograph[1] in which high-level platforms are discussed in the context of the daring theory of major eustatic changes of sea-level.

With the field thus fertilised, Sections C (Geology) and E (Geography) devoted a session to a joint symposium and discussion on "Denudation Chronology" at the Norwich meeting of the British Association on September 9. The regions discussed included south-east England, Devon and Somerset, South Wales, southern Ireland, the East Midlands, Yorkshire and the Channel Islands. Any attempt fully to correlate work from so wide an area would be premature, but a most welcome concurrence of opinion was manifest both as to the methods of research and the general results obtained. The histories of denudation in the several areas proved indeed so generally comparable as to point a most hopeful future for such investigation and to foreshadow theoretical results of high importance.

An initial problem to be solved in most areas is the differentiation of older surfaces—stripped planes of unconformity, from those formed during the middle and later portions of Tertiary time. There is a general tendency among the students of the older rocks tacitly to underestimate the erosional work of Tertiary time, and to regard the dominant hill-top surfaces of relict Palæozoic uplands as the basal planes of Triassic, Jurassic or Cretaceous rocks, which, buried far beneath the adjoining plains, rise to join the hill-top surface of the 'Massifs', thus signifying a former wide extension of the sediments above them. So cavalier a dismissal of some sixty million years of geological work is theoretically unacceptable, and as a hypothesis it fails to fit the facts. Wherever they are examined in Britain, the 'fossil peneplains' of pre-Permian to pre-Cretaceous date are relatively steeply inclined away from the Palæozoic uplands. Even if their slope flattened as traced away from the heavily loaded areas of the plains, they must nevertheless have passed far above the

existing hill-top surfaces, having, in general, been destroyed in cycles of erosion which ran their course before the current cycle or its immediate predecessor. Recent American work points to a similar conclusion. The Schooley peneplain which bevels many of the summits of the Northern Appalachians was formerly regarded as a landward continuation of the surface below the coastal plain sediments (the fall zone peneplain). D. W. Johnson gives good reasons for supposing that it is a much later feature[2], probably not younger than Early Tertiary.

These considerations enforce the necessity of beginning work on any general scheme of denudation chronology in south-east England, where surfaces can be dated by reference to known Tertiary deposits. There are two major surfaces in this region: (*a*) the folded sub-Eocene surface, which emerges from beneath its sedimentary cover on the lower slopes of the chalk round the margins of the London and Hampshire Basins, and (*b*) the mid-Tertiary (probably late Miocene) surface which forms the general hill-top plane of the south-east, bevelling the escarpments. Most of the true clay-with-flints rests on this latter surface, which was locally warped down before uplift to admit a Pliocene sea over parts of the area. It is hence difficult in places to distinguish between the late Miocene sub-aerial peneplain and the sub-Pliocene marine surface, largely stripped of its thin veneer of sand and shingle. Later, less extensive, surfaces of Pliocene and Pleistocene date—in reality old valley floors—can be traced throughout the region, and the record is supplemented and confirmed by the testimony of cyclic river-profiles, which reveal former sea-levels, closely comparable with those deduced by J. Hanson-Lowe in the Channel Islands. It cannot be too strongly emphasised that the whole south-eastern region (excluding the margins of the unstable North Sea depression) has evolved under the influence of uniform changes of base-level, during its later history. The last traceable act of warping was that which slightly deformed the late Miocene peneplain.

The two major surfaces noted above represent periods of erosion so protracted that corresponding features should certainly be distinguishable in the uplands of the north and west. In south-west England a convenient upper datum in time is provided by the Pliocene marine notch and associated coastal ledge at about 400 ft. O.D. This is unwarped, but the Early Tertiary (pre-Oligocene) surface is evidently largely warped or faulted, as witnesses its depression to low levels along a zone running from Bideford Bay via Petrockstow and the Moretonhamstead syncline to the Bovey Tracey basin. Nevertheless, it may conceivably be represented by the sloping hill-top surface of parts of Exmoor and the Brendon Hills (1,100–1,400 ft.). At lower elevations, there is a 900–1,000 ft. platform and a well-marked very uniform surface which dominates central Devon, ranging in height from 600 ft. to 800 ft. One of these surfaces, probably the latter, is to be identified with the Miocene peneplain of the south-east.

Comparable features have been investigated by A. A. Miller in South Wales and South Ireland. In both regions he finds a sloping surface extending from low levels near the coast to an upper limit at 800-900 ft. This might be interpreted as the product of an advancing or a retreating sea, or even as a sub-aerial feature. It should be added that Prof. Trueman and Miss Goscar find some evidence in South Wales that the general profile is 'stepped' or composite in places, revealing separate platform levels, at 200 ft., 400 ft. and 600 ft., and Miller's work on the river-profiles and the wind-gaps lends some support to such an idea.

In northern England, Prof. H. H. Swinnerton has recognised a high-level surface in south Derbyshire, possibly the sub-Cretaceous plane, but more probably, in the light afforded by the other regions, an early Tertiary feature. Lower platforms representing stages in the excavation of the Trent valley fall into a series generally comparable with those of the Thames valley. Of particular interest has been the discovery by Dr. H. C. Versey, following J. W. Stather and others, of probable early Tertiary deposits on the higher parts of the Yorkshire wolds. These rest on a surface which appears to be traceable in the North York Moors and also, though less certainly, in the Pennine region.

In conclusion, it may be remarked that the study of erosion surfaces is far from being of purely academic interest. From the geological point of view, such surfaces afford a record complementary to that of deposition, but there is a geography as well as a geology of surfaces. Recognition and delimitation of landscape facets is an essential part of geographical analysis, if only because of their influence on soil character and land-utilisation. It is clearly a matter of first importance whether a surface retains relics of an Eocene, Cretaceous or other covering, recently removed, or is mantled by a strongly leached regolith exposed to the atmosphere since Middle or Early Tertiary times. Many agricultural contrasts in Britain can be explained on these lines, and whether in conducting soil-surveys or planning the improvement of agricultural land, such facts should receive full attention.

S. W. WOOLDRIDGE.

The Interaction of Gases with Solids

THE last important discussion on adsorption phenomena in Great Britain took place in January 1932 at Oxford, under the auspices of the Faraday Society. At that meeting, the topic which evoked most controversy was that of the activated adsorption of hydrogen on metals and on metallic oxides, that is, on solids particularly active as hydrogenating catalysts. While a great deal of work has been done in the intervening four years, it cannot be said that the matter is at all thoroughly elucidated. Meanwhile, however, several new independent lines of attack have been brought to bear on the varied phenomena encountered in the interaction of gases with solids, which may ultimately lead to more precise views on the question of activated adsorption. On November 21, therefore, Prof. E. K. Rideal opened a discussion at the Chemical Society in order to direct attention to recent work and to focus opinion on a subject still in a state of flux.

Many of our modern ideas on the mechanism of heterogeneous catalysis are based on the pioneering work of Langmuir on the interaction of gases with hot filaments. That the subject is far from exhausted is amply demonstrated by the recent work of Roberts[1] with tungsten. The basis of these experiments is the development of two separate physical methods of studying adsorption. The first arises from the fact that the accommodation coefficient of a neon atom on a tungsten surface is particularly sensitive to the presence of adsorbed films. For example, the accommodation coefficient on a bare surface at 273° K. is 0·08. When the tungsten is covered with a layer of oxygen atoms, the value rises to 0·25. The second method consists in actually measuring the heat of adsorption of gases on a clean tungsten filament by determining the rise in temperature (only 0·01°) which occurs when gas is adsorbed.

One of the most surprising results of the application of these methods is that hydrogen is practically instantaneously adsorbed when it encounters a tungsten surface even at so low a temperature as 83° K. If very small amounts of hydrogen are admitted, the gas is completely adsorbed, the heat of adsorption being about 40 kgm. cal. After sufficient hydrogen has been admitted to cover the tungsten surface, that is, one hydrogen atom to one tungsten atom, there is no further adsorption, and therefore no heating of the filament. That the hydrogen is chemisorbed is proved by the high heat of adsorption and by the fact that the film of hydrogen can only be removed (probably as atoms) by heating the filament to 700° K. The chemisorption of hydrogen on tungsten therefore proceeds with a very small energy of activation. This is in marked contrast to the considerable energy of activation observed for metallic powders, such as tungsten, nickel and copper. To prevent sintering, these absorbents cannot be outgassed at high temperatures. Hence it may well be that the surface is not free from gas, and that therefore the phenomenon usually observed is really the interaction of hydrogen with a gas-covered metallic surface. It is a matter for further experiment to decide whether this non-activated type of chemisorption on clean surfaces will be observed with metals other than tungsten.

Similar phenomena occur with oxygen and tungsten: the oxygen is immediately adsorbed. From the heat evolved and the energy of dissociation of molecular oxygen, it may be shown that the energy of desorption of an oxygen atom is about 130 kgm. cal., which is in good agreement with Langmuir's value of 160 kgm. cal. derived from the effect of oxygen on the thermionic emission of tungsten. Oxygen atoms go on in pairs, one oxygen atom to one tungsten atom. As this bombardment goes on, a time will come, if the oxygen atoms are immobile, when only single isolated atoms of tungsten are left. It is evident that an oxygen molecule cannot be dissociated on colliding with these isolated atoms. Instead, it is adsorbed as a molecule with a smaller heat of adsorption. Thus at high enough oxygen pressures, the ordinary film of atomic oxygen, necessarily containing gaps, has on top a relatively dilute film of molecules covering about 8 per cent of the surface.

Having obtained conclusive evidence of the nature of adsorbed atomic films, the next question which arises is the rate of migration on the surface of the solid and the rate of penetration into the body of the metal. One ingenious way of following surface migration has been developed by R. C. L. Bosworth[2]. By means of a positive ion gun, a beam of sodium ions is projected on to a negatively charged tungsten strip. The strip is then heated electrically, the sodium atoms migrating. The progress of migration is followed by allowing a spot of light to fall on the sodium-covered tungsten surface, the resultant photo-electric emission at various positions along the strip serving as an indicator of the surface concentration of the sodium atoms. In this way, the rate of migration may be

determined as a function of the temperature and of the surface concentration.

The diffusion of gases through solids is controlled partly by the interaction of the gas with the surface and partly by processes occurring in the body of the solid, both of these in general being specific, for example, H_2-Pd, O_2-Ag, N_2-W. An exception to the rule is the diffusion of hydrogen, helium, neon, argon, nitrogen and oxygen through silica glass[3]. There is no doubt in the case of the inert gases that the forces which the atoms encounter in their passage through silica are purely of the van der Waals' type. In fact, it may be shown by calculation that the energy of activation for the passage of an inert gas atom through a square of similar atoms can attain values commonly associated with chemical reactions, such as 30 kgm. cal. Migration appears to take place through the solid lattice, for the rate is independent of the firing and other treatment of the silica. With oxygen and nitrogen, on the other hand, the rate is very sensitive to surface imperfections, firing and the like, which would point to the diffusion occurring along slip-planes and cracks in the glass.

Much has been written about the usefulness of deuterium as a tool for investigating the mechanism of chemical reactions. Taken along with the ortho-para conversion, the behaviour of deuterium yields important evidence about catalytic hydrogenation and dehydrogenation reactions. For example, if ammonia and ortho deuterium are allowed into contact with an iron catalyst, A. Farkas has found that the rate of conversion of the ortho deuterium is inhibited by the ammonia, and simultaneously there is a slow exchange reaction resulting in the production of deuterammonia. This shows at once that ammonia partially covers the iron surface, that deuterium is dissociated on the portions not covered with the ammonia, and that the rate of exchange is slower than the dissociation of deuterium molecules, the latter reaction therefore not being the rate-determining step.

These few examples suffice to demonstrate that the field of inquiry is an extending one, and that well-defined progress is being made in drawing a more precise picture of the interaction of gases with solids.

Obituary

Mr. F. Escombe

EVERY student and teacher of botany must be familiar with the classic work of Brown and Escombe on the germination of refrigerated seeds; the relative roles of endosperm and embryo in germinating barley; on the static diffusion of gases and liquids in relation to photosynthesis and translocation in plants; the influence of varying amounts of atmospheric carbon dioxide on photosynthesis and plant growth; the interchange of energy between the leaf and its surroundings; the determination of carbon dioxide in the air absorbed by plants, based on the rate of its absorption by a free surface of a solution of caustic alkali; and they will learn with regret of the sudden death of the surviving author of these important researches on October 12. Brown, who was a much older man, died in 1925. Fergusson Escombe, who was only sixty-three years of age, had given up his active career at a comparatively early age owing to ill-health and other circumstances, and thus, though his work will always hold a high place in botanical research, he himself had almost been forgotten, save by a few.

Born in Hampshire in 1872, Escombe went to a preparatory school at Bournemouth and thence to Haileybury for two years. He matriculated in 1892, and later obtained the degree of B.Sc., with honours in botany, at the University of London, from King's College, London. There he won the Carter Gold Medal and Prize for botany. He studied also at Downton Agricultural College, at Neuenheim College, Heidelberg, and at the Kaiser Wilhelm University at Strassburg. Whilst at the latter, he worked on the chemistry of the cell membranes of lichens and fungi, and published a paper on it in 1896, "Beitrag zur Chemie der Membranen der Flechten und Pilze" (*Hopp.-Seyl. Z. Phys. Chem.*, **22**, 288–306; 1896–97), a preliminary investigation to determine the existence of chitin and cellulose in these groups. This showed his early leaning towards biochemistry.

Shortly afterwards, Escombe went to work with Brown at the Jodrell Laboratory, Kew, on the researches which were published jointly in the Royal Society *Proceedings* and *Philosophical Transactions*, 1897–1905, and which gained for Escombe an established place in botanical science. There is no necessity to summarise these researches—indeed it would be quite impossible except at great length—since they have passed into botanical history and are described in every botanical textbook. They marked, however, a great advance in the state of knowledge then of the essentials of the physiological processes of germination and nutrition. Being reduced to mathematical precision, the results were enunciated so that in some cases they could be stated in formulæ. Special methods and apparatus had to be devised to carry out such delicate experiments, and novel

methods of study adopted to demonstrate the physical laws that controlled plant activity.

Following these fine contributions to biochemical and biophysical science, both Brown and Escombe took up appointments in the Scientific Research Laboratory of Messrs. Guinness and Co. at Dublin, Brown as director and Escombe as vegetable physiologist. The work on improving the malting qualities of barley was published (unsigned) in the Laboratory *Transactions*. Escombe worked there from July 1901 for three years. Readers of NATURE will remember the excellent reviews by Escombe on German biochemical works by Emmerling, Schulz, Czapek and Wieler about this time (1902–6). He wrote for *Science Progress*, 1897–98, two papers on germination generalised from the Royal Society researches.

Escombe then held the post of lecturer in botany and head of the Botanical Department at the South-Eastern Agricultural College, Wye, following Mr. (now Sir) Albert Howard, and at the same time gave County Council lectures in Kent and Surrey. He was at Wye from July 1905 until July 1907. This ended his active career at the age of thirty-five. He returned to Kew to do some physiological work at the Jodrell Laboratory in March and April 1910. After that, save for work during the Great War at the Admiralty (1917–22), he retired, from ill-health and other circumstances, to his native county, Hampshire (where also lived his great friend, Dr. D. H. Scott), living with his family, and latterly, since 1929, in rooms at East Meon, where he made his home until his death.

There Escombe took an active part in the life of the village, and his chief hobbies were reading and walking, and exploring the flora and fauna of the district. He studied the two Arums, and carried out an exhaustive series of researches on their life-history and ecology, later studying that difficult group of trees, the elms. In both cases he wrote valuable notes upon the species, which, with excellent material, he sent to Kew. He also there wrote a treatise on "Buds in Winter". All these should be published posthumously, since they are characterised by the same masterly grasp of details, and the clear and well-conceived enunciation of principles, or of classification, with brilliant and sound analogy, which marked the Royal Society papers published in conjunction with Brown.

Fergusson Escombe was a very reserved man, and of a refined nature. Properly understood, he was a charming companion. He had a most gentle nature, and a great love of animals and for children and old people. His scientific work was characterised by thoroughness and avoidance of hurry, and his experiments were conducted with carefulness and exactitude. It seems a tragedy that a man gifted by Nature with exceptional scientific ability, enlarged by special training, and with so sound a knowledge of biochemistry and physiology, should have had to disappear, through ill-health, from the arena of science at so early an age. Ill-health caused his career to be prematurely shortened, and heart failure has now snatched him from the world, his relations and friends all too soon. A. R. H.

Senator Paolo Orsi

WE regret to record the death of Senator Paolo Orsi, the distinguished Italian archæologist, which took place at Rovereto on November 8 at the age of seventy-six years.

Paolo Orsi was born in 1859 at Rovereto, which was then Austrian territory, but on completing his studies he settled in Italy. In 1888 he became an inspector of the Museum of Syracuse, and soon afterwards was appointed its director. He applied himself to the exploration of the antiquities of the island of Sicily, and by his discoveries revealed the sequence of Siculan culture from early chalcolithic times down to the period of Greek colonisation, a sequence in which he showed that four separate types of civilisation were to be distinguished. His excavations, more particularly in the neolithic villages of Stentinello, the burial grounds of Megara near Syracuse, and at Gela, made his museum one of the richest, and in some respects of the first importance, for the study of certain aspects and periods of Mediterranean archæology.

In 1907, Orsi was appointed *superintendente* of Calabria and Basilicata. Here he continued his investigations and discovered the pre-Hellenic sites of Torre Galli, near Monteleone, and of Canale, near Locri, both of crucial importance for the study of the prehistory of the Calabrian peninsula. He undertook a number of excavations under the auspices and mainly at the expense of the Societa Magna Græcia, of which he was president at the time of his death. Among his discoveries was that of an Ionic temple at Locri, the only known example in Magna Græcia. The material from these excavations will be exhibited in a museum now in course of construction at Reggio-Calabria. He was also an authority on Byzantine antiquities, which he had studied in both Sicily and Calabria.

At the close of the Great War, Orsi took up his residence in retirement at Rovereto. He was a member of the Accademia dei Lincei, and was made a Senator in 1924. He was an honorary member of the Society for the Promotion of Hellenic Studies and an honorary fellow of the Royal Anthropological Institute.

WE regret to announce the following deaths:

Prof. James H. Breasted, professor of Egyptology and oriental history in the University of Chicago from 1905 until 1933, and director of the Oriental Institute, Chicago, on December 2, aged seventy years.

Prof. J. D. Cormack, C.M.G., C.B.E., regius professor of civil and mechanical engineering in the University of Glasgow, on November 30, aged sixty-five years.

Prof. David C. Gillespie, professor of mathematics in Cornell University, for several years editor of the *American Mathematical Monthly*, on October 13, aged fifty-seven years.

Prof. J. E. A. Steggall, emeritus professor of mathematics at University College, Dundee, in the University of St. Andrews, on November 26, aged eighty years.

News and Views

The Royal Society: Officers and Council

THE anniversary meeting of the Royal Society was held on Saturday, November 30, being St. Andrew's day, and the following officers and members of council were elected: *President:* Sir William Henry Bragg; *Treasurer:* Sir Henry George Lyons; *Secretaries:* Sir Frank Edward Smith, Prof. Archibald Vivian Hill; *Foreign Secretary:* Prof. Albert Charles Seward; *Other Members of the Council:* Prof. Edgar Douglas Adrian, Mr. David Leonard Chapman, Prof. Arthur William Conway, Dr. William Henry Eccles, Prof. Arthur Stewart Eve, Prof. Louis Napoleon George Filon, Dr. James Gray, Sir Alfred Daniel Hall, Dr. Stanley Wells Kemp, Sir Patrick Playfair Laidlaw, Sir Gerald Ponsonby Lenox-Conyngham, Dr. Gilbert Thomas Morgan, Prof. Robert Robison, Dr. Bernard Smith, Prof. Walter Stiles, Mr. Wilfred Trotter. An unusually large number of fellows took part in this election on account of a notification that it was to be contested. Several months ago, a group of about ninety fellows of the Society signed a memorial advocating certain changes in the methods of nominating and electing the officers and members of council and in their periods of service. Following up their suggestions, the memorialists substituted other names for those of fellows nominated officially as president, treasurer, two secretaries, and foreign secretary, and of four members of council. Fellows were not asked to support the individual claims of those included in the unofficial list, but to record their votes for them as an expression of no confidence in the existing methods of selecting officers and council. The result of the ballot was nearly ten to one in favour of the Council's list printed above, the number of votes for each officer and member of council in this list being about 190 and that of fellows in the unofficial list being about 20. In the absence of a postal vote, it may therefore be assumed that the general body of fellows of the Society are satisfied with the existing rules and with the statement issued by the Council after full discussion of the changes suggested by the memorialists.

Industry and Technical Education

THE Right Hon. Oliver Stanley, president of the Board of Education, distributed prizes and certificates at the Northampton Polytechnic, Clerkenwell, on November 28. During the course of his address, Mr. Stanley referred to the changes which have been accelerated by the War and which have resulted in the loss of the advantage as an industrial nation which we acquired a century earlier. Yet with all these difficulties in the way of production, we have got to compete if we are to live; and we are being driven more and more to rely on superior skill, superior technique, superior training and superior workmanship, to take the place of those more fortuitous advantages which used to give us our superiority before the War. We can only regain the prosperity of our own traditional industries if we adopt new and up-to-date methods. We are forced to keep ahead of new and severe competition in the new industries, and it is natural that we should turn to institutions like the polytechnics to ask how they can help and are helping both with the old and with the new. Speaking of the type of training for which polytechnics are responsible, Mr. Stanley said that in talking with leaders of industry about technical education he has found everywhere the feeling that colleges should keep in closer touch with actual experience in the workshop. From this point of view he commended the 'sandwich' course of training in engineering, and expressed his regret on learning from the Principal's report that, owing to changes contemplated in the University of London regulations for degrees in engineering, difficulties have arisen with regard to the organisation of such a course in the future.

The Engineer and the Community

IN an address to the Birmingham and District Association of the Institution of Civil Engineers on October 31, Mr. C. H. Bailey made an eloquent plea for wider vision and much closer concern on the part of the engineer with the consequences of his work. We live to-day in an engineer's world, he said, yet an attempt to give a continuous direction to the efforts of the engineer is needed, and in the past, engineers have too lightly assumed that all their achievements result in benefits to their fellow men. Machines are neither wholly good nor wholly bad. They are bad in so far as they hinder men and women from developing creative skill of hand and eye; the mere use of better and more abundant goods can never compensate for the loss of constructive opportunities or powers. It is certain, however, that such production must go on, and that the engineer must continue to strive for more and more efficient machines while mankind learns to adapt itself to the new conditions. While, however, the engineer has transformed our powers of production and means of communication, we are still attempting to force these inventions into an economic, financial and political system which they do not fit. On the other hand, these same developments in production and communications have brought men closer together and made them more dependent on one another. At the same time, the engineer has given the world a greater chance of real freedom than ever before, if we learn to use our new resources and try to modify the new conditions, seeking to create new beauty where we have destroyed. While the engineer should beware of extravagant claims to a larger share in the control of the community, he should endeavour to participate more effectively in the planning required under the new conditions, and to devise some form of co-operation which would make available the benefits latent in his achievements.

Science and the Architect

DR. R. E. STRADLING, director of Building Research under the Department of Scientific and Industrial Research, opened a materials gallery at the Liverpool School of Architecture in the Leverhulme Building of the University of Liverpool on November 29. In his address on the "Architect and Building Materials", Dr. Stradling said that the architect is required to create some form of protection, usually from the weather, which shall meet some intimate practical requirement of human existence, and in a progressive society meet it in such a way that beauty is added to everyday life. It seems almost self-evident that the knowledge of materials must be an ever-present mental background upon which the architect's mind must instinctively call if his artistic ability is to have reasonable scope. He must be equipped to meet his modern conditions, and there is an absence of adequate training on this side. In traditional English house design one usually finds a pitched roof with appreciable eaves, reasonable sills at the top and bottom of windows and doors, the walls constructed of brick or stone, or may be rough cast. No matter whether this type of design is artistically good or bad, such construction is usually thoroughly weatherproof if reasonably carried out in traditional materials. A typically modernist design consists of a box-like structure with flat roof, no weather projection over parapets, windows or doors; walls rendered in smooth Portland cement rendering. From inquiries received at the Building Research Station, it seems such structures are often anything but weather-proof. Before discarding old forms, it is essential to make sure that the new ones meet the essential protection requirements for which the building industry really stands. The real architect-artist is urgently required with all the pioneering fire of which man is capable, but he must be properly trained to meet modern conditions. This can only be done by very much more intensive science work than is usual at present, for he must have a very real knowledge of the media in which he is to design.

Minoan Survivals in Later Crete

SOME remarkable vistas in the history of European civilisation are opened up in the report by Sir Arthur Evans of the discovery in October last of a temple of early Greek age in the island of Crete. The temple, which has been excavated by Dr. Marinatos, Ephor of Antiquities, is situated in the eastern part of the island on the hill site of the ancient town of Dreros, overlooking the lagoon of Spinalunga. It dates from the early part of the eighth century B.C., and is, therefore, the earliest known temple of the Greek age in the island. It differs, however, in proportions and character from other early Greek temples, and Sir Arthur in his communication in *The Times* of November 20 fully concurs in the view of Dr. Marinatos that it presents close affinities with pre-existing Minoan cults, such as might be preserved in an ancient Cretan tradition. He recalls that it was in this part of the island that the ancient Eteo-Cretan language survived down to historic times. Among the more noteworthy objects of the shrine, which was found in the characteristic Minoan position on the back-wall of the cella, are the cist-like altar filled with earth and quantities of goats' horns, reminding Dr. Marinatos of the altar erected by Theseus in honour of Ariadne, his Cretan consort, and bronze figures made of hammered plates, which had been fitted on to a wooden core, the first known examples of a technique to which reference is frequently made by Greek writers. Of these figures two, one male and one female, are evidence of the persistence of the 'mother and son' cult, which provides Sir Arthur with a link in a chain of evidence by which he traces the fundamental religious belief of the eastern Mediterranean from Knossos to Bethlehem.

Explorations in New Guinea

ADDITIONAL interest was attached by recent controversy to the account of his explorations in New Guinea which Mr. Michael Leahy gave to the Royal Geographical Society on November 21. It will be remembered that it has been suggested that Mr. J. G. Hides, who recently brought back some remarkable data relating to the unknown peoples he had encountered in the interior, had been in touch with some of the peoples of the Mount Hagen area discovered by Mr. Leahy, of whom an account has already reached England through Mr. E. W. P. Chinnery, the Government anthropologist of Papua. (See NATURE, September 1, p. 328, August 17, 1935, p. 251 and August 24, p. 290.) The culture of the Mount Hagen people as described by Mr. Leahy does indeed present certain features of similarity, such as the interest the people display in their gardens, which justify the comparison. Mr. Leahy's cinematograph film, especially in the war scenes—he was fortunate enough to obtain a record of an inter-tribal war in actual progress—gave a detailed picture of a remarkable, and in its environment unusual, culture. Especially interesting to archæologists was his report of the custom of cutting off a finger-joint at the death of a relative. This custom of finger mutilation is widespread among the more primitive peoples, and, as is well known, evidence of it is to be seen in the imprints of hands found among the prehistoric cave and rock paintings. The Mount Hagen peoples also practice preserving the skulls and some of the bones of their deceased relatives, which are placed in shrines along the road-side. It is to be noted that they are not cannibals, and expressed horror at the suggestion, although the practice exists among tribes nearer the coast. As a whole, Mr. Leahy's report has provided much interesting material for comparative study.

Stone Age Culture in Colorado, U.S.A.

DR. FRANK H. H. ROBERTS, JR., of the Bureau of American Ethnology, has resumed his investigation of the Lindenmeier site in Northern Colorado, U.S.A. (see NATURE of October 5, p. 535), and for some weeks has been engaged in driving trenches in various directions near the habitation and factory site of Folsom man which he discovered in 1934. No less

than seven hundred implements belonging to this early phase of the American stone age, it is stated in a communication issued by Science Service of Washington, D.C., have been discovered, among them being a number of new types. The variety in type of the implements continues to be a marked feature of the site. A find of considerable importance is recorded, which corroborates conclusively previous evidence for the contemporaneous existence in this region of man and an extinct fauna. This is the discovery of the vertebra of a bison, in which is still embedded the stone point of the lance or dart with which it had been struck by the primitive hunter. The vertebra belongs to the extinct form of bison already found here and elsewhere in association with the artefacts of Folsom man. It has already been pointed out (see NATURE, *loc. cit.*) that the Lindenmeier site gives *in situ*, for the first time, a view of the Folsom implement as forming part of a cultural complex, and thus justifies the use of the term 'Folsom culture'. To this complex must now be added an art form, the first known in this early phase of culture, which appears on a flat bone disc showing decorative marks around the edge. No information is as yet available on the further investigation of the stratigraphy of the site and its relation to adjacent gravels, from which it is hoped to attempt a dating of this centre of the Folsom culture.

A Thames Barrage

WITH the arrestive title of "Dam the Thames", a brochure has been issued by the Thames Barrage Association advocating the scheme put forward a short time back in a paper read before the London Society by Mr. J. H. O. Bunge, who is honorary secretary of the Association since formed to promote the impounding of a large section of the Thames estuary. The original proposal is modified in respect of the position of the proposed barrage, which it is now suggested should be located at Woolwich. The cost of the scheme is estimated at about 4½ millions sterling, but, as has been abundantly demonstrated in other projects of corresponding magnitude, this figure must be received with a certain amount of reserve. According to the pamphlet, the resultant savings, enumerated under eighteen categories, would aggregate about £611,000 per annum, representing a capitalised value of 20 millions sterling. Some of the items of this calculation seem to be based on data of a rather uncertain character, so that here, too, the estimate must be considered more or less speculative. An official, public inquiry into the merits of the scheme is urged on the grounds that the scheme, if carried out, would be of great advantage to navigation in maintaining a permanent water level in the river and so enabling craft to move freely, and independently of tidal restrictions, in and out of the docks, and to and from the riverside wharves above Woolwich; in excluding sewage effluent at present brought up-river by tidal flow from the outfalls at Crossness and Barking; and in avoiding the risk of flooding at times of abnormally high tides. Various other benefits are categorically enumerated.

ALTHOUGH an inquiry, which would involve some time and expense, might resolve some of the problems connected with the formulation of the barrage scheme, it must be borne in mind that an enterprise of this magnitude cannot be embarked upon without a considerable degree of risk to important interests, however propitious the general circumstances may appear to be. It will be recalled that a cognate scheme, the Severn Barrage, was definitely promoted by the Government and became the subject of a prolonged and searching inquiry by experts; but the findings of the committee, although favourable, have not, so far, resulted in the materialisation of the project, which, in the language of the Ministry of Transport, was to bring "within the reach of all classes of the community the blessings of light, purity and power". It is also to be noted that the Port of London Authority has had the present proposals before it, and has not accorded them its support. The reasons have not been stated, but it is clear that they were such as to carry preponderant weight with those most intimately concerned with the great shipping and commercial interests of the port. This does not, in itself, suffice to condemn the project; but it rather discounts the florid assertions of the promoters, and justifies an attitude of caution and reserve.

Ice Accretion on Aircraft

LECTURING before the Royal Aeronautical Society on November 4, Mr. Lockspeiser, of the Royal Aircraft Establishment, Farnborough, described experiments upon this subject which have led to the recommendation of a certain method of combating this. It consists of forcing ethylene-glycol through a porous leather strip which can be attached to, or form part of, those surfaces upon which ice appears to form. This presents the greatest danger when on the leading edges of the various lifting surfaces and the airscrew. In such cases it not only adds to the weight to be carried but it also reduces the efficiency by changing the shape, and in the case of the propeller it causes out of balance forces that necessitate slowing it down with still further loss. The action of the ethylene-glycol is to prevent the ice from adhering to the surface. Mr. Lockspeiser referred to thermal methods for prevention of ice formation, and mechanical methods for dislodging it, but said that neither of these has the simplicity and the general application to all cases of the evaporation method. Thermal methods, using the engine heat to warm the wing surfaces, may become more attractive upon larger thick-winged monoplanes, where the 'plumbing' difficulties would be less. Mechanical methods of dislodging the ice from the planes have been used for some time in the United States, but are not applicable to the propeller. Experiments are now being made with devices similar to the British ones, using rubber sheathing and oil. The experiments described were undertaken originally for R.A.F. requirements; but the question was considered to be so vital to civil aviation, that the results have been made public and the device is to be marketed by the Dunlop Company.

Forestry Research

THE Forest Products Research Laboratory at Princes Risborough has begun a new issue entitled *Forest Products Research Records*, of which Nos. 1 and 2 have been issued (H.M. Stationery Office, 1935). No. 1 deals with the testing of timbers at the Forest Products Research Laboratory, and describes in clear language the *raison d'être* for the Laboratory and the objects at which it aims. It is pointed out that the object underlying the work of investigating the properties of timbers, the practical application of the results of the tests and their importance to the timber-using professions and industries as well as to timber merchants, are not fully understood. Nor are the facilities offered by the Laboratory for supplying information fully realised. It is the object of the *Records* to supply this want. The first number describes the work of the different sections of the Laboratory under the headings: structure, timber physics, seasoning, timber mechanics, woodworking and preservation, with sections dealing with entomology, mycology, wood chemistry and utilisation.

IN the second number of the *Forest Products Research Records* the subject of "The Strength Tests of Structural Timbers" is discussed. Both Canada and the United States have been engaged upon research work in this direction for a number of years. Until recently the subject has received very little attention in Europe, which accounts perhaps for the fact that handbooks providing tables do not agree among themselves owing to important factors being overlooked by earlier investigators. For example, mention is made of one record which cites Memel redwood as 60 per cent and English oak as 20 per cent stiffer than greenheart, whereas it has now been established that redwood and oak are approximately equal in this property and no more than half as stiff as greenheart. With the object of coming into line with the Canadian and American research work, an extensive programme of tests was commenced some time ago at Princes Risborough. Work was started in testing redwood from the White Sea and from Gefle. The Timber Trade Federation became interested in the work, and with its co-operation the scope was considerably extended. The results of the tests on redwood from those two areas are detailed in the *Record*.

New Box Testing Laboratory

THE Department of Scientific and Industrial Research has set up equipment at the Forest Products Research Laboratory for testing packing-cases, boxes, etc., under stresses similar to those encountered during rail or road transport. The installation is the first of its kind in Great Britain, but several are in use in the United States, where the experience gained has considerably reduced the claims for damages paid by the railways. The plant at Princes Risborough tests both the endurance and strength of the boxes. For the former test, the cases are placed inside a large rotating drum, which revolves twice a minute, wooden baffles on the inner face causing the article to fall in different positions in turn. A moderately well-made container was found to collapse after about thirty falls, whereas one of really good design could withstand 150 or more falls. A 'dropping machine' tests the resistance to falls on the face, corner or edges at will, while in a further apparatus resistance to crushing can be determined. The efficiency of nailing, different types of fastenings and packings are also being investigated, and on behalf of the Ministry of Agriculture special tests are being made with the view of drawing up a standard specification for fibre-board containers for National Mark eggs. The Box Testing Laboratory will be available to manufacturers and others who wish to study possible improvements in methods of box construction and in the packing of contents to give the greatest protection. The scale of charges, and a statement of the conditions under which tests will be made, can be obtained from the Director, Forest Products Research Laboratory, Princes Risborough, Bucks.

Air-Conditioning in the Tropics

ATMOSPHERIC conditions in the tropics have serious effects, both physical and mental, upon the inhabitants. In an article in the *Electrical Review* of November 8, Prof. C. A. Middleton Smith of the University of Hong-Kong states that it is difficult for those who live in temperate regions to realise the depression produced on human energy by living for months in a climate with a night and day temperature of about 90° F. and a relative humidity of more than 90 per cent. With the help of electrical power and the new methods of producing cold mechanically, it is now possible to manufacture climatic conditions that are almost perfect. By the use of a small electrically driven machine in his private room in the University, Prof. Smith can make the climate in it as pleasant as on a summer day in England. Six hours after the machine has been at work, it has extracted a gallon and a half of water from the air in the room. The effect of the two contrasting atmospheric conditions within and outside the room upon bodily comfort is most marked, and he has found by experience that he can double his lecture hours and yet be less fatigued at the end of the day. He says that no educated person in the tropics who can afford an electrically driven refrigerator would now risk having a 'disease carrying' ice box. He has for the last sixteen years advocated air-conditioning in the tropics. One of the most extensive applications of the system in China to-day is that of the new million pound building of the Hong-Kong and Shanghai Bank. There are six air-conditioning plants for the whole building. Electric motors are used for driving the ammonia compressors. Three pumps are required for the condenser water circulation and there are six inlet fans which drive 229,000 cubic feet of air a minute. The total rating of the electric motors used is 800 horse-power.

Radio Research Laboratories Abroad

THE rapid and widespread growth of radio communication and its associated industries has been one of the most notable events during the past fifteen

years. The inception and development of broadcasting, and later of television, resulting from the earlier introduction of the thermionic valve to industry, have revolutionised the scope of normal commercial telegraphic and telephonic communication. These developments have naturally been accompanied by the establishment of radio frequency research laboratories in all parts of the world, some of these being controlled by government administration, while others are associated with private enterprise. The issue of *La Nature* of September 15 is devoted to an illustrated account of several such radio research laboratories. Much space is devoted to the work of the French institutions, Le Laboratoire National de Radio-Electricité, Le Laboratoire du Comité Consultatif, Les Laboratoires de Recherches du "Matériel Téléphonique", and to the private laboratories engaged on television. In addition, however, the work of the Heinrich Hertz Institute and of M. von Ardenne in Berlin are described briefly; while attention is also devoted to the Philips Laboratories at Eindhoven, the Bell Telephone Laboratories in New York, the Italian Television Laboratory and that of the Baird Television Laboratory, the only English laboratory mentioned. Further articles deal with work in France in connexion with broadcasting, valve manufacture and research on the interference problem. The whole issue presents an interesting summary of the scope and position of research in the institutions enumerated.

Solar Physics Observatory, Cambridge

In his twenty-third annual report to the Solar Physics Committee the Director of the Solar Physics Observatory, Cambridge, is able to point to a number of interesting results obtained from a particularly active year. To begin with, the 3-ft. Common mirror has been refigured by Dr. Burch, who has developed a special new method of testing paraboloids in this connexion. The performance of the mirror is greatly improved, and it is hoped to improve the 10-in. secondary mirror used with this large mirror and so obtain really good definition with the 3-ft. telescope. The year's work on stellar spectroscopy has been notable on account of special observations made during the eclipse of ζ Aurigæ and for the work on Nova Herculis. A very special effort was made, and altogether 284 spectra were secured on 137 nights between December 13, 1934, and July 31, 1935. This is a very fine performance for the climate of Great Britain, and was only made possible by enthusiastic team work by the staff and research workers at the Observatory. An item of interest is the attempt made by Drs. Redman and Bullard to determine the diameter of Antares by observing the brightness during an occultation by the moon. Unfortunately, the apparatus broke down at a critical point in the observation, but there appears to be nothing unworkable in the method, which is of extreme interest, and it is to be hoped that the experiment will be repeated at the next favourable occultation. The solar work has continued, perhaps the most noteworthy item being the accurate determination of the central intensity of the line at 4227 A. (due to Ca^+) by Dr. Redman, the result being 2 per cent—possibly the lowest central intensity yet accurately measured. The Observatory has arranged to send an expedition to observe the total solar eclipse of June 19, 1936, the site chosen being in the island of Hokkaido. Finally, the work on meteorological physics has been continued, and the work on the Fe^+ laboratory spectrum has been brought to a successful conclusion, 58 new multiple terms and 157 levels having been determined.

Archæology in South-East Essex

Local archæologies and local histories have a useful function which is seldom fulfilled satisfactorily. To write them successfully requires a nice perception of the balance between the foreground of local interest and the background of the general trend of history or cultural development. Of the importance of the detailed record of local finds there can, however, be no two opinions. The studies of East Anglian archæology which we owe to Sir Cyril Fox have demonstrated the almost kaleidoscopic changes in the generalised picture as the records of local finds are brought more and more into focus. An excellent example of a method of treatment of local antiquities, which may be followed to advantage, is afforded by "The Archæology of Rochford Hundred and South-East Essex" by Mr. William Pollitt (Southend-on-Sea Museum, Handbook No. 7, pp. 59 with 22 plates, 6*d*.), in which the author follows up a survey of the archæology of the district from pre-palæolithic down to and including Saxon times with a detailed list of the 'finds' in the area, classified according to period and arranged under parishes, the present location of each specimen being noted where known. The distinction to be drawn between south-east Essex and the central and north-western areas of the county on geographical lines is no less apparent in its archæology. For this reason, if for no other, the general background becomes of no little importance for the appreciation of the significance of the finds. Here, it will be found, fully adequate provision has been made for the needs of those who will use the handbook. A map, or series of maps, showing the localities in which the antiquities were found, would have been a useful addition to the ample and excellent illustrations.

Shipbuilding by Welding

Electric-arc welding has now arrived at the stage where it is recognised as an important aid to shipbuilding, and its field is being extended so rapidly that there are few shipbuilders or repairers who do not now avail themselves of its use. With this statement, Messrs. N. M. Hunter, vice-president, and H. W. Townshend, associate member, opened a paper read to the North-East Coast Institution of Engineers and Shipbuilders on November 15. They deal with the subject descriptively, and explain the methods used in the fabrication of various parts of the hull structure. The amount of work now done by welding and the marked advantages gained in some instances testify to its growing importance. Welding the steel decks has, for example, produced

water tightness, greatly to the benefit of the crews, while in trawlers the welding of seams has eliminated the trouble with loose rivets caused by the impact of the heavier portions of the fishing gear. It is inevitable that this method will profoundly modify both the design and the building of ships, as the pre-construction of parts is more suitable to the technique of welding.

Catalogue of Earthquakes, 1925–30

ALL those who have used the late Prof. Turner's catalogue of earthquakes for the years 1918–24 will welcome its continuation for the next six years by Miss E. F. Bellamy "as a contribution to earthquake science and as a personal memorial of respect to Prof. H. H. Turner". The catalogue (British Association, Burlington House, London, W.1. 2*s*.), as before, is compiled from the International Seismological Summary, and gives for each earthquake the time at the origin, the position of the epicentre, the number of stations providing records of the earthquake, the last occasion on which the same focus was in action, and the number of "minor entries" or records that are not sufficient to determine the position of the epicentre. The appendix contains notes on earthquakes with unusually deep foci, etc. The number of new epicentres determined is 1,052, raising the total number of known epicentres to 6,215. A remarkable feature of the catalogue is that, with its thousands of entries, it yet seems unusually free from errors, printer's or otherwise, only one so far having been discovered (Nov. 31 for Nov. 13, p. 12).

Investigation of British and Irish Earthquakes

THE study of British and Irish earthquakes, carried out by Dr. C. Davison between 1889 and 1916, has been resumed by Dr. A. T. Dollar, who appeals for assistance in completing the catalogue of those earthquakes which occurred between January 1, 1916, and the present date, and also in recording future disturbances of the same kind. Personal experiences, or relevant cuttings from accounts in scientific journals and newspapers are sought. To facilitate the reporting and recording of data, a questionnaire and circular letter will be forwarded (together with a stamped, addressed envelope) on request to Dr. A. T. Dollar, Emmanuel College, Cambridge.

An Earthquake Research Commission for India

THE Bihar earthquake of 1934 and the Quetta earthquake of the present year have shown the need for an Earthquake Research Institute in India on the same lines as that which has done such admirable work in Japan. A recent issue of *Culture and Science* (1, 233, 274, 288; 1935) has several paragraphs on the subject. A committee of the Geological Survey, consisting of Dr. A. M. Heron, Mr. W. D. West and Mr. J. B. Auden, has drawn up a list of Indian stations at which it is desirable that seismographs should be erected. The list was communicated to the Council of the National Institute of Sciences, India, and it was agreed that the Institute should urge the Government to instal instruments at the places mentioned. The Council has also appointed a subcommittee—Dr. S. Banerji, Dr. M. N. Saha, Dr. N. R. Sen and Mr. W. D. West (secretary)—to advise the Institute on seismological questions, and it was considered that the subcommittee might afterwards be merged into an Indian National Commission for the study of earthquakes. It is satisfactory to learn from the daily Press that the Government is contemplating the appointment of such a commission.

Centenary of Ampère

ACCORDING to the *Revue Scientifique* of October 26, arrangements are being made at Lyons to hold an exhibition next spring in connexion with the commemoration of the centenary of the death of the eminent French physicist, André Marie Ampère. The exhibition will be arranged to illustrate the many applications of electricity. Ampère was born at Lyons on January 22, 1775, being the son of a merchant of that place who was beheaded during the Terror. He became a professor at the Ecole Polytechnique in 1805, and was elected a member of the Paris Academy of Sciences in 1814. His discovery of the fundamental laws of electro-dynamics was made in 1820. His death took place on June 10, 1836, at Marseilles, where he was buried, but in 1869 his remains were transferred to the cemetery at Montmartre, Paris. A statue of him was erected at Lyons in 1888.

Exhibition of Microscopes

MESSRS. W. WATSON AND SONS, LTD., have arranged an exhibition of microscopes to be held in the Central Hall, Westminster, London, S.W.1, on December 9–14. A large number of representative microscopes will be on view, many with prepared slides already mounted. The object of the exhibition is not only to popularise the microscope, but also to demonstrate its utility in various forms of scientific inquiry, in biology, geology, metallurgy, etc. Some telescopes will also be on view. Messrs. Chance Bros. will exhibit various glass products and Messrs. Kodak will exhibit different types of photomicrographs. The Quekett Club is arranging an exhibition of various slides, including specimens of living pond life. During the exhibition, the following lectures will be delivered: "The Part the Microscope plays in the Scientific Control of the Railway", by T. H. Turner, on December 10; "The Microscopist at the Seaside", by Martin Duncan, on December 11; "The Manufacture of Optical Glass", by H. C. Rands, on December 12. The lectures are at 7 p.m. The exhibition is open to the public free of charge. Catalogues and further information can be obtained from Messrs. W. Watson and Sons, Ltd., 313 High Holborn, London, W.C.1.

Another Large Sunspot

FOR the third time within a month, a new group of sunspots large enough to be seen with the naked eye has appeared, and is in transit across the sun's disk from November 26 until December 9, the date of central meridian passage being December 2·1.

The area of the present group, which consists of a long stream of spots over 100,000 miles in length with a large component in the middle, increased from about 400 millionths of the sun's hemisphere on November 27 to 1500 millionths on November 29. Since the typical curve of growth of large spots shows the maximum area to be reached between the fifth and tenth days after their initial formation, it is probable that the group may grow still larger before it disappears around the western limb. In any event, a maximum area of 1500 millionths has not been equalled since February 1933, when the last big group of the preceding cycle (ending about 1933·8) was recorded.

Announcements

PROF. F. O. BOWER, emeritus professor of botany in the University of Glasgow, has been elected a corresponding member of the Prussian Academy of Sciences.

PROF. W. H. HOFFMANN, of the Finaly Institute of Havana, has been elected president of the recently founded Cuban Society of Biology.

SOVIET RUSSIA has fifty aeroplanes fitted up as small hospitals, the smallest having room for three patients, a doctor and two assistants. In urgent cases, important operations can be performed during flight.

A CONFERENCE on "Mechanization in Mixed Farming" will be held under the joint auspices of the School of Rural Economy, the Institute for Research in Agricultural Engineering and the Agricultural Economics Research Institute of the University of Oxford at Rhodes House, Oxford, on January 7–10. The opening address will be delivered by Prof. J. A. S. Watson, Sibthorpian professor of rural economy in the University. Further information can be obtained from the Conference Secretary, Institute for Research in Agricultural Engineering, Parks Road, Oxford.

THE seventh Pan-Russian Congress of Balneology will be held at Moscow under the presidency of Prof. Danielevsky on December 25–31, when the following subjects will be discussed: the balneological resources of the Soviet Union and the immediate prospects of their utilisation; mineral waters and the indications for their application; radioactive waters; comparative action of sulphurous and bicarbonate waters; medical climatology and climatotherapy; bath treatment of children's diseases. Further information can be obtained from the organising committee, Boulevard Novinsky 9, Moscow.

AT the Sixth International Congress of Genetics held at Ithaca, New York, 1932, a Permanent International Committee of Congresses of Genetics was elected consisting of representatives of fifteen different countries, and Prof. Otto L. Mohr, professor of medicine in the University of Oslo, was elected chairman. This committee has accepted the invitation of the Academy of Sciences of the U.S.S.R. to hold the Seventh International Congress in Moscow and Leningrad in 1937. The date of the Congress will be decided upon later. It may be mentioned that in 1937 an All-Union Agricultural Exhibition will be held in Moscow, which undoubtedly will prove of great interest to many members of the International Congress on Genetics.

THE issue of "Illustrations of New Conifers" by the late H. Clinton-Baker and A. Bruce Jackson, in one volume at 84*s*. is announced. The book will supplement the "Illustrations of Conifers" issued more than twenty years ago. It will be published by Messrs. Simson and Co., Ltd., 12 and 14 Parliament Square, Hertford, Herts.

WE have received from Messrs. Flatters and Garnett, Ltd., 309 Oxford Road, Manchester, 13, their new Catalogue "S" of stains and reagents for microscopical work, chemicals, and bacteriological culture media. A new item included is their "neutral mountant" for mounting microscopical specimens in the place of the ordinary Canada balsam. This is stated to be quite neutral in reaction and non-crystallisable, and not to affect stains.

WE have received the first number of *Revista de Quimica e Farmacia*, July 1935, published at Rio de Janeiro and edited by C. H. Liberalli, who writes an introductory preface. The journal, which is published monthly, is divided into scientific and professional sections: articles in the first part include one by Prof. Costa on the biochemistry of zinc and another by Liberalli on the reaction of tartrates with the Möhler-Deniges reagent: gluconic, lactic and pyruvic acids also give a red-violet colour with the reagent, and bromine and iodine hinder its appearance, but permanganate and bichromate in small amounts do not interfere. The journal also contains abstracts from current literature.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

An assistant (Grade III) for research on internal combustion engines in the Royal Aircraft Establishment, South Farnborough, Hants (Dec. 13).

A lecturer in electrical engineering in the Sunderland Technical College—The Chief Education Officer, 15 John Street, Sunderland (Dec. 16).

A director of sponge fisheries investigations, and a biological and a chemical assistant—The Director of Recruitment (Colonial Service), 2 Richmond Terrace, Whitehall, S.W.1 (Dec. 31).

A Lancashire-Spencer professor of physics in University College, Nottingham—The Registrar (Jan. 20).

A director of the Indian Lac Research Institute, Namkum, Ranchi—The High Commissioner for India, General Department, India House, Aldwych, London, W.C.2 (Dec. 21).

A professor of physics in Raffles College, Singapore—The Secretary, Universities Bureau of the British Empire, 88A Gower Street, W.C.1.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 917.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Isotopic Structure of Iridium

FROM an examination of the hyperfine structure of certain lines of the arc spectrum of iridium, Prof. B. Venkatesachar and L. Sibaiya[1] have recently concluded that iridium must have two isotopes, and give reasons for assuming the mass numbers to be 191 and 193. I have recently verified this conclusion by a direct mass-analysis of the iridium ions formed by a high-frequency spark between electrodes made of platinum–iridium alloy.

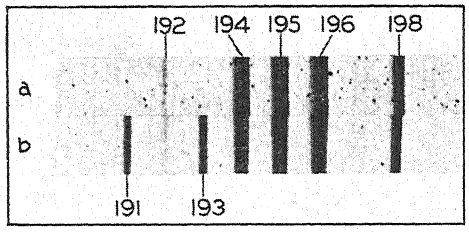

FIG. 1.

The analysis of the five platinum isotopes from an iridium-free electrode has been previously reported[2], and a print of one of these mass-spectra is reproduced in Fig. 1 (*a*). The centre lines are much over-exposed in order to bring out the very faint isotope at 192. When electrodes made of platinum–iridium alloy were used, two new lines appeared, as shown in Fig. 1 (*b*), indicating that iridium has two isotopes with mass numbers 191 and 193.

These two masses are the only gaps in the mass number scale in this region not occupied by osmium or platinum isotopes. No further isotopes would be expected from the rule followed by elements of odd atomic number. The heavier isotope at 193 is definitely stronger than the one at 191, thus giving a third exception, along with thallium and rhenium, to the rule that the lighter of a pair of isotopes of an odd numbered element is the more abundant.

Thermal Decomposition of Certain Gaseous Organic Compounds

IN a letter in NATURE of March 30, I asked for suspension of judgment regarding a difference of opinion between Mr. Hinshelwood and his colleagues on one hand, and myself and my co-workers on the other, with regard to the possibility of measuring the rate of chemical reaction in the thermal decomposition of gaseous acetaldehyde by observing the rate of increase of pressure at constant volume, and also as to the mechanism of the chemical process involved. Mr. Hinshelwood has published an account of his latest work on this subject, and Mr. R. V. Seddon and I have carried on our own work to a point at which publication is possible. We believe that our results support our views on the case.

In the thermal decomposition both of ethylene oxide and of acetaldehyde the main reaction is represented by the equation, $C_2H_4O = CH_4 + CO$. The reaction can only be followed accurately by observing the rate of formation of methane, for in each case the main reaction is accompanied by secondary reactions which do not yield methane. Unless the rates of these reactions are also known, the results of observations of increase in pressure cannot be interpreted.

In the case of acetaldehyde, there is a secondary reaction which leads, through the aldol condensation, to propylene, and the propylene undergoes condensation. The formation of propylene is certainly a wall reaction; for if, for example, the surface area is increased five times, the rate of formation of propylene is increased four times, and the rate of the main reaction is decreased to one half. The main reaction, and the process leading to the formation of propylene, result, individually, in increase of pressure in the system, and if the rate of one falls off, the increase in the rate of the other may balance it. The condensation process involves a decrease in volume; so that increase in the rate of formation of propylene, by packing a reaction tube, may have the result that the final volume of the system, at an apparent end point, is less when the tube is packed, than when the tube is empty. Thus all the results obtained by Mr. Hinshelwood and his colleagues are fully accounted for, and also the fact that, by relying on pressure measurements as a means of following the course of the main reaction, they have missed the fundamental fact that increase in surface materially decreases the rate of it.

When the rate of the main reaction is followed by means of the analytical method which has been fully described elsewhere, by measuring the rate of formation of methane, it is observed that in neither case does the rate of reaction diminish with time, as the classical theory demands. In the case of acetaldehyde it either increases slightly at first, or remains constant; but in the case of ethylene oxide, there is a marked induction period, during which the rate of reaction increases very quickly. In both cases, when the reaction has proceeded for a time, it suddenly slows down, and then again accelerates, continuing at a rate slower than the initial rate. The phenomenon is similar to that attributed by Mr. Hinshelwood to the existence of acetaldehyde molecules in different states of activation. However, the pressure measurement method does not reveal the exact nature of the phenomenon, since the rate graphs are not segmented.

but may rather be described as being looped, since the sudden reduction in the rate seems always to be followed by a rapid recovery.

It will now be clear that phenomena, which are generally accepted as criteria of chain mechanism, are observed in both cases. In the case of acetaldehyde, the initial rate of decomposition is considerable, and we must suppose that the main process is carried forward both by the formation of new primary centres, and to a very material extent by chain mechanism. In the case of ethylene oxide, the rate of formation of primary centres is obviously very small, and the main process is carried forward mainly through the operation of the chain mechanism. In this case, surface does not influence the rate of the main reaction.

In both cases the secondary process conforms to the main reaction, and when breaks occur in the graphs representing the latter, they also appear simultaneously in the graphs representing the former. It would appear therefore that the *breaking of chains*, at the walls or in the gas phase, does not merely involve the dispersal of energy, but also the formation of new primary centres, of the kind referred to by Semenoff as *degenerate*, from which the secondary process originates. Three-body collision must obviously play an important part in these processes.

We have made a further study of the influence of neutral gases, such as hydrogen and methane, on the rates of reaction. The phenomena are much more complex than was indicated by our first experiments. The work is being continued, and will, we hope, throw light on the phenomena associated with the breaks in the rate graphs.

This work, and investigation carried out with Mr. P. F. Gay on the thermal decomposition of dimethyl-ether into methane and formaldehyde, and other similar experiments, seem to be leading definitely to the conclusion that in all spontaneously occurring processes of this kind, the probability that the process will be continued by a chain mechanism is never zero. Semenoff has referred to the free energy of the process as giving a measure of the probability of the continuation of the process by chain mechanism. The term 'free energy' can only be used qualitatively, but so far as our work goes the principle seems to be well established.

Initial Formation of Methyl Alcohol in the Oxidation of Methane

ALTHOUGH a paper published about a year ago from our research laboratories, by Dr. D. M. Newitt and Mr. P. Z. Szego[1], described experiments in which large yields (up to 50 per cent of the theoretical) of methyl alcohol had been obtained by the slow reaction of methane–air mixtures at 430° and 50 atmospheres pressure, up to then no direct evidence had been obtained of its formation during the slow combustion of methane at atmospheric pressure.

Since then, however, further experiments by Dr. Newitt and Mr. J. B. Gardner have resulted in the isolation of methyl alcohol from the reaction products of a $2CH_4 + O_2$ mixture at 450° and atmospheric pressure, in contact with a porcelain surface, proof also being forthcoming of its formation preceding that of formaldehyde.

Such result led Dr. J. Bell to repeat some former experiments upon the explosions of a $5CH_4 + 2O_2$ mixture at initial pressure of about 50 atmospheres in a bomb (1 litre capacity), so arranged that the burning medium would be suddenly cooled by expansion after bursting a disc at a point (320 atmospheres) during the actual combustion period short of the maximum pressure of 430 atm., and that the cooled products would be retained in a large expansion chamber for subsequent analysis. Later examination of the suddenly cooled products has proved the presence therein of about 0·13 per cent of methyl alcohol and 0·03 per cent of formaldehyde, the alcohol having been isolated and identified as methyl 3 : 5 dinitro benzoate, m.p. 107·5°.

In none of the experiments referred to could even the faintest sign of 'peroxide' formation be detected.

Radioactivity of Oil-Waters in Czechoslovakia

PROF. V. J. VERNADSKY has directed attention to the investigations of Chlopin, Kurbatov[1] and other Russian scientific workers on the radium and meso-thorium content of the brine of the Russian oil districts. In general, the radium content was found to be much higher than the normal content of surface waters (10^{-15} gm. radium per gm. water). The maximum was found in the water of the oil beds of Novyj Groznyj in the Northern Caucasus, with $1{\cdot}46 \times 10^{-10}$ gm. radium per gm. water. In several places the mesothorium content was likewise considerably higher, though there were scarcely any traces of thorium.

Later, O. Hahn and H. J. Born[2] put forward the view that the high radium content of the waters of the oil beds would account for the occurrence of helium in sylvine, as the alkali chlorides form mixed crystals with lead. During its secondary formation, the sylvine might therefore receive the isotope of lead, radium D, from underground waters rich in radium.

In connexion with these questions and also to ascertain how far the higher radium content of the oil-waters depends upon the kind of oil and the place of its occurrence, a preliminary survey has been made of the radium content of the brine of two oil beds in Czechoslovakia, at Gbely (Slovakia) and at Jasina (Carpathian Ruthenia).

Technically important occurrences of naphtha and natural gas are found in Czechoslovakia only in the Carpathian system. Compared with the other Carpathian countries—Poland and Rumania—the naphtha resources of the country are at present neither so important nor so well explored (Fig. 1). We find here two types of naphtha beds: beds of a light paraffinic naphtha limited to the Carpathian flysh belt (Cretaceous and Palæogene beds), and beds of a heavy naphtha without paraffin and without asphalt, of the naphthenic series, occurring in the Neogene of the Vienna basin. Light naphtha is met with in Moravia at Bohuslavice nad Vlárou and at Ratiškovice, in Western Slovakia at Turzovka and at Popradné in the Trenčín district, in Eastern Slovakia at Komárník na Dukle, at Miková,

Krivá Olka and Radváň near Medzilaborce, in Carpathian Ruthenia at Luhy in the Užok Pass and at Jasina. Heavy naphtha forms far more important beds and it is extracted from the Sarmatian Cerithian beds at the State mines at Gbely in Slovakia and at the mines of the Moravian Company at Hodonín in Moravia. At Gbely exploitation began in 1914 shortly after the occurrence of naphtha had been discovered by chance.

The naphtha-b aring area has been explored since then by nearly four hundred borings, hand-borings as well as exploitation- and deep-borings. At Gbely, naphtha is exploited in two fields, in the so-called "old field" and in the new field opened up in 1929. There are two naphtha horizons in the Sarmatian beds, which are covered by the younger Congerian beds of the so-called Pontian. Quaternary sediments are well represented (diluvial gravel and sand, loess,

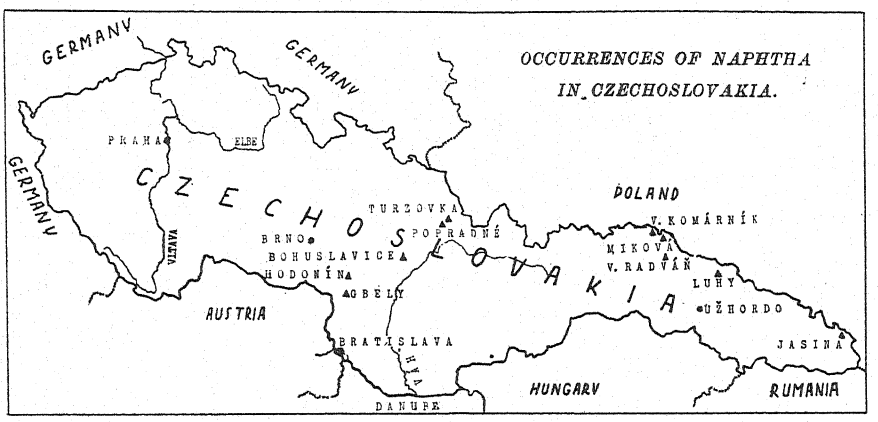

FIG. 1.

river deposits and quicksand). Several deep borings go down through the Sarmatian into the Second and First Mediterranean, the deep borings H_2 and H_6, with a depth of 986 metres and 1,420 metres respectively, going down even to the Palæogene. (For details of the geological structure, see, for example, L. Sommermeier, "Erdölgeologie der Tschechoslovakei", Höfer, "Das Erdöl", second edition.) In the experimental measurements of the radioactivity of the waters at Gbely, we studied samples taken from the water horizons in the diluvial, Pontian, Sarmatian and Mediterranean beds. Some of them are characterised by a fairly high content of iodine.

One of the samples from Jasina-Stebná examined with regard to its radioactivity came from a depth of 779–786 metres, from the experimental boring No. 1. This occurrence, which was studied last century to some extent by forty not very deep borings, when it yielded a small quantity of light naphtha, is situated in the Palæogene flysh beds. These beds are composed of variegated clays and sandstones of the lower Eocene and of slaty marls of the upper Eocene (the so-called upper hieroglyphic layers) and of menilitic slates and sandstones of the Oligocene.

The radium content was determined by measuring the emanation. The coefficient of repartition of the emanation was determined for oil waters and air. This coefficient does not differ much from the coefficient generally given for water (0·25 at a temperature of 20° C.).

The radium content of thirty samples from different borings at Gbely and one sample from a boring at Jasina (Carpathian Ruthenia) was determined. The samples of water came from different horizons and different depths (between 8·7 m. and 521 m.). The highest content of radium found was $7{\cdot}25 \times 10^{-10}$ gm. in one litre of water (the water from the horizon at a depth of 262 m.). Only eight samples of water had a radium content of the order of 10^{-10}, the others being of the order 10^{-12}–10^{-11}. No distinct correlation between the depth of the horizon and the radioactivity of the corresponding oil-water could be established; even from the greatest depths, activities of the order of 10^{-12} were established. From the experimental boring at Jasina the water from the horizon at 779–786 m. was examined with regard to its contents in radium; and it was found to be no higher than that of the waters from Gbely ($3{\cdot}8 \times 10^{-10}$ gm. in one litre). Waters from other borings at Jasina are also to be examined with regard to their radioactivity.

With turbid and polluted waters, the muddy particles were separated by filtration and the radium content was measured separately in the filtrate, but without obtaining any abnormally high values. An experiment was made by the Elster-Geitel method with the residue by evaporation from waters with radium content of the order 10^{-10} in one litre, so as to ascertain the nature of the radioactive elements the water contains. The presence of elements of the thorium series could not be proved. The content of radium elements is therefore much lower in the oil-waters of Czechoslovakia than in those of Russia.

Recoil by β-Decay

IF one investigates the recoil of a light nucleus by emission of an electron and a neutrino, it is important to consider that for a given direction of the electron the angular distribution of the neutrino is not isotropic. The details of the β-decay naturally depend on the assumptions made about the interaction between the heavy particle and the electron-neutrino field; in particular, they determine the energy distribution of the electron. But even if this distribution were known, apart from any theory, the recoil would still depend on the special form of the interaction energy, in so far as this form also determines the coupling between the directions of electron and neutrino. Such a coupling is a general consequence

of the theory of β-decay, although the wave-lengths have to be assumed to be large compared with the nuclear dimensions. In the case of the two forms of interaction proposed by Fermi[1] and Konopinski and Uhlenbeck[2] of the type (0,0) and (0,1) respectively[3], the coupling is due to the fact that the four amplitudes of the wave-functions depend on the direction of the particles. For the type (1,1) as well as in the case of higher derivatives, the coupling appears explicitly in the interaction energy.

For a given velocity v of the electron, the probability that it will be emitted within the solid angle $d\Omega$ under an angle δ against the direction of the neutrino, is in the three cases mentioned given by:

$$(0,0) : (1 + \frac{v}{c} \cos \delta) \frac{d\Omega}{4\pi}$$

$$(0,1) : (1 - \frac{v}{c} \cos \delta) \frac{d\Omega}{4\pi}$$

$$(1,1) : (1 - \frac{v^2}{c^2} \cos^2 \delta) (1 - \frac{v}{c} \cos \delta) \frac{d\Omega}{4\pi (1 - v^2/3c^2)}$$

Here we have neglected the Coulomb interaction between the nucleus and the electron; this is justifiable for small atomic numbers. Since for (0,0) (0,1) (1,1) it is most likely that the two particles will be emitted parallel, opposite or perpendicular to each other respectively, the recoil distribution will depend on which of the proposed forms of the interaction energy has to be accepted. Experiments on the β-recoil might thus enable a decision to be made between the alternatives.

Electrolytic Separation of the Oxygen Isotopes

WASHBURN and Urey[1] first directed attention to the fact that fractionation of the isotopes of oxygen occurs simultaneously with that of the hydrogen isotopes during the electrolysis of water. The electrolytic separation coefficient α for the oxygen isotopes has been determined in a series of experiments carried out in the Research Laboratories of Imperial Chemical Industries, Ltd., and was found to be 0·87 when using nickel electrodes and 1·25*N* NaOH as the electrolyte. This value is in good agreement with that of $\alpha = 0{\cdot}85$ calculated from the results of Washburn, Smith and Smith[2] who used nickel-plated cast iron electrodes—the electrolyte being 5*N* NaOH.

A sample of pure D_2O has recently been prepared, in which the oxygen isotope ratio has been adjusted to its normal value[3]. The density was found to be $d^{25°}_{25°} = 1{\cdot}1074$, which is lower than the value previously cited[4] of $d^{25°}_{25°} = 1{\cdot}1079$. If the difference is ascribed to concentration of oxygen isotope during the process of electrolysis, then it is possible to calculate an approximate value for the oxygen isotope separation coefficient α, and this is found to be 0·84. The separation coefficient probably depends to a certain extent on the electrode material and the nature of the electrolyte, for Johnston[5], using iron electrodes and caustic potash solution as the electrolyte, obtains a value of α of $0{\cdot}992 \pm 0{\cdot}003$.

It is possible to arrive at a theoretical value for α if the assumption is made that whatever the mechanism of electrolysis, the rate-determining step is the passage of a $O^{18}H$ or $O^{16}H$ complex over or through an energy barrier. Previously, it has been assumed that the possibility of 'tunnelling' by particles of mass greater than 2 would be so small as to be negligible. Actually, it can be shown using a modification of the method applied by Ogden and Bawn[6] to the hydrogen isotopes, that there is a small but quite definite probability for the 'tunnelling' of energy barriers by complexes such as $O^{16}H$ and $O^{18}H$. From these considerations it can be shown that α has values lying between 0·86 and 1, depending on the width and height of the energy barrier.

Taking the most favourable value for α, the oxygen isotope O^{18} concentration in pure D_2O, prepared by electrolytic methods, can never be more than about 0·6 per cent, that is, while the concentration of deuterium increases from about 1/5,500 to 100 per cent, the oxygen isotope concentration only increases from 0·15 per cent to 0·6 per cent.

I am indebted to the directors of Imperial Chemical Industries, Ltd., for permission to publish this note.

Chemistry of Œstrogenic Substances

WE have reported that we were unable to obtain any evidence of œstrogenic activity in rats with benzylidenepyruvic acid and furylidenepyruvic acid or their sodium salts[1]. These negative results were attributed by Friedmann[2] to the use of insufficient doses (100 mgm. per rat), and to an unsuitable spacing of the doses. Friedmann predicted that 240 mgm. of dry sodium salts would be sufficient to produce œstrus in rats, and claimed to have obtained œstrus in mice with 24 mgm., injected in three doses at intervals of 24 hours.

We have carried out further experiments using both rats and mice. Five ovariectomised rats, which had been shown to respond normally to œstrone, were each given subcutaneous injections of 300 mgm. of sodium benzylidenepyruvate dissolved in 3 c.c. of water, the injections being spaced over three days. Three rats died on the third day of the test, one on the fourth day, and neither these nor the surviving rat showed any sign of œstrus.

The mice used in our tests were pure strain 'Simpson' mice, all of which, after castration, gave a full œstrous response with 0·2γ of œstrone. Ten mice were injected with sodium benzylidenepyruvate, and ten with sodium furylidenepyruvate. Each animal received three subcutaneous injections, at 24-hour intervals, of 8 mgm. of the sodium salt, dissolved in 0·25 c.c. of normal saline. Thus, the total dose was 24 mgm. per mouse. Vaginal smears were examined twice a day for 72 hours following the last injection, and then daily for four days. Although the injections produced considerable

necrosis, 18 mice survived the whole experiment (9 in the case of each compound), and none of these showed the slightest suggestion of œstrous response.

These results give no support to Friedmann's claim that the compounds in question have œstrogenic properties.

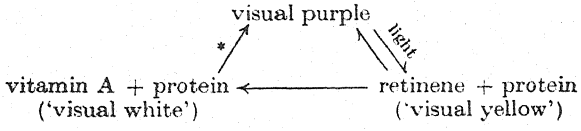
The Visual Purple System in Marine Fishes

I HAVE recently examined the eye tissues of the sea robin (*Prionotus carolinus*), the black sea bass (*Centropristes striatus*), and the porgy or scup (*Stenotomus chrysops*). The visual purple system in these animals is identical chemically with that in frogs[1]. It is described partly by the equations:



All of these reactions but the one starred occur in the isolated retina as well as in the intact eye.

The results of an experiment with scup retinas, typical for the other forms also, are shown in Fig. 1. Right and left retinas of five dark-adapted scup were prepared separately. One set of five retinas was extracted thoroughly in the dark with benzine. The extract, tested with antimony trichloride reagent, yielded a blue colour of which the lower curve is the absorption spectrum. The dark adapted retina contains a small quantity of vitamin A alone (615 mμ chromogen).

The same retinas were bleached to an orange colour ('visual yellow') in bright light, and immediately re-extracted with benzine. The extract, tested as before, yielded the upper left curve. Light, in bleaching the visual purple to yellow, liberates a large quantity of retinene (664 mμ chromogen).

The second set of five retinas was bleached and left for an hour at room temperature before being extracted with benzine. During this period the visual yellow faded to colourlessness ('visual white'). The extract yielded the upper right curve of the figure. Retinene liberated by light is eventually converted quantitatively to vitamin A.

Köttgen and Abelsdorff[2] found the absorption spectrum of visual purple from eight species of fresh-water fishes to have a maximum at about 540 mμ; while that from amphibia, owls and mammals was of the same general form, but displaced so that the maximum occurred at about 500 mμ. This spectral peculiarity, if general, might have made an examination of fish retinal processes of special interest. However, the absorption spectra of visual purple from the species used in the present experiments are practically identical with that from frogs, the maxima falling in every case at about 500 mμ. The nature of the possible disagreement between these and previous data[2] is being investigated.

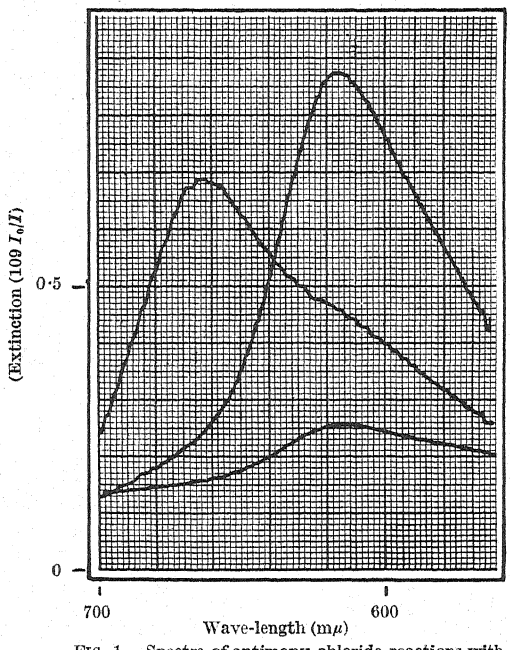


FIG. 1. Spectra of antimony chloride reactions with scup retinas, recorded automatically with a photo-electric spectrophotometer at the Massachusetts Institute of Technology (Hardy, A. C., *J. Opt. Soc. Amer.*, **25**, 305; 1935).

The combined pigment epithelium and choroid layer of these eyes contain vitamin A, an unidentified xanthophyll and flavine.

Details of this work will appear in the *Journal of General Physiology*.

Oxidative Inactivation of Co-zymase with Schardinger Enzyme Preparations

IN continuation of experiments showing that a reversible oxidative inactivation of glycolysis or fermentation (Pasteur reaction) may take place[1], the action of Schardinger enzyme (xanthine oxidase) on fermentation was tried. Schardinger enzyme was prepared from milk by the method described by M. Dixon and Kodama[2] or that due to Toyama[3]. In a mixture of such a milk preparation and yeast macerate (Lebedew) a considerable inhibition of fermentation appears after shaking with oxygen for about 1–1½ hours. In the absence of oxygen, no appreciable inhibition appears in this time.

Fig. 1 shows the results of an experiment in which, before the addition of glucose, the mixture was shaken for 1½ hours with oxygen and nitrogen

respectively. Removal of the oxygen did not restore fermentation. Fermentation recommenced, however, upon addition of a small amount of boiled yeast macerate, or of highly purified co-zymase, for which I am indebted to Prof. von Euler. The oxidation of the nucleotide part of the co-zymase seems very improbable, because Dixon and Lemberg[4] have shown that nucleotides, and also crude co-zymase preparations, are attacked by xanthine oxidase only after hydrolysis by an enzyme contained in the milk

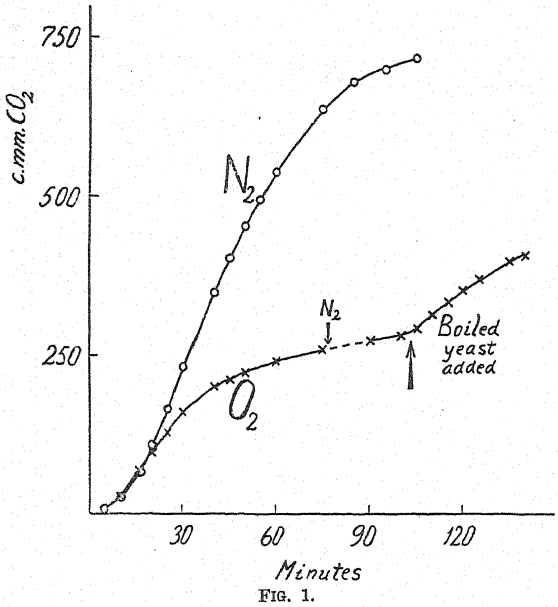

FIG. 1.

preparations. Although the real nature of the oxidative inactivation of co-zymase is not clear, the catalysis of the process by an enzymatic system appears to be of interest in connexion with the mechanism of the Pasteur reaction.

The present report of results, in this stage, is due to the very recent appearance of a publication by B. Andersson[5] from Prof. von Euler's laboratory, also dealing with the action of Schardinger enzyme on co-zymase.

Adsorption of Grass and Butter Carotenes on Alumina

WE have recently reported that the petrol-phasic carotenoid fraction of butter unsaponifiable matter, when subjected to chromatographic adsorption on alumina, separates readily into two coloured zones, the upper red-brown, the lower yellow[1]. The appearance and location of the zones, and the absorption spectra of the elutriated pigments, are consistent with the presence of appreciable quantities of α-carotene in butter. The α-isomer has since been independently detected in butter[2], using magnesium oxide as adsorbent.

A re-examination, however, of the adsorption of butter carotene on each of these two adsorbents shows that alumina gives an apparent α-carotene content much greater than does magnesium oxide.

In studying these anomalous results, we carried out adsorption experiments on pure β-carotene itself, the specimen used (*ex* cocksfoot grass; m.p. 180°–182°; rotation nil) being made available through the kindness of Prof. A. C. Chibnall. When this material is submitted to adsorption on alumina (Brockmann's, *ex* Merck, diluted 1 in 3 with inactive alumina), petroleum ether (b.p. 70°–80°) being used as solvent, the adsorbed pigment appears to be homogeneous. If, however, the carotene is washed off the adsorbent with petrol (or elutriated with methyl alcohol), recovered, and readsorbed, it separates clearly into two zones of pigment, the absorption maxima of which, on elutriation, are as follows:

Upper zone	483	452 mμ	in petroleum ether (b.p. 70°–80°);
Lower zone	477	447 mμ	

that is, identical with those of β- and α-carotene respectively. The lower zone thus contains a pigment formed during the adsorption process, and moreover, elutriation and readsorption of *either* of the two zones gives another separation into two zones with properties as before, on each subsequent adsorption, the process thus being reversible and never complete.

Calcium hydroxide, which separates α- and β-carotenes[3], also converts pure β-carotene into this yellow substance, but not so readily as does alumina. Magnesium oxide, also used for separating α- and β-carotenes[4], gives no evidence of separation of pure β-carotene into two zones even after four adsorptions. Further, carotene made separable by alumina or calcium hydroxide adsorption is apparently homogeneous when adsorbed on magnesium oxide.

The change has been obtained with pure crystalline β-carotene from both grass and carrots and also with the petrol-phasic carotenoid fractions of butter[1] and blood serum[5]. In the last two cases the pigment separated readily with one adsorption, whilst with the purified pigments a preliminary adsorption was necessary before the separation was evident.

Genuine α-carotene *ex* palm oil[6] has also been examined. Repeated adsorption on alumina changes this pigment also, giving two zones which, on elutriation, exhibit absorption maxima as follows:

Upper zone (α-carotene ?)	477	447·5 mμ	in petrol (b.p. 70°–80°).
Lower zone	469	440 mμ	

This second substance on readsorption suffers partial reversion, again giving two zones of pigment with absorption maxima as just stated. The absorption maxima characteristic of the lower zone are closely comparable with those already reported, for a yellow substance occurring in small quantity at the bottom of the column, when α- and β-carotene mixtures are adsorbed on calcium hydroxide[3].

It might appear that on repeated adsorption β-carotene undergoes a *reversible* change into the α form, but the observation that genuine α-carotene changes into a substance with absorption maxima at shorter instead of longer wave-lengths makes this unlikely.

Whatever the explanation of the foregoing observations, which we are now investigating further, it is

clear that, *following the usual procedure* for the chromatographic technique, carotene undergoes change into another pigment when repeatedly adsorbed on alumina, even when oxygen is rigorously excluded.

In view of the widespread and successful use of chromatographic methods[7] in the carotenoid field, it is important that the possibility should be recognised that changes can occasionally be brought about by the process itself.

Plasticity of Bismuth

IN an earlier letter[1] one of us (W. F. B.) tried to explain the discrepancies which exist concerning the plasticity of bismuth. It was confirmed that crystals obtained by different methods behave quite differently; for example, that soft crystals, that is, crystals which slip in tensile tests at room temperature, occur among those made in air (Czochralski method), whereas only hard crystals are obtained *in vacuo* (Bridgman method). Since the crystals made under atmospheric pressure were found to contain some gas, it was suggested that the gas was responsible for their softness. Hard crystals made *in vacuo* were found to slip in compression tests at room temperature and in tensile tests at higher temperatures[2]. Experiments by Gough[3] and by Andrade and Roscoe[4] seem to support these findings.

Since the difference mentioned above is not the only one in making the crystals, it was desirable to apply a method which would allow the crystals to be grown *in vacuo* or under pressure while keeping all other factors constant. A method devised by Andrade and Roscoe[4] has been found suitable for this purpose. In it a furnace travels horizontally along a wide glass tube, in which lies a thin piece of wire to be made into a single crystal. The glass tube can be evacuated or filled with gas. By this method it is easy to get crystals of any desired orientation by using a seed crystal.

The wires used were 1–2 mm. in diameter and were obtained by casting *in vacuo*, to be sure that they were free of gas. The material was (1) that used in the earlier experiments, (2) Hilger's spectroscopically pure Bi No. 9506, the same material, we understand, as used by Andrade and Roscoe[5]. Crystals were grown from (1) *in vacuo*, and in nitrogen, hydrogen, carbon dioxide; from (2) *in vacuo* only. The rate of growth was 1·6 mm./min.

Under all conditions some of the crystals obtained were soft. So far as the experiments on crystals grown under atmospheric pressure are concerned, these results are a qualitative confirmation of those of Georgieff and Schmid[6], since their crystals, obtained by the Czochralski method, contained gas. We consider the fact that crystals grown *in vacuo* show a similar behaviour, goes beyond their results, and it also seems at variance with the results of Andrade and Roscoe[5]. It remains to be seen whether the conformity of the crystals grown in gas and *in vacuo* is a quantitative one. We believe that the crystals made in vacuum exhibit the 'true behaviour' of bismuth, because the Andrade method seems the least objectionable of all. Any hard crystals found could be explained by unsuitable orientation[6]. Thus the gas content seems to have little influence, and another explanation has to be found to show why bismuth crystals grown by Bridgman's method are hard. Here the material is cast into glass tubes and remains there while solidifying. Owing to the well-known anomalous behaviour of bismuth, it seems possible that it becomes subject to heavy stresses from the surrounding glass while cooling under such conditions. We have confirmed the fact, already stated by Gough and Cox[7], that one seldom finds a bismuth crystal obtained by this method which does not show mechanical twinning. It thus appears likely that the hardness of such crystals is but another example of strain hardening.

[7] *J. Inst. Metals*, **48**, 227; 1932.

DR. BERG has invited me to comment in print upon an earlier version of the above letter. In view of the somewhat contradictory nature of the findings communicated in his last two letters on the subject, I think that any attempt to estimate how far he has gone beyond Georgieff and Schmid may well await his final results, which will, no doubt, be shortly published with due circumstance in one of the technical journals. I have been unsuccessful in a private attempt to make Dr. Berg understand what I consider to be the significance of our results on bismuth, and I do not think that it would be profitable to renew the attempt in public. The letter does, however, contain one fact, previously unknown to me, which I note with interest, namely, that Dr. Berg has found useful our technique for growing strain-free single crystals*, which we had the pleasure of demonstrating to him in detail when he paid a personal visit to our laboratory last year.

Coalescence in Stages between Two Drops of a Liquid

IN a letter in NATURE of August 3[1], Ian W. Wark and Alwyn B. Cox record their observation that "Small drops directed obliquely on to the surface of tap water do not immediately coalesce with it", and they suggest that the reason for this lies in the contamination of the surface by a thin film of grease or dust.

So far as one can see from this short description, the phenomenon seems to be identical with, or similar

to, that which I described a few years ago[2]. If a fine jet of water issuing from a fine nozzle with a moderate velocity reaches the surface of tap or distilled water in its instability range, it is resolved into many floating drops which last about three seconds. I noticed that the chief condition for the success of the experiment was the freshness and cleanness of the water used. Even the least trace of grease, for example, the very touch of the surface with the fingers, lessened the range and life of the drops, or even made success impossible. In so far as the same phenomenon is in question, the interpretation of the above-mentioned authors is opposed to these observations of mine.

Cytoplasmic Bodies in the Oogenesis of *Lumbricus*

BY those[1] who have worked on the oogenesis of *Lumbricus* or allied forms, the vitellogenesis is believed to be one of the simplest known, though there is no general agreement.

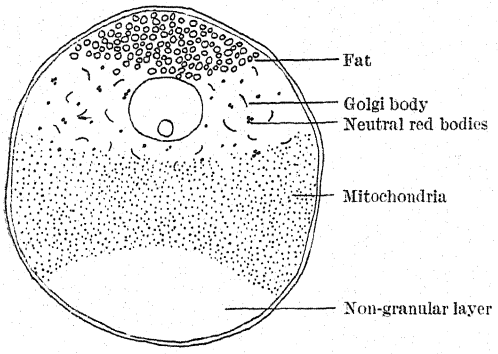

FIG. 1.

We have recently used the Beams' ultra-centrifuge on these eggs, and our findings are as follow. The cytoplasmic granules form a number of layers, consisting of fat granules above, Golgi elements below and in the region of the nucleus, mitochondria lower still, and the lowermost layer formed of a homogeneous and non-granular substance, as shown in the semi-diagrammatic reproduction (Fig. 1). The mitochondria are granular, not filamentous. No protein yolk could be found, and the larger granules to be seen so clearly in the living eggs are fat, not Golgi bodies; when previously stained supra-vitally in neutral red, before centrifuging, the globules so produced take up a position mainly between the fat and the mitochondria, that is the region where the dictyosomes of the Golgi apparatus come to lie.

Age of the Universe

SIR JAMES JEANS has recently pointed out[1] that observations of binary stars indicate 10^{13} years as the order of age of the universe, while the recession of the nebulæ, indicated by their spectral shift, suggests an age of the order of 10^{10} years.

In a recent publication[2], however, we have shown how the spectral shifts may be accounted for by a variation with time of certain electrical and quantum quantities; this allows a way out of the difficulty. In order to measure times over long periods, one must define a standard for measuring time intervals at different epochs; such a standard might depend either on gravitational or electrical measurements, and the two systems, though by definition agreeing now, might differ in the results for a period of time in the past. Thus the age of the universe might well be 10^{13} years when measured in terms of a gravitational definition of the year, and at the same time 10^{10} years when measured in terms of an electrical definition of the year. The apparent discrepancy now becomes a way of determining the relative values of electrical and gravitational phenomena in the past.

The Spectrum of γ Cassiopeiæ

ON and since October 7, a very strong and very sharp absorption line, the strongest and sharpest absorption line in the whole spectrum, suddenly appeared in the spectrum of γ Cassiopeiæ. This line is nearly coincident in position with that which should be occupied by the bright violet component of Hζ. On receiving this information, Prof. A. Fowler has suggested that it is probably the neutral line of helium (λ 3888·646) intensity 10, this line being the strongest line of the principal series of the triplet system. The next line in this series is at λ 3187·743 (intensity 8), but this falls outside the region photographed at Sidmouth, so its presence cannot be ascertained.

In view of the other important changes in the spectrum to which I have recently directed attention, the spectrum evidently needs careful watching for further variations.

Fossil Human Occipital Bone from Thames Gravels

UNDER "News and Views" in NATURE of October 19, page 638, the discovery at Swanscombe of a human skull fragment by Mr. Marsden is recorded and the note says, *inter alia*, "The bone was associated with Acheulean flint implements". We should like to put on record that in our experience the middle gravel of the 100-ft. terrace, in which the bone was found, contains, in addition to Acheulean hand-axes and flake tools, artefacts of Clacton III type closely resembling those of High Lodge, and also a few flakes exhibiting a Levalloisian technique.

Both of us have been privileged to examine the actual spot where the skull fragment was found, and we can record that at the horizon in question unabraided Clactonian flakes and tools are almost as common as Acheulean ones.

Recrystallisation accompanying an Allotropic Change

DR. W. G. BURGERS and Dr. van Amstel are to be congratulated on their success in obtaining a cinematograph record of the $\alpha \rightleftarrows \gamma$ change in iron by the very beautiful method they describe in NATURE of November 2 (136, 721). Their photographs show that recrystallisation at an allotropic change point is similar to that occurring on heating coldworked metal. Some years ago, in order to settle this same point, I examined a number of salts which undergo allotropic changes of a similar character. Ammonium, potassium and silver nitrates are particularly suitable as they can be melted on a slide and, if crossed Nicol prisms are used, the whole process can be studied. In every case the change began at the crystal boundaries or round an inclusion or blow-hole, by the appearance of new crystal nuclei which rapidly spread across the field. I then found that the rate of change could be slowed down by the presence of a cover-slip and by regulating the thickness of the fused salt, and obtained a series of photographs—some of them in colour—illustrating the change over.

Points from Foregoing Letters

Mass spectrograms of platinum and platinum–iridium alloy obtained by means of a high-frequency spark are submitted by Prof. A. J. Dempster. They confirm the existence of two iridium isotopes of mass numbers 191 and 193, the existence of which was recently deduced by Venkatesachar and Sibaiya from the arc spectrum of iridium. These two isotopes fill the only gaps in the mass number scale in this region.

Prof. M. W. Travers discusses the processes involved in the thermal decomposition of acetaldehyde and of ethylene oxide, concerning the mechanism of which a divergence of opinion exists. Prof. Travers claims that additional experiments support his view that the reactions depend upon the surface of the system and that they involve a 'chain' mechanism.

The detection by Dr. J. Bell of small amounts of methyl alcohol (0·13 per cent) and of formaldehyde (0·03 per cent) in the suddenly cooled products of the explosion of a methane-oxygen mixture is reported by Prof. W. A. Bone.

The radioactivity of oil-waters from Czechoslovakia has been measured by Prof. F. Běhounek, V. Santholzer and Prof. F. Ulrich. The highest content of radium found is $7{\cdot}25 \times 10^{-10}$ gm. in one litre of water, from a depth of 262 metres. This is much lower than the radioactivity reported by Vernadsky from oil-waters in the Northern Caucasus ($1{\cdot}46 \times 10^{-7}$ gm. per litre).

In order to account for the production of electrons of different energies by radioactive elements, some physicists have been led to postulate the simultaneous emission of neutrinos, which are uncharged particles of mass comparable with that of the electron. Drs. F. Bloch and C. Møller discuss the probable relation between the direction of emission of the electron and that of the neutrino.

The electrolytic separation coefficient for the isotopes of oxygen is found by Geoffrey Ogden to lie between 0·86 and 1·0, depending on the width and height of the energy barrier, and taking into account the possibility of 'tunnelling' of the barrier by the $O^{16}H$ or $O^{18}H$ complex. This range of values is in good agreement with the available experimental results.

Further experiments on the chemical changes taking place in the retina, connected with the visual purple system, are reported by G. Wald. He finds that in the retina of fishes, as in that of frogs, the following cycle occurs: visual purple → retinene → vitamin A → visual purple.

In connexion with processes that may affect the glycogen → lactic acid fermentation (Pasteur reaction), Dr. F. Lipmann reports that an inhibition of fermentation takes place when yeast macerate is mixed with a milk preparation containing xanthine oxidase (Schardinger enzyme), in the presence of oxygen. Fermentation recommences upon addition of boiled yeast macerate or purified co-zymase.

A. E. Gillam and M. S. El Ridi present evidence to show that, when pure β-carotene from grass is twice adsorbed on alumina, it changes partially into a substance similar to α-carotene. The process is reversible, as this substance on readsorption reverts in part to the original β form. Genuine α-carotene is also changed under these conditions, and it is therefore important to recognise that surface adsorption can itself change certain pigments as well as separate them (chromatographic adsorption).

Applying the method of Andrade and Roscoe for growing metal crystals under atmospheric pressure or *in vacuo*, leaving all other factors constant, Dr. W. F. Berg and L. Sandler show that bismuth crystals, which slip in tensile tests at room temperature, can be obtained in gas and *in vacuo*. The hypothesis that gas was responsible for the softness of bismuth crystals, put forward by Dr. Berg in an earlier letter, is now withdrawn. The hardness of bismuth crystals obtained by Bridgman's method is tentatively explained as strain hardening.

A diagram showing the order in which the various constituents of the egg of the earthworm (*Lumbricus*) arrange themselves under the influence of a strong centrifugal force is given by Miss Gertrude Norminton and Prof. J. Brontë Gatenby. No protein yolk could be found, though yolk formation is believed by some to be one of the simplest of life processes.

Dr. J. A. and Mr. B. Chalmers claim that the discrepancy between the age of the universe deduced from the 'reddening' of the light from nebulæ (10^{10} years) and that computed from observations of binary stars (which indicate a period a thousand times greater) may be simply explained by a change in the time standard at different epochs, since the standard may depend upon gravitational and electrical factors.

Research Items

Alaskan Archæology

DR. ALEŠ HRDLIČKA, the Smithsonian Institution of Washington, D.C., reports, has recently returned from his fourth successive season of excavation on a habitation site on Kodiak Island, off the coast of Alaska. He is more than ever convinced that this is one of the key sites of North American archæology. It covers four acres, and in places the deposits are more than sixteen feet in depth. At least one more season is required to complete the excavation; and judging from the manner in which new and disturbing factors have occurred unexpectedly in the exploration of previous years, Dr. Hrdlička regards it as unsafe at present to draw anything but the most tentative conclusions in the interpretation of the evidence. As the result, however, of a personal examination of the prehistoric evidence from British Columbia, he is convinced that the peoples of Kodiak and the British Columbia coastal area are identical in physique and culture. The Kodiak culture in its earliest phase is dated at approximately two thousand years ago. Only shortly before did the island become inhabitable, owing to the shrinkage of glaciers. The glacial period was followed by a deposit of loess on the glacial till, and it was on this loess that the first settlement took place. The first settlement was of brief duration, the people possibly migrating to the north-west coast. A further deposit of four or five inches of loess was succeeded by a period of pluviation, which covered the island with vegetation; and from this time forward, it was inhabited continuously until about the time of the coming of the Russians, when it was abandoned. For about the last fifth of this occupation the island was inhabited by people of Aleut type who had massacred the older inhabitants. In all the periods of the older occupation there was a relatively high type of culture, the oldest being in some respects the most advanced. It was in this earliest period that carving in wood, bone and ivory flourished, most characteristic being a realistic form of portraiture, in which one specimen shows the feature, rare among North American indigenes, of a chin beard.

Elasmobranchs from Puget Sound

WHILST collecting on the shrimp trawler *Audrey*, Allan C. DeLacy and Wilbert M. Chapman captured some interesting adult elasmobranchs and egg-cases (*Copeia*, No. 2, 1935). Egg-cases of *Apristurus brunneus* were taken from the female, and others were found attached by their tendrils to a sea-whip, *Stylatula*. The adult is little known, but twenty-two specimens were taken by the *Audrey* in Saratoga Passage and along the east side of Camano Island. Other egg-cases described are those of *Raja rhina*, taken abundantly off Everett and a few from the San Juan Islands, and *Raja binoculata* from the latter locality, taken commonly throughout the summer. Two young skates of *R. binoculata* measured shortly after they had hatched from an egg-case in an aquarium were 194 mm. and 197 mm. in total length respectively. Egg-cases of the ratfish, *Hydrolagus colliei*, were also common, the length ranging from 114 mm. to 140 mm. A tendril 120 mm. long was seen on one freshly deposited case. The cases were always empty, or contained undeveloped eggs. In one instance, the trawl brought up a female ratfish to which the egg-cases were still attached by their long anterior filament. Embryos of *Squalus neckleyi* were examined, and here the eggs in the Müllerian duct are enclosed in a long tubular case, transparent, flexible and entirely smooth, which ends in a single horn bearing a tendril which in one specimen was 70 mm. long. When the embryos have developed to a size not exactly known, the egg-case is resorbed or sloughed off, and the embryos continue their development in the Müllerian duct, which is abundantly supplied with large blood vessels and has, dependent from the inner side, innumerable small platelets also liberally supplied with blood vessels. When the yolk has been completely absorbed, the young dogfish are born alive. 1–4 eggs may be enclosed in one case.

Japanese Freshwater Cladocera

DR. MASUZO UÉNO, following his first paper (1927, in the same periodical), continues his study of the freshwater Branchiopoda of Japan in three further papers (*Mem. Coll. Sci., Kyoto Imp. Univ., B*, 8, No. 3, 1933; 9, No. 4, 1934). Many lakes and ponds have been investigated in various localities. Only eighteen species of *Cladocera* have been found in the waters round Hokkaidô, *Daphnia longispina* and *Bosmina coregoni* showing the widest range of distribution. The second paper deals with *Daphnia pulex* and *D. longispina*; the latter in a small oligotrophic pond in Kyoto was observed for two years, with the result that two maxima occurred in each year, a conspicuous one in April, and a weak one in autumn. Such a type of seasonal succession in the genus has never been observed in European waters. The rate of growth is greatest in early spring, falling towards summer, and again increasing markedly in autumn. Accordingly the animals are small in size during the summer months, though there was seen no distinct seasonal change in shape from spring to winter. The population was dicyclic in the first year and monocyclic in the second year. The production of males or ephippial females were conspicuously scarce, and the number of parthenogenetic eggs markedly decreases before the commencement of sexual periods, the males always occurring shortly after an extreme maximum of the population. In the third paper it is shown that the local variation of this species is greater than in the other species, its external appearance differing much from lake to lake.

Abdominal Mechanisms of a Grasshopper

UNDER the foregoing title, Mr. R. E. Snodgrass, of the U.S. Bureau of Entomology, has written a memoir which forms a natural sequence to his earlier study entitled "The Thoracic Mechanism of a Grasshopper". The present contribution forms No. 6, vol. 94 of the Smithsonian Miscellaneous Collections (Sept., 1935). The primary object of the work has been to arrive at an understanding of the mechanisms of copulation and oviposition in the family Acrididæ,

which presents various peculiar features. It is, in fact, a study in functional morphology, and consequently very full consideration is given to the musculature of the abdomen and its associated organs. Following this, the ovipositor and its related parts are treated in detail and likewise the male genitalia. The general title of the paper is, perhaps, too restricted in its implication since it comprises a survey of abdominal organs in the main groups of the Acridiidæ. Like all Mr. Snodgrass's contributions, the work is the result of its author's first-hand study, and is illustrated by numerous excellent text-figures. Space does not admit of any discussion of the author's conclusions and theories; it will serve here to direct the attention of morphologists to a contribution of major importance.

Bombay Grasses

SINCE the publication of the "Flora of Bombay" (1903), many additions have been made to the grass flora of the Presidency, and there have been many changes in generic concepts. In a recent volume (Imp. Council Agric. Research; Scientific Monograph No. 5, 1935) Blatter and McCann have brought up to date the systematic account of the Gramineæ of this area. More than three hundred species belonging to 110 genera are described, and many are illustrated. In the definition and sequence of the tribes, the authors have followed Stapf. Full descriptions of the species are supplemented by vernacular names, notes on etymology, ecology, economic uses and distribution. Keys are given for the genera and species.

The Ranges of Eastern Siberia

MUCH new light on the Yablonovi and Stanovoi and associated ranges of eastern Siberia has been shed in recent years by the work of Russian travellers. This is expounded by Prof. V. A. Obruchev in an article in the *Geographical Journal* of November. Most older maps showed these ranges as marking a continuous divide between the Arctic and Pacific drainage from Mongolia to Bering Strait. Kropotkin, however, separated the two and made the Stanovoi a continuation of the Great Khingan Range. It would now appear that the Yablonovi, which is in the main a faulted horst of crystalline and metamorphic rocks, consists of more than one range, and only in its middle part takes the form of a step between the higher plateau to the west and the lower to the east. On the south it begins about the Chikoi River and on the north it seems to end about the Olekma River. The Stanovoi, on the other hand, is a much longer range beginning at Lake Baikal in the south but not forming a main drainage divide between Arctic and Pacific north of about lat. 60° N. It then curves inland to the north and north-west and cuts off the distinctive north-west and south-east ranges of the extreme east of Siberia. In structure, the Stanovoi is complicated, but the present relief is due mainly to faulting in metamorphic and other ancient rocks, and the formation of a series of horsts and troughs, the former dissected into numerous peaks.

Tokyo Earthquakes in 1934

IN four *Seismometrical Reports* issued by the Earthquake Research Institute, lists are given of the earthquakes felt in Tokyo during the year 1934. Within about eighty miles of the capital, there is a network of fourteen stations, the records at which enable the position of a focus to be determined. During the year, 64 earthquakes were sensible in Tokyo, a number slightly above the annual average, none of them of destructive intensity and one only (in the Idu peninsula) strong enough to throw down vases, etc. Most of the epicentres lie on land to the north of Tokyo Bay, but 2 are under Sagami Bay and 14 beneath the Pacific Ocean and within 45 miles from the coast. In 56 of the earthquakes, the depth of the focus is estimated, ranging from $2\frac{1}{2}$ to 50 miles, with an average of 30 miles.

Turbulence of the Lower Atmosphere

Geophysical Memoir No. 65 of the Meteorological Office is an account of valuable experiments made in 1931–33 on various aspects of turbulence in the layer of atmosphere nearest to the ground, by A. C. Best, under the title "Transfer of Heat and Momentum in the Lowest Layers of the Atmosphere". The experiments were carried out on a ridge of high ground on the south-eastern edge of Salisbury Plain. The instrumental equipment included apparatus for determining the difference of temperature over various height intervals, the lowest layer extending from 2·5 cm. to 30 cm. and the highest from 7·1 metres to 17·1 metres. Thermo-electric couples were used for the lower intervals; these were housed inside concentric tubular nickel-plated brass radiation shields provided with aspiration pipes leading to an electric fan. For the study of the vertical gradient of wind velocity near the ground, air meters of the conventional vane type were used, also special low-speed meters calibrated for velocities as low as 0·3 metres per sec., and a hot wire anemometer that was specially designed for this investigation in order that wind measurements could be made 2·5 cm. above the ground. To those unfamiliar with conditions very near to the ground in clear weather, some of the figures are likely to prove startling, as for example, those giving the absolute extremes of temperature difference between heights of 2·5 cm. and 30 cm., which include a lapse of 10·8° F. on a sunny morning in May and an inversion of 11° F. between the same heights during a night of clear sky in March. The former figure is about 2,000 times the dry adiabatic gradient, a rather larger ratio than has been deduced by D. Brunt as the maximum possible for stable conditions, but Brunt's formula was well supported by the rather lower extremes obtained for hourly means of temperature difference.

Combined Alternating Stresses

A PAPER entitled "The Strength of Metals under Combined Alternating Stresses" was read to the Institution of Mechanical Engineers by Dr. H. J. Gough and Mr. H. V. Pollard, of the Engineering Department, National Physical Laboratory, on November 1. It describes a research, by means of a specially designed high-speed testing machine, into the resistance of metals under combined alternating plane flexural and torsional stresses. A comprehensive study was made of three materials—a normalised 0·1 per cent carbon steel, a heat-treated 3·5 per cent nickel-chromium steel and a silicon cast iron—which were subjected to plane bending stress, torsional stress and five combinations of these. The results showed a simple relation

$$f^2/f_1^2 + q^2/q_1^2 = 1$$

to exist, where f and q represent the bending and

torsional stresses at the fatigue limit due to the applied load, while f_1 and q_1 denote the fatigue limits of stress under simple bending and torsion respectively. It is proposed to apply similar tests to a wide range of steels but, meantime, the authors are of the opinion that "until data for other metals become available it appears unlikely that any serious error would be involved in estimating the fatigue resistance of ductile metals to combined stresses by the use of this equation and the experimentally determined values of f_1 and q_1". The specimens of ductile steel yielded no data regarding the plane on which failure first occurs, whereas the cast iron specimens exhibited close agreement between the fracture plane and that of greatest principal stress.

X-Ray Study of Substituted Edingtonites

In a paper read before the Mineralogical Society on November 14, W. H. Taylor described an X-ray examination of substituted edingtonites. X-ray investigations of base-exchange products of analcime and natrolite have shown that a monovalent ion like silver takes up the exact position previously occupied by the sodium ion which it replaces. Each divalent barium ion of edingtonite $Ba_2Al_4Si_6O_{20}.8H_2O$ is replaced, however, by two monovalent ions. X-ray work on the thallium compound $Tl_4Al_4Si_6O_{20}.8H_2O$ shows that there is no essential change in the framework of (SiO_4) and (AlO_4) tetrahedron-chains lying parallel to the *c*-axis. The four thallium ions are, however, distributed uniformly among six possible positions made up of a two-fold group and a four-fold group. Of the six possible positions, two are near the positions occupied by barium ions in the mineral edingtonite, the remaining four (one half occupied) are as far distant as possible from other positive ions—thallium, silicon and aluminium. A study of potassium edingtonite yields an almost identical distribution for the potassium ions; small differences in distribution are probably due to incomplete replacement of the barium ions. The observed arrangement of cations satisfies the condition of a uniform distribution of residual valency.

Concentration Cell in Quantitative Analysis

A rapid and accurate electrometric technique for the determination of small amounts of substances which may occur in salts has been worked out by N. H. Furman and G. W. Low (*J. Amer. Chem. Soc.*, **57**, 1585; 1935) and applied to the determination of small amounts of chloride. It depends on the use of a concentration cell with silver – silver chloride electrodes. The cell is very simple in construction and the results are comparable in accuracy with those obtained by the nephelometer, with the advantage that foreign salts do not cause difficulties as they do in the use of the nephelometer. Traces of chloride so low as 0·00035 gm. per litre were accurately measured. In a second paper the authors compare five different methods for chloride determination, three electrometric and two nephelometric. A new photronic nephelometer is described. The general result is that the electrometric methods are more accurate, easier to perform and less time-consuming. The general experience with nephelometers, that the chief difficulty lies in the reproducibility of the suspensions, was confirmed.

Determination of Iodine in Biological Substances

Iodine plays an important part in the metabolism of the body, since it is present in the molecule of thyroxine, the hormone of the thyroid gland; the normal level of metabolism in warm-blooded animals is only maintained when this gland secretes into the blood-stream for distribution throughout the body adequate amounts of thyroxine. The removal of the iodine atoms from thyroxine leaves a compound which has none of the specific activity of the former substance. Iodine is therefore an important constituent of the diet, but the amounts found in natural sources are exceedingly small and difficult to estimate. The need of a reliable method of estimation is shown by the facts that the incidence of goitre in different regions is related to the iodine content of foodstuffs and the water supply, and that in the converse condition of hyperthyroidism, the blood content of iodine is much greater than normal. C. O. Harvey has recently published the results of an investigation, carried out under the auspices of the Medical Research Council, into methods of estimating minute amounts of iodine, together with a description of a standardised reliable method, based on Hurtley's modification of Von Fellenberg's procedure (Special Report Series, No. 201. London: H.M. Stationery Office, 1935. 1*s*. 0*d*. net). Briefly, the method consists in the digestion of the material with caustic potash, followed by ignition in a nickel dish and extraction of the alkaline mass from the carbon with water. The iodide is extracted with alcohol, oxidised to iodate with bromine water, and the iodine, liberated by addition of potassium iodide, titrated in the usual manner with sodium thiosulphate. Nitrite is destroyed by addition of sodium azide before the oxidation with bromine. Harvey gives full details for carrying out the process, including the methods of preparing the reagents. By his method the iodine in 50 ml. milk, 5 gm. dried vegetable material or 10 ml. blood can be determined, the amounts present being of the order of 1 gamma. With strict attention to all the details of the process, the method has given comparable results in the hands of different workers.

Intensities of Fraunhofer Lines

In the *Memoirs of the Commonwealth Solar Observatory*, No. 5, Parts 1 and 2, Dr. C. W. Allen discusses the measurement of the intensities of Fraunhofer lines in the spectral region 4036 A.–6600 A. This is the most extensive series of observations which has as yet appeared. The author has used the standard methods of photographic photometry, and his results agree largely with those of other observers who have worked on more limited regions of the spectrum; but the general standard of agreement between one observer and another using this method is not very high. Two observations of the same line, made at different observatories, differing by five per cent between themselves, would count as substantial agreement under present conditions. Dr. Allen confirms the well-known result that solar multiplet intensities can only be reconciled with laboratory and theoretical intensities if a damping constant ten times that given by Lorentz on the classical electromagnetic theory is used in computing the correction for Doppler effect. He is able to show a connexion between the sharpness of the line and the excitation potential of the lower state, and to deduce values for the abundance of the elements in the sun which are in substantial agreement with Russell's values.

Anniversary Meeting of the Royal Society

ON St. Andrew's Day, November 30, the customary anniversary meeting of the Royal Society was held, and Sir Frederick Gowland Hopkins delivered his presidential address. In the course of the address, he referred to the work of the fourteen fellows and four foreign members of the Society who have died since the last anniversary meeting. Speaking of the Report of Council, he stated that a gift of £10,000 has been recently received at the instance of Prof. P. E. Newberry and Mrs. Newberry from the trustees of the late William Johnston, of Liverpool, for the foundation of a fellowship or studentship for research on problems of health. He also said that, in the last ten years, both the *Philosophical Transactions* and *Proceedings* of the Society have doubled in bulk, while the Society's present expenditure on research is nearly ten times that of twenty-five years ago.

At the conclusion of his presidential address, parts of which are printed in this issue (p. 893), Sir Frederick presented the medals for 1935; extracts from his remarks in making the presentations are given below.

Presentation of Medals

Copley Medal, awarded to Prof. C. T. R. Wilson

Prof. Charles Thomson Rees Wilson is awarded the Copley Medal for his contributions to the progress of modern physics by his work on the use of clouds in advancing our knowledge of atoms and their properties. How wide the field of his work has been can be seen from the following summary of his researches. He studied the phenomena of condensation of vapour to form drops by the use of expansion apparatus—which he designed. He discovered the existence of 'rainlike' and 'cloudlike' condensation of water vapour, and measured the corresponding supersaturations and critical expansions. He also measured the supersaturations requisite to produce condensation of water vapour on ions of both signs produced in various ways. He devised and constructed various types of electrometers, and with them and with his cloud apparatus demonstrated the so-called natural ionisation of air and other gases. With a new form of expansion apparatus, he photographed the tracks of ionising particles and radiations traversing gases.

Prof. Wilson next developed methods of measurement which he applied to the study of thunderstorm electricity. In this work the main phenomena relating to the electric field changes produced by lightning discharges were observed for the first time, studied quantitatively, and the principles of their interpretation outlined.

Prof. Wilson further extended the use of the cloud-chamber method. Stereoscopic methods of photographing ionisation tracks in the cloud chamber were applied successfully to the investigation of the properties of photo-electrons and Compton recoil electrons, including their ranges. In recent years, he has continued to make numerous and important contributions to the study of atmospheric electricity and, by introducing important improvements and modifications into his cloud-chambers, he has greatly extended their use.

A Royal Medal, awarded to Prof. C. G. Darwin

A Royal Medal is awarded to Prof. Charles Galton Darwin for his researches in mathematical physics, especially in quantum-mechanics, optics and statistical mechanics. His papers on the reflection of X-rays are now regarded as the fundamental researches on the subject.

In a series of papers on statistical mechanics, written in collaboration with R. H. Fowler, he published a new mathematical technique by which the relation of thermodynamics to statistics was placed on a satisfactory basis, and the way was opened for extensive subsequent developments.

Perhaps the most original and influential of Darwin's papers have been those concerned with quantum-mechanics. The quantum theory of the motion of an electron in an electromagnetic field, as it had been developed before 1925, gave results not in accordance with experiment. To obviate this, in 1925, the assumption was introduced that the electron has a mechanical angular momentum and a magnetic moment; but this conception did not admit of the application of wave-theory, since the waves corresponding directly to such an electron would be in space of six dimensions. It was Darwin who in February 1927 put forward the idea which led ultimately to the solution of these difficulties; he assumed that, just as there are two independent polarised components in a wave of light, so there are two independent components in the wave of an electron. He then constructed a pair of equations to represent the fine structure of the hydrogen spectrum, obtaining all the levels correctly except the *s*-levels, and showed how the equations could be expressed in vectorial form, so that, as he expressed it, the electron was a vector wave.

Among the quantum papers is also numbered the celebrated memoir on "Free Motion in Wave Mechanics", in which he took up the general question of aperiodic phenomena and dealt with it in masterly fashion, the principles of description and interpretation which are now universally accepted being formulated and applied to the free motion of electrons and atoms in various types of field.

A Royal Medal, awarded to Dr. A. Harker

A Royal Medal is awarded to Dr. Alfred Harker as the greatest British petrologist since that subject became a science. In 1886 he published a paper on slaty cleavage, which added considerably to the better understanding of the nature and laws of cleavage phenomena. His next important contribution was the Sedgwick Prize Essay of 1889 on the Bala Volcanic Series of Carnarvonshire. In collaboration with his colleague, J. E. Marr, he published a notable work on the Shap granite and associated rocks.

It is probably true to say that Harker's greatest achievement is the geological mapping of the island of Skye in 1895–1901, the results of which were published as a memoir of the Geological Survey in 1904. This monumental work has had a very wide influence upon the science of petrology: in this memoir and in the subsequent memoir on the Smaller

Islands of the Inner Hebrides, Harker set a high standard of work both in the field and in the laboratory. His book on the "Natural History of Igneous Rocks", published in 1909, has been described as "a work which has had a greater effect than any geological publication in the last fifty years". He has also made contributions of great value to the subject of differentiation of rock magmas, etc. His latest book on "Metamorphism", published in 1932, is the best contribution to the subject written in any language.

Davy Medal, awarded to Prof. A. Harden

Prof. Arthur Harden is awarded the Davy Medal in recognition of his distinguished work in biochemistry and especially of his fundamental discoveries in the chemistry of alcoholic fermentation. In 1904, in collaboration with his colleague W. J. Young, he showed that the alcoholic ferment of active cell-free yeast juice, the preparation of which had been achieved a few years earlier by E. and H. Buchner, could be separated into two components, a thermolabile non-dialysable enzyme complex and a thermostable dialysable co-enzyme, both of these being essential for the fermentation of sugar. They observed that the fermentation of sugars by this yeast juice was profoundly affected by an addition of inorganic phosphate, and followed up this discovery by a detailed and systematic investigation of the carbon balance, from which they showed that, for each hexose molecule broken down to carbon dioxide and alcohol, another molecule became esterified with phosphoric acid. From the fermentation products, hexosediphosphoric and hexosemonophosphoric esters were afterwards isolated by Harden and his colleagues. These discoveries have been the foundation upon which much of our present knowledge of the intermediate changes in the enzymic breakdown of carbohydrate has been established.

Harden has made important contributions to our knowledge of chemical reactions effected by bacterial enzymes, especially those concerned in carbohydrate metabolism. He has also taken an active part in the development of vitamin research in Great Britain, while as editor of the *Biochemical Journal* since 1911 he has influenced deeply the development of this branch of chemistry.

Hughes Medal, awarded to Dr. C. J. Davisson

A Hughes Medal is awarded to Dr. Clinton Joseph Davisson for his discovery that electrons are diffracted like waves of light. Like many other discoveries, this one disclosed itself gradually; but its origin can certainly be traced to some experiments on the scattering of electrons by nickel made by Davisson and Kunsmann in 1921. Davisson recognised at the time that the observed effects did not harmonise with the existing theories of matter and electrons. Owing to the polycrystalline nature of the metals investigated, the correct interpretation to be put upon the results was not at all clear. Davisson fully recognised the importance of this discrepancy, and this he and his assistants proceeded to investigate with great pertinacity and skill.

Towards the end of 1926, Davisson and Germer succeeded in making similar experiments with a single metallic crystal surface, so that the results were simple enough to be interpreted easily. It was then at once seen that the electrons were diffracted like waves of light of the wave-length required by the theory which had in the meanwhile been put forward by M. de Broglie towards the end of 1924. The first announcement of Davisson and Germer's results was published in NATURE of April 16, 1927. This publication was the first clear experimental proof of the wave character of the electron.

Davisson has also made important contribution to thermionics.

Thixotropic Colloids

A PUBLIC lecture on some recent developments of colloid science was delivered at Queen Mary College, London, on November 29 by Prof. H. Freundlich.

Prof. Freundlich pointed out that, whilst it has long been known that a solid gel, such as a gelatin gel, may be liquefied to a sol on heating, and that it returns reversibly to the state of a gel on cooling, investigators in colloid science scarcely realised until recently that an isothermal, reversible, sol-gel transformation is also very frequent. Many gels may be liquefied by shaking or stirring and set to a gel again, in a definite time, when left to themselves. This phenomenon is called thixotropy. It is found not only in true sols and gels (of oxides like Al_2O_3, Fe_2O_3, of gelatin, etc.), but also in concentrated suspensions of coarser particles (of clays, bentonite, etc.). In many cases, thixotropy may be regarded as a first, reversible stage of coagulation, causing the whole sol to unite to one large flake, so to say, which is able to enclose all the liquid present.

Under suitable conditions, some thixotropic sols may be solidified much more rapidly by a gentle, regular movement, a phenomenon called rheopexy. Thus there is a distinct difference between the liquefying action of strong and irregular movement and the solidifying influence of regular, weak vibrations and similar kinds of movement.

Thixotropy generally, perhaps always, involves a loose packing of the particles. The plastic behaviour of such masses also depends upon their loose packing. Hence thixotropy and plasticity are in opposition to Osborne Reynolds's dilatancy, which involves close packing; moist, pure quartz sand shows dilatancy, becoming hard and dry when displaced by an external force, and returning to its original, moist state when this force ceases to act. Foreign substances, such as clay, etc., when added to the sand, form water-binding layers round the particles, thus causing loose packing and thixotropy. A case of quicksand was found the thixotropic behaviour of which was caused by the presence of a fine, clay-like substance; this may be a fairly frequent occurrence. Moulding sands are also plastic and thixotropic because they contain clay and iron compounds.

In many other technical processes (plastics, paints, drilling fluids in the petroleum industry, etc.) thixotropy turns out to be an important factor. Protoplasm is frequently thixotropic, or may readily become so in the course of biological processes.

Educational Topics and Events

CAMBRIDGE.—Trinity College announces the usual offer of a research studentship open to graduates of other universities who propose to go to Cambridge in October 1936 as candidates for the degree of Ph.D. The value of the studentship may be as much as £300 a year. The studentship is open this year only to men who have not reached the age of twenty-six years before May 1, 1936. Applicants shall ordinarily be nominated by the authorities of their universities. Applications must reach the Senior Tutor not later than May 1, 1936. The same College offers, as usual, Dominion and Colonial exhibitions to students of Dominion and Colonial universities who wish to go to Cambridge next October as candidates for the degree of B.A., M.Litt., M.Sc., or Ph.D. These exhibitions are of the titular value of £40. Candidates must apply through the principal authority of their University, and applications should reach the Senior Tutor (from whom further particulars may be obtained) by May 1, 1936.

OXFORD.—In Congregation on December 3, it was proposed to make statutory the decree governing the relations between the committee of the Museum of the History of Science and those bodies which use part of the Old Ashmolean building where the Museum is housed. A concordat was recently arrived at in which the Museum obtains the whole building in "1942 or earlier". By making the decree statutory, the proposers hoped to get this vague phrase interpreted as "early as possible". The motion was defeated by 75 votes to 46. The speakers against it were all sympathetic to the objects of the Museum but they pointed out that until the new extension of the Bodleian library is available, the work in the large room required by the Museum could not be conveniently removed elsewhere. It was stated that probably by 1941 the whole of the building could be given to the Museum.

READING.—Following the installation of Sir Austen Chamberlain as Chancellor of the University on December 2, the honorary degree of D.Sc. was conferred on Sir Rowland Biffen, Sir Frederick Gowland Hopkins, Lord Rutherford and Sir J. J. Thomson.

Later in the day, Sir Austen announced that the installation of the new Chancellor is being commemorated by the gift from Mr. Reginald Marden of the freehold of Shipley Court Farm, a fine property of more than 300 acres, representing a value of £10,000–£15,000.

DR. ERNEST RENAUX has been nominated successor to Prof. Jules Bordet in the chair of bacteriology in the University of Brussels.

THE annual Conference of the Geographical Association will be held in the London School of Economics on January 1–3. On January 1, Mr. J. Fairgrieve will deliver his presidential address entitled "Can we Teach Geography Better?" On January 2, a symposium on "Soils in Geography" will be held, when the speakers will be Dr. W. G. Ogg, Dr. S. W. Wooldridge and Dr. L. Dudley Stamp. On the same day, Dr. E. B. Worthington will deliver a lecture on "A Biologist Looks at Africa", and a discussion on "The Use of the Epidiascope in the Teaching of Geography in Schools" will be opened by Mr. L. S. Suggate. On January 3 there will be two discussions, namely, "Higher Certificate Courses in Geography", to be opened by Mr. L. B. Cundall and Mr. H. W. Ogden, and "A Geography Course in Senior Schools", to be opened by Mr. A. E. Moody; and a lecture by Dr. H. J. Wood on aspects of irrigation development in the western United States. On January 4, there will be a demonstration of films for use in the teaching of geography in the Gaumont-British Theatre, Film House, Wardour Street, W.1. This will be followed by a discussion. Further information can be obtained from the Secretary, Geographical Association, Municipal High School of Commerce, Princess Street, Manchester, 1.

Science News a Century Ago

Faraday and Lord Melbourne

PRIOR to 1835, several men of science had received the honour of knighthood, and during the first administration of Sir Robert Peel, which lasted from December 16, 1834, until April 18, 1835, Civil List pensions were bestowed on Mrs. Somerville and Prof. Airy. Faraday's name had also been put forward in connexion with the award of pensions. After at first refusing to acquiesce in the proposal, Faraday had his memorable interview with Peel's successor, Lord Melbourne, which led Faraday afterwards to write to his Lordship: "The conversation with which your lordship honoured me this afternoon, including as it did your Lordship's opinion of the general character of the pensions given of late to scientific persons, induces me respectfully to decline the favour which I believe your Lordship intends for me. . . ."

An article afterwards appeared in *Fraser's Magazine* entitled "Tory and Whig Patronage to Science and Literature", which purported to give an account of the interview. Comments on the article appeared in the Press, and on November 28, 1835, *The Times* gave a long extract from it. On December 7, Faraday wrote to the editor of *The Times* saying, "neither directly nor indirectly did I communicate to the Editor of *Fraser's Magazine*, the information on which that article was founded, or further, either directly or indirectly, any information to or for any publication whatsoever." The letter was published on December 8.

Airy Declines a Knighthood

IN his autobiography, Airy noted under the year 1835: "On Dec. 8th Mr. Spring Rice and Lord John Russell offered me knighthood, but I declined it." At that time, Lord Melbourne was Prime Minister, Spring Rice Chancellor of the Exchequer, and Lord John Russell Home Secretary. Airy's letter to Spring Rice declining the honour was written from the Observatory, Cambridge, on December 10, just before he left for Greenwich.

In the course of his letter, Airy said: "The unalterable custom of this country has attached a certain degree of light consideration to titles of honour which are not supported by considerable fortune; or at least, it calls for the display of such an establishment as may not be conveniently supported by even a comfortable income. The provision attached to

my official situation, and the liberality of the King towards one of the members of my family, have placed me in a position of great comfort. These circumstances however have bound me to consider myself as the devoted servant of the country, and to debar myself from efforts to increase my fortune which might otherwise have been open to me. I do not look forward therefore to any material increase of income, and that which I enjoy at present is hardly sufficient, in my opinion, to support respectably the honour which you and Lord John Russell have proposed to confer upon me. . . ."

Sir Charles Bell and his Edinburgh Professorship

ON December 8, 1835, when Sir Charles Bell was about to succeed to the chair of surgery at Edinburgh, he wrote from London to his brother George: "I have seen enough to satisfy me of what the world can offer to a man—I mean this great world; and were you to look back to my letters, you would find the opinion, uniformly expressed, that the place of a professor who *fills his place* is the most respectable in life. My hands are better for operation than any I have seen at work, but an operating surgeon's life has no equivalent rewards in this world; I must be the teacher and consulting surgeon to be happy. Do you remember this is the fifth offer I have had to return to lecturing?" The same day his brother wrote from Edinburgh: "You are now an adopted member of this University, and with the unanimous assent and acclamation of a Town Council composed of persons of all parties, chosen by the several wards of this intellectual city. And surely never was an offer more honourable to an individual, for I do assure you it has the approbation of all ranks and classes of men, and of none more than the Professors of the University and the whole medical profession."

Electrostatics: a Cold Night on the Roof

"IT may be a question," wrote Faraday on December 10, 1835, "whether every case of electric residence on the surface of conductors in our atmosphere is not a case of induction"; and proceeded to try experiments to see if a metallic surface could retain any charge if there was no other surface or object opposite to it. A large concave mirror was insulated on the lecture room table, its curved surface facing upwards to the ceiling, and charged electrically. When the distribution of charge was examined, it was found to correspond with that in earlier experiments. The intensity was greatest at the edges; no electricity could be obtained from the lowest central part. The topmost point only of a ball rested at the centre showed a feeble charge.

But these effects might be due to inductive action of the ceiling, thought Faraday, although it was far above the lecture table; and so: "Then removed all this apparatus to the roof of the house, into a situation where a straight line drawn from the upper point of the 3 inch ball in the mirror, and passing by the edges of the mirror, could reach no external object except the starry sky. The sky was clear; the stars bright; the cold great, being about 27° or 28° and freezing fast at the time. Then repeating the experiments as within the house as nearly as possible, the same electrical effects were produced. Hence electricity can exist upon surfaces which are not inductively related to other surfaces of conducting matter".

Societies and Academies

DUBLIN

Royal Irish Academy, November 11. W. B. MORTON: Settlement from a suspension flowing through a tube of circular section. The rate of precipitation is examined on the two limiting assumptions of steady Poiseuille flow and of a distribution of particles maintained in uniformity across the section of the tube by eddies. J. J. NOLAN and V. H. GUERRINI: The diffusion coefficients and velocities of fall in air of atmospheric condensation nuclei. Methods for determining these quantities are described. The values found for nuclei in Dublin air are $D = 18 \times 10^{-6}$ and $V_g = 7{\cdot}5 \times 10^{-5}$. From these values the mass of the nucleus is deduced to be $1{\cdot}68 \times 10^{-16}$ gm. and its radius $2{\cdot}85 \times 10^{-6}$ cm. As the concentration of nuclei in air falls off with time, the nuclei are found to be of larger size. The bearing of this variation in size on the part played by the nuclei in the equilibrium of atmospheric ionisation is pointed out.

PARIS

Academy of Sciences, November 4 (*C.R.*, **201**, 801–860). LUCIEN DANIEL: The heredity of monstrosities in the descendants of the Jerusalem artichoke grafted on the annual sunflower to the eighth sexual generation. JEAN LE ROUX: Non-Euclidian distances. NICOLAS LUSIN: The choice of a perfect ensemble distinguished in an arbitrary analytical complement having non-enumerable constituents. G. DRINFELD: Integral invariants. N. ARONSZAJN: The metric characterisation of Hilbert space, of vectorial spaces and of certain metric groups. ANTOINE APPERT: New remark on the maximum of semi-continuous functionals. MAX SERRUYS: A rational scale of classification of fuel for internal combustion engines. The fuel is used in a motor under closely defined conditions of working, and compared with a fuel composed of a definite mixture of heptane and *iso*-octane. MARCEL CHÂTELET and FRANÇOIS KERTÉSZ: The activity of the chlorine ions in some solutions of complex chlorides of cobalt and chromium. ALBERT PORTEVIN and MICHEL CYMBOLISTE: Study of electrolytic baths. JEAN SWYNGEDAUW: The phenomena of electro-filtration in the electrolysis of gels. LÉON BLOCH, EUGÈNE BLOCH and CHOONG SHIN-PIAW: The emission spectrum of the selenium oxide, SeO. The fundamental vibration frequencies of the molecule SeO in the normal and excited state are 908·9 cm.$^{-1}$ and 533·4 cm.$^{-1}$. The energy of dissociation of the molecule in the normal state was found to be 5·31 volts. FRÉDÉRIC JOLIOT, ANDRÉ LAZARD and PIERRE SAVEL: The synthesis of radio-elements by deuterons accelerated by means of an impulse generator. ALBERT MICHEL-LÉVY and ANDRÉ MURAOUR: The variation of detonation spectra with the nature of the surrounding gas. A mixture of tetranitromethane and toluene was detonated in different gases, argon, krypton, carbon dioxide, nitrogen, air, helium, hydrogen and chlorine. Reproductions of the spectrographs obtained are given. The results support the hypothesis attributing the observed luminosities to the stimulation by the shock waves of the gas molecules surrounding the explosive. WILFRIED HELLER: The distances between the colloidal particles in the bright layers of certain iron oxide sols. The author has found a method of preparing artificially the bright layers discovered by

Zocher: the method is based on the slow hydrolysis of solutions of ferric chloride. An outline of the theory of the phenomena is given. JEAN SAVARD: The Raman spectra of methyldiethylcarbinol, dimethylbenzylcarbinol and the corresponding ethylene hydrocarbons. Frequencies due to the phenyl group, and the C.H and C=C linkages are given: tentative frequencies for other groups are suggested, but require confirmation by further work. All compounds containing the ethyl group give an intense line of frequency about 720. ARAKEL TCHAKIRIAN and MICHEL LEWINSOHN: Preparations of alkyl trihalogenides or of phenyl germanium of the type $RGeX_3$ and of methylene germanium hexachloride. ANDRÉ CORNILLOT and RENÉ ALQUIER: The reaction of acetylene with acetyl chloride. In the presence of aluminium chloride, acetylene and acetyl chloride give methyl-β-chlorvinylketone, $CH_3.CO.CH=CHCl$. This is very unstable: treated with boiling alcoholic soda, besides much tarry matter, this compound gives 20–25 per cent of triacetylbenzene. JACQUES BOURCART: The Quaternary of the coast of Rabat (Morocco). S. DEB: The discovery of an Orbitoid in the Annot (Alpes-Maritimes) grits. JACQUES FROMAGET: New observations on the upper Trias of western Tonkin and on the Norian age of the *Myophora napengensis* layers. FERNAND OBATON: A method for the rapid determination of the quantity of water contained in the soil. The method is based on the determination of the electrical resistance of a column of soil under a fixed pressure. The conversion of electrical resistance into moisture content is based on a curve reproduced. RENÉ SALGUES: The erythrocytes, hæmoglobin and the globulin value in the bird. JACQUES PELLEGRIN: The buccal variations in the barbel of the Kivu region. ROBERT WEILL: The working of the colloblasts. MAURICE CAULLERY: Remarks on the preceding communication. J. TIMON-DAVID and G. CERESOLA: The influence of sex on the lipids of some marine molluscs. JEAN COURTOIS: The action of various chemical compounds on the plant phosphatases. MME. PAULETTE CHAIX: The action of some compounds containing sulphur on the fermentation of glucose by propionic bacteria (*Propionibacterium*). WACLAW MOYCHO: Do bacteria secrete protease? Oppenheimer and Enler hold that living bacteria have not the power of secreting proteolytic enzymes, the latter only being liberated after the death of the cell. This view has not been proved experimentally, and has been adversely criticised. The author describes experiments with *B. prodigiosum* which he regards as clearly proving that the enzymes are only liberated after the death of the bacterium.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, 21, 561–585, Oct. 15). C. P. HASKINS: A determination of the magnitude of the cell 'sensitive volume' associated with the white-eye mutation in X-rayed *Drosophila*. The results of exposure for different periods to the same source of X-rays suggest that passage of a single electron through this locus is sufficient to cause a mutation. Assuming that every electron causes a mutation, the minimum volume of the white loci in the X-chromosomes of all cells of the optic *anlage* at the time of treatment is $37{\cdot}06 \times 10^{-18}$ c.c. TH. DOBZHANSKY and A. H. STURTEVANT: Further data on maternal effects in *Drosophila pseudo-obscura* hybrids. CHESTER STOCK and FRANCIS D. BODE: Occurrence of Lower Oligocene mammal-bearing beds near Death Valley, California. This is the first time these fossils have been recorded in the Great Basin Province, which is far from previously known areas of occurrence. A definite age determination has been made for the lowermost formational unit in the Tertiary rock sequence of the Grapevine and Funeral Mountains forming the north-east wall of Death Valley. Geological sections are given. ARTHUR E. KENNELLY: Adoption of the metre-kilogram-mass-second (M.K.S.) absolute system of practical units by the International Electrotechnical Commission (I.E.C.), Brussels, June 1935. An account of the history of electrical units and a list of sixty-one quantities with their symbols, M.K.S. and C.G.S. units. BERTIL HANSTRÖM: Preliminary report on the probable connexion between the blood gland and the chromatophore activator in decapod crustacea. Extracts from the eyestalks of most of the crustaceans examined cause concentration of pigment within the skin chromatophores. The active regions on microscopic examination are found to contain the blood gland and the X-organ, both of which receive nerves from a part of the brain connected with the optic paths. It is believed that the blood gland is the source of the chromatophore activator, though the X-organ may also be concerned with the colour changes of crustaceans.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Sunday, December 8

BRITISH MUSEUM (NATURAL HISTORY), at 3 and 4.30.—M. A. Phillips: "Fossil Mammals".*

Monday, December 9

BRITISH MUSEUM (NATURAL HISTORY), at 11.30.—C. Musters: "Some Zoological Collecting Trips".*

SWINEY LECTURES ON GEOLOGY, at 5.30.—(at the Imperial College of Science, Exhibition Road, South Kensington, S.W.7).—Dr. Frederick Walker: "The Formation of British Coast Lines" (succeeding lectures on December 11, 13, 16, 18, 20, January 1, 3, 6, 8, 10 and 13).*

Tuesday, December 10

PHARMACEUTICAL SOCIETY, at 8.30.—Dr. P. Hartley: "International Biological Standards for Drugs and Therapeutic Substances".

Thursday, December 12

ROYAL ASIATIC SOCIETY, at 4.30.—Mme. Gabrielle M. Vassal: "The Temples of Yunnan".

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Dr. Cecil Wall: "The Surgeons' Company, 1745–1800" (Thomas Vicary Lecture).*

Friday, December 13

ROYAL SOCIETY OF ARTS, at 4.30.—Khan Bahadur Sheikh Sir Abdul Qadir: "The Cultural Influences of Islam in India" (Sir George Birdwood Memorial Lecture).

ROYAL INSTITUTION, at 9.—Sir Richard Paget: "Sign Language as a Form of Speech".

Saturday, December 14

ROYAL INSTITUTION, at 3.—Dr. W. Percival Yetts: "Chinese Bronzes".

EXHIBITION OF MICROSCOPES BY W. WATSON AND SONS, LTD., December 9–14.—To be held in the Central Hall, Westminster, S.W.1.*

December 10, at 7.—T. H. Turner: "The Part the Microscope plays in the Scientific Control of the Railway".*

December 11, at 7.—M. Duncan: "The Microscopist at the Seaside".*

December 12, at 7.—H. C. Rands: "The Manufacture of Optical Glass".*

Nazi-Socialism and International Science

EVENTS of the past few years have accustomed us to the knowledge that the position of 'non-Aryan' scientific colleagues in official positions in the German Reich has become intolerable, even in the few cases where they have not been expelled from office. Now a new situation is developing which may be fraught with considerable danger to the continued co-operation of workers in other countries with their German colleagues. This new development carried to the limit can only result in the isolation of German men of science in all matters of international organisation.

The unwelcome move, to which attention has been directed in a recent issue of the *Basler National Zeitung*, is the use that the Nazi authorities intend to make of international congresses for their own purposes. The Reichsminister of Propaganda has created a 'Science Congress Centre' (Wissenschaftliche Kongres-zentrale), one of the objects of which is to use scientific congresses as opportunities to influence public opinion through the medium of the important persons attending. No longer is this to be left to the chance of personal and friendly relations between the foreigners and the Germans present, but, where possible, steps are to be taken to introduce ideas of a Nazi-socialistic stamp into the discussions of matters of world moment.

For meetings held in Germany, the new centre would act as an intermediary between the Government and party officials on one hand, and the president and officers of the congress on the other. The programmes of the meeting and the lists of speakers would be subject to the approval of the centre: thus international conferences held in Germany are to be sifted of undesirable elements by the authorities beforehand and to survive as meetings approved by the Nazi party. For meetings held outside Germany the control must necessarily be much less, but here too it is possible to influence matters by sending German members to a meeting as a delegation under an appointed leader chosen for his reliability as a member of the Nazi party.

The meeting of the Astronomische Gesellschaft held at Berne last summer may be cited as an example of the working of the new machine. The Astronomische Gesellschaft is a long-established body with headquarters in Germany but with strong international affiliations, which have been particularly stressed by the Germans in recent years. One of the valued secretaries of the Astronomische Gesellschaft came up for re-election at the meeting and in the ordinary course of events would have been re-elected without question: on purely scientific grounds there was every reason for his continuance in office. This was, however, against the views of the German delegation, whose members were instructed not to vote for a Jew: alternative names were put forward and it became clear in the course of the meeting that something more vital was at stake than the question as to the holder of a particular office; in fact, nothing less was at issue than the question whether an organisation of international standing and repute should come under the control of an anti-Semitic clique. When the vote was ultimately taken by secret ballot, it was found that the Nazi element had failed in its attempt, and the threatened secession of non-Germans from the Astronomische Gesellschaft was averted for the time. But the danger of subsequent development remains a source

of anxiety to those concerned in international scientific relations.

It should be added in fairness to the Germans that internal persecution of a minority is not limited to their country, nor even the use of international gatherings to spread nationalist political propaganda. Both these undesirable practices are to be found in more than one country: we have no sympathy for either. But when these tendencies spread and a nationalistic movement tries to secure the control of international scientific work, it is time to call a halt.

Health and Safety in Industry*

THE report of the Chief Inspector of Factories and Workshops for 1934 gives some interesting illustrations of the part which science has still to play in the prevention of industrial accidents and the safeguarding of industrial health. Scientific investigation is, of course, a main factor in the continuous improvement of processes so that operating conditions more and more eliminate dangers to health from noxious fumes or poisonous substances.

It is not, however, the field for further investigation which is here presented or the lack of exact knowledge of the effects of many well-known substances, particularly their cumulative effect, that is most impressive in the present report. Welcome as may be the evidence of the painstaking effort in this field to track down causes and to foresee possible dangers, a good deal remains to be done to secure effective co-operation and co-ordination between different branches of science, as well as between employer and employee.

The further we advance in this field of industrial health, the more important voluntary effort and the less effective legal compulsion become to secure the ends in view. Scientific research must supply the exact knowledge upon which effective action is based. Then comes the problem of securing that effective action is taken, and in this matter the co-operation of the employer and employee is essential. Once more, however, the report provides evidence that only continuous and expert supervision can ensure that co-operation is unbroken either by ignorance, indifference or neglect, whether studied or involuntary.

What is required is not merely the supervision exercised by inspectors of factories, but also the close and continuous oversight which can only be exercised by a scientific personnel in industry. Where in this way expert knowledge and a trained mind can be brought to bear on the design of plant or development of processes from the point of view of the health and safety of those operating them, and still more on any unforeseen emergency which may arise, the risk of untoward injury to health is largely reduced. Where scientific personnel is absent or too heavily charged with other duties to exercise such oversight, the risks are correspondingly greater; the report refers, for example, to a factory in which all the processes entailing the most serious risks, were carried out by a proprietor who had a scientific training and the necessary knowledge and skill to avoid serious injury. So long as this process (the manufacture of hydrogen cyanide) can be kept in the hands of persons with the requisite knowledge it appears that the danger of the process can be controlled but as a result of increased demand for the acid the manufacture may possibly fall into the hands of inexperienced persons, with consequent risk.

This reference alone demonstrates sufficiently that it is not only in the manufacture of pharmaceutical preparations intended for the internal treatment of human ailments that properly qualified supervision is required in the public interest. There are many other processes and operations which equally demand the personal control of a properly qualified chemist, engineer, physicist or other scientific worker or technician, and this is a matter which demands the continuous attention of the professional organisations of chemists and others.

Equally impressive, however, is the picture the report supplies of the need for co-operation, and particularly on the medical side. Much of the value of medical supervision is lost because of the lack of knowledge of many general practitioners of the work of the medical inspectorate of factories, of factory legislation and of diseases of industry. The psychological effects of ill-founded sickness certificates "due to employment" are far-reaching

* Annual Report of the Chief Inspector of Factories and Workshops for the Year 1934. (London: H. M. Stationery Office, 1935.) (Cmd. 4931.) 2*s*.

and as serious to the individual as they are embarrassing to industry and to the scientific investigation of the incidence and causes of industrial disease. Any efforts at educational work such as the inclusion of appropriate lectures in the medical curriculum which facilitates co-operation should be of immense ultimate benefit.

Another direction in which co-operation is called for is between different classes of scientific workers. Notably is this true of the work of the medical officers now to be found in most large works or firms on a part-time or full-time basis. While it is essential that, with the medical man as with the chemist or engineer or other professional worker, his own professional associations and traditions should come first, professional independence should not be allowed to stand in the way of team work. It is only as the medical man takes his place in the industrial team in this field in the same way as the engineer, the chemist, the biologist, physicist or administrator, and knowledge and experience gained from many angles is pooled for the general advantage, that we can hope to secure the maximum elimination of industrial risks.

The possibilities in this field indeed have scarcely been glimpsed, although Dr. L. Teleky has directed attention to the opportunities and need for co-operation in research, and Dr. H. E. Collier in a recent address before the Industrial Welfare Society's Advisory Medical Committee gave an inspiring vision of the place of a university in an industrial hygiene service. Certain of the functions outlined, such as training the personnel of such a service, propagating existing knowledge and establishing or maintaining organic contact with those actually engaged in health work in industry, have scarcely yet been touched.

The training of personnel for industrial health work is closely allied to a matter on which special stress is laid by the Chief Inspector's report. The high incidence of industrial accidents among juvenile workers is not generally realised, and although the accidents themselves are less serious, as indicated by a lower fatality rate, the situation is one which demands every effort to remedy. Certain qualities of youth probably render the young entrant to industry specially susceptible to accidents, and it is as incumbent on us to give him an apprenticeship in safety as in his productive work, and to see that he is adequately forewarned of the dangers inherent in all industrial life. Pre-eminently this is a field in which goodwill and voluntary efforts of employers and of responsible officers are far more valuable than legislation which would be equally difficult to draft and to enforce.

Sir Donald MacAlister

Sir Donald MacAlister of Tarbert
By his Wife. With Chapters by Sir Robert Rait and Sir Norman Walker. Pp. vii + 392. (London: Macmillan and Co., Ltd., 1935.) 12*s*. 6*d*. net.

WHEN in January 1934 Sir Donald MacAlister died at Cambridge, there passed from among us one of the most influential men of our time. He had been for forty-four years a member of the General Medical Council, and for twenty-seven its president. He had also been principal and Vice-Chancellor of the University of Glasgow for twenty-two years, and its Chancellor for the last five years of his life. It is a remarkable record, particularly when we remember the numerous and varied official and unofficial public duties fulfilled within the same period of life. Both these official posts were concerned with what is called administration, but in MacAlister's career, the administrative faculty was combined with exceptional, not to say extraordinary, capacities in other directions. Here was a man who began as Senior Wrangler at Cambridge in 1877, and was teacher and tutor in his College, linguist, poet, mathematician, physician, physiologist, pharmacologist, biologist, and even moralist. He could apparently have excelled alike in the medical, administrative, judicial or ecclesiastical spheres—an 'Admirable Crichton', or a model for Angus Sutherland in William Black's yachting novel, "White Wings".

The story which Lady MacAlister tells is full of interest, happiness and inspiration, and most of the many readers who will turn to it, old students of Cambridge and Glasgow and medical men the world over, are likely to find its 390 pages all too short for their desire. Donald MacAlister deserved indeed to become the titular head of

British medicine, for added to his natural gifts he lived a life of immense diligence and devotion to the task in hand. Public service was his native breath, and strenuous toil his daily lot. He was born in Perth in 1853, the son of a publisher's agent and manager, of good Presbyterian stock; he was at school first in Aberdeen and, when ten years of age, in Liverpool, whither his parents had removed. It was at the Liverpool Institute that Sir Henry Roscoe learned the elements of chemistry as MacAlister those of mathematics, but the latter obtained more material reward in the nature of prizes and scholarships, which took him to St. John's College, Cambridge. After winning the senior wranglership he taught mathematics at Harrow, then under Dr. Montagu Butler, afterwards returning to Cambridge and St. Bartholomew's Hospital to study medicine. He took his M.B. in 1881 and his M.D. in 1884, supporting himself, both as student and after qualification, by literary work for the *Journal of Education*, *The Times*, and the *Pall Mall Gazette* in the days of Mr. John Morley. After a few months physiological work under Karl Ludwig at Leipzig, and having been awarded a fellowship of St. John's, he settled down at Cambridge, filling a number of medical posts, including a lectureship and tutorship at St. John's, a medical appointment at Addenbrooke's hospital, and private medical practice. He married a 'Highland cousin' in 1895.

It was during his early days at Cambridge that MacAlister became interested, with several of his fellow students, in the education of adults, becoming a teacher in the Nelson Street Adult School. "From an early age the things of the spirit meant much to Donald"—then, and afterwards, he became a student of the Bible in various languages, a practice which widened his interests and qualified him in exceptional degree for his public reading and exposition in after days at Glasgow. This particular interest was doubtless the mainspring of his social interest in Toynbee Hall, university extension work with Prof. James Stuart, the physical training of youth, his work for the Carnegie Foundation, his devotion to the welfare of university students, the Workers' Educational Association, and the School of Social Study. He was both cosmopolitan and catholic in spirit, and always the friend of well-designed schemes of social reform.

In 1907, MacAlister's intention of writing the biography of Prof. John Couch Adams, the discoverer of the planet Neptune, and for 'going round the world' were frustrated by his appointment, by the Prime Minister, as principal of the University of Glasgow. He accepted this high post with some hesitation, "for seven years and no longer". But he stayed there for twenty-two years. Something of what he accomplished is described in the book by his successor, Sir Robert Rait. Though never physically strong, since an attack of rheumatic fever in childhood, and often suffering pain, he carried through the immense and ever-extending burden of routine administrative work involved in such an onerous appointment. Particularly, of course, his advent strengthened the faculty of medicine, extending the hospital teaching provision, enlarging the professoriate, providing for women medical students, reorganising the curriculum of study, introducing new research facilities and making larger arrangements for the social life and well-being of the students. Not the least of his labours was that of piloting a great and growing university through the years of the Great War. Yet in the ten years after the War, so solid was the reconstruction that no fewer than fifteen new professorships were founded in the University.

It is perilous to compare the values of the achievements of a man's life. Sir Donald MacAlister was for a whole generation one of the outstanding figures in the public and educational life of Great Britain. As principal, and finally as Chancellor, after Lord Rosebery, of a large university sending its alumni all over the Empire, his influence was ever widening and deepening; as president of the General Medical Council for twenty-seven years his wise guidance of the medical profession is not less immeasurable. His consummate learning, his versatility, his extraordinary circumspection, his lucidity and understanding, his wisdom and judgment were placed for this long period at the service of the profession he had chosen. It was accompanied, almost invariably, by patience, courtesy and good humour —"never hurried, never annoyed, never out of temper, never bored, never at a loss". What a temperament and what a testimony such words truly represent!

One of MacAlister's duties, first and last, was to clear up and dissipate misconceptions about the Medical Council. "It is scolded for doing what the law says it *shall* do. It is bitterly reproached for leaving undone what the law gives it neither power nor means to do". Its purpose is not to protect doctors but the public. It is a council of *education*; a board of *registration* of the qualified men; a professional court of justice, the only sentence of which is erasure from such register. From 1889, when he was elected to represent the University of Cambridge, until 1933, when he retired from the representation of Glasgow, MacAlister devoted his mind and his energy to the guidance and service of the Medical Council. He began as the wise reformer of the medical curriculum, which is recommended by the Council

to the teaching and examining bodies; he was one of the principal designers and critics of the "Pharmacopœia" issued by the Council; he reorganised the procedure and finance of the Council; he strengthened mutual 'reciprocity' between medical men throughout the Empire; above all, he laboured for a 'clean' register, by regularising the arrangements for ensuring justice. Every complaint against the conduct of doctors must be properly explored, and proved to the satisfaction of their peers on the Council. There must be nothing arbitrary, accusative or capricious, and the doctor must be fully and fairly heard. All this was carried through, year after year, within the requirements of the Medical Acts, under the supervision of the Privy Council, and before the eyes of the public. The honour and dignity and usefulness of the healing art must always be safeguarded. Little wonder that confidence in the Council has steadily increased in the profession, among the public, and by the courts of justice. Much of this achievement was part of MacAlister's life-work.

Lady MacAlister has given us an admirable record, lucid and business-like as MacAlister himself would have wished, but happily warmed with many homely touches of his humanity and lovable character. The two great positions which he adorned had inevitably a tendency to separate him from his fellows, a differentiation already marked by his great abilities and learning, but to those who knew him personally he was a charming, faithful and affectionate friend. To all men his life was indeed a noble example. G. N.

The Botanist in the Garden

The Living Garden:
or the How and Why of Garden Life. By Dr. E. J. Salisbury. Pp. xi+338+17 plates. (London: G. Bell and Sons, Ltd., 1935.) 10*s.* 6*d.* net.

FIFTY years ago botany, so far as the class-room was concerned, was very much a matter of definitions, just as field botany was concerned almost wholly with the making of a herbarium of local species. The student found himself set to learn a new language—dichasial inflorescences, gynandrophores, campylotropous ovules—as though designed to inculcate the advantages of a classical education. This conception survived pretty well to the end of the nineteenth century. Towards the close of the 'nineties, when examining a school which professed botany, and turning over the notebooks, I found this sentence, evidently taken down by the whole class from dictation, or rather copied from the blackboard, for the spelling would otherwise have offered variants: "Amaryllis—fruit a bilocular loculicidal capsule, a diplotegium". One of my co-examiners breathed his gratitude that he had been introduced to the lady under a happier star and had been learned instead "to sport with Amaryllis in the shade".

As a youngster keen on wild flowers and tasting all sciences that came within reach, I made two attempts to read botany, but each time fell back repelled by the mere cataloguing that was presented for study. It was only on reading Darwin, and in a lesser way Lubbock and Grant Allen, that one discovered a purpose in plant structure; the translation of Sachs appeared in 1875, and with it botany was reborn as the study of the living plant.

Then as time went on and I became more and more engrossed with the wholesale aspects of plant nutrition in agriculture and horticulture, I began to pick up a notion or two about plants of all kinds—wild as well as cultivated. I was always hoping that someone would produce a British 'flora' that would tell me not merely the habitat of a given plant but also whatever was known about its mode of life; how the *Colchicum* remakes its corm every year, how the *Arum* works the flytrap and uses contractile roots to draw its seedlings down to the proper depth. That 'flora' is still to seek, but Prof. Salisbury has produced for the garden the very thing I had dreamt of for the wild. It is a book not only for the young botanist or the gardener who is trying to obtain a scientific foundation for his art, but also for that ever-increasing number of intelligent amateurs who want to have an understanding of their garden and to find a reason for the practices that the professionals inculcate.

Prof. Salisbury begins by telling what the soil does, and then expounds the prime fact that the plant is a machine driven by light, able to move in one direction or another in response to differences of illumination. In his excellent discussion of the natural history of a lawn, he explains how the leaves of the rosette plants—the plantains and dandelions—press downwards because of the more

rapid growth of the illuminated upper surface. Has he ever noticed how these plants will be found sticking upright after the removal of a marquee that had been erected on a lawn for a couple of days? The effects of cold, frost and fog are dealt with at length, though he seems to hesitate a little between the winter killing due to sheer cold and the more usual destruction due to drying out when the soil temperature is too low to allow the roots to function. A mulch of stable manure over the lower part of a tea-rose cannot keep it warm, but prevents a dangerous loss of water.

There are very useful chapters on root development ("The Garden under the Soil"), and on vegetative propagation, which discusses the rooting of cuttings, budding and grafting, with a digression on graft-hybrids and chimæras, where Prof. Salisbury might have extended his illustrations to the relatively frequent cases of chimæras in the variegated hollies, *Euonymus*, and privets of our shrubberies. There is a delightful chapter on the "Spring Emergence"; how the shoot may form a spear that can push through a gravel path or even a layer of asphalt. The chapter on the sources from which our garden plants have been brought might bear expansion, though it would be difficult to know where to stop with so fascinating a subject. Again, the chapter on fertility and inheritance, which begins with an excellent account of the process of fertilisation, might well be extended. So many amateurs want to know a little more about the raising of new varieties, hybridisation and selection. The germination of seeds is well treated, and will introduce to many readers the fact that an initial chilling or freezing may be helpful in inducing 'difficult' seeds to start. The sequence of events during the year, and the daily responses to the rhythm of temperature and light, provide material for another stimulating chapter, and the book concludes with a discussion of the end of the chain—the death of the individual—a remote conclusion with some plants since the Saffron crocus, the actual individual, for the countless corms form but one clone, must be more than four thousand years old.

The book is delightfully illustrated with photographs by the author and with drawings by Mrs. Caroe, which bring out the points at issue as well as any diagram, but yet preserve the aspect of the plant and are enjoyable as drawings. Altogether Prof. Salisbury has produced a notable book; the critical reader may demur to a statement here and there, and have an illustration or two to suggest; let him send them to the author for the benefit of future editions. Finally, let us hope that Prof. Salisbury's book may be the means of leading some of our young botanists out of their laboratories into the garden.

A. D. HALL.

Origin of the Solar System

The Solar System and its Origin

By Henry Norris Russell. Pp. vii + 144. (New York: The Macmillan Co., 1935.) 8*s*. 6*d*. net.

THE spectroscopic study of the planets has made great advances in the last ten or fifteen years, and in the present book a distinguished astrophysicist gives a summary of the results and their application to the problem of the origin of the solar system. We now know that Neptune's rotation is direct, though the revolution of its satellite is retrograde, so that the satellite must be approaching the planet, like Phobos. The temperatures of the planets have been measured and found to be in fair agreement with those that would be maintained by solar radiation; the surfaces of the great planets are at liquid air temperatures or less, as was predicted by me in 1922. The compositions of the visible parts of the sun and planets are now known; the great planets have atmospheres consisting mainly of ammonia and methane, and Venus one of carbon dioxide.

Prof. Russell shows that these results are such as would be expected if the planets had been generated at high temperatures from the sun, the lighter ones losing their volatile constituents at an early stage owing to their small gravitation. At this point he overlooks a difficulty about the compositions of the terrestrial planets. The increase of density towards the centre of the earth is too great to be attributed to compression, and demands a large central core of some heavy material, probably iron. But the densities of the moon and Mercury forbid such a core of any appreciable size; Venus resembles the earth, and Mars is intermediate. It is very hard to see how the moon and Mercury can have lost all their iron and retained silicates, and this seems to me to be a great difficulty in every theory of the origin of the solar system yet proposed, not excepting my own. The author devotes a good deal of attention

to the comets, but reaches no definite conclusion as to whether they originated within the system or outside it.

The last third of the book deals with theories of the origin of the planets, and is a very careful and critical treatment. It may be said at once that every theory has to meet a difficulty of the same type: all require some agency to separate the planets from the sun or the parent nebula, and all need to explain how the planets managed to hold themselves together immediately afterwards. Disruption has to be followed by condensation in any case, and while it is fairly easy to make theories to explain either separately, it is very hard to make one cover both. All forms of the nebular theory fail completely here. The tidal and collision theories, while very incompletely worked out, offer some hope, not that the whole of the ejected matter would be condensed, but that enough of it would be retained to make planets of reasonable sizes.

Prof. Russell insists on p. 109 that the resisting medium (formed of the escaped constituents), which the last two theories use to explain the later rounding-up of the planetary orbits, would be collected by the planets. This seems to me definitely wrong. Such a medium would have to be mainly hydrogen, with a density of the order of 10^{-15} gm./cm.^{3}, and a mean free path of some kilometres. He considers seriously the possibility that the free path may be long compared with the diameters of the planets, for which I can see no justification. But his main point is that molecules of the medium would be entangled in the atmosphere and ultimately added to the body of any planet influenced by them. It seems to me, on the other hand, that close to each planet the ordinary theory of gaseous atmospheres must apply. There will be a definite limit to the density attainable, and any addition will be prevented by elastic forces. How great this limit would be depends on the general motion of the medium as disturbed by the planets, which offers a definite though still unsolved problem of hydrodynamics. Permanent addition to the body of the planet requires something to combine with the gas and give a liquid or solid; only oxygen appears to be available for the purpose, and much too little of that; besides, the earth seems to be the only planet that can ever have had an appreciable amount of free oxygen in its atmosphere. It would be expected that the density of the medium near the planets would be greater than elsewhere, but not that this excess would increase indefinitely with the time.

Prof. Russell gives what looks like a serious objection to the tidal and collision theories when he considers the angular momentum that would have to be communicated to the ejected matter. He points out that the angular momentum is closely connected with the perihelion distance; it is strictly connected with the semi-latus rectum, but in elliptic orbits this can range only from one to two times the perihelion distance. Consequently the original perihelion distances of the planets must have been at least half the present ones. But the original supply of angular momentum can be attributed only to friction during the passage of the star and to transverse attraction while the star was within a distance of a few solar diameters, and it is difficult to see how the distance of the matter from the sun at this stage can have been more than a few times the sun's diameter.

If this objection is valid, and I can see no reply at present, we have no satisfactory theory of the origin of the solar system. The objection is in the opposite sense to the one that various writers have made to the nebular hypothesis; the conditions needed to make this hypothesis lead to disruption imply too much angular momentum in the system, while those needed for the tidal and collision theories imply too little. We cannot escape by assuming a greater diameter for the sun at the time, for it is now clear that the sun 2,000 million years ago must have been in very nearly its present state. Incidentally, this point disposes of the nebular hypothesis by itself.

Towards the end of the book, Prof. Russell considers the possibilities that the sun may have been a binary or a nova when the planets were formed, but shows little satisfaction with either.

The book was printed before the publication of the recent theory of Lindblad[1]. There seem to be objections to this theory also, but it contains at least one feature that calls for attention. Previous theories considered the primitive planets and satellites as held together only by gravity. But if the pressure of a gas exceeded the vapour pressure corresponding to the temperature at the surface of a solid, the gas would proceed to condense on the solid, however small the latter might be. Such a mechanism may well account for the formation of meteors in interstellar space, and should be relevant to part of Russell's book. But if the planets were formed in this way it is difficult to see how their orbits failed to be perfectly circular from the start.

It appears that the problem of the origin of the solar system is still unsolved; and perhaps the intermediate stage covered by the resisting medium and tidal friction is the most hopeful for investigation at present. Prof. Russell's book will be indispensable to all interested in our system.

HAROLD JEFFREYS.

[1] NATURE, **135**, 133-135; 1935.

An Introduction to Atomic Physics

By Dr. John Thomson. Pp. ix+228+4 plates. (London: Methuen and Co., Ltd., 1935.) 10*s*. 6*d*. net.

THIS clear and systematic presentation of the fundamental facts and theories of atomic physics consists of three parts, each complete in itself. The first part deals with the experimental basis of the subject; starting with the atomic nature of electricity and the carriers of the atomic charge, the composition of the elements is developed with special reference to the contribution of the mass-spectrograph and Wilson cloud-track methods. The elementary quantum is introduced through Einstein's photo-electric equation and Millikan's verification, after which the work of Planck, and the quantum in X-rays and spectral series are described, concluding with a survey of critical potentials. Part II, on the theory of atomic structure, opens with a detailed survey of the Bohr atom, the deficiencies of which lead to a systematic derivation of the Hamiltonian functions used in general dynamics, as an introduction to a good account of the Schrödinger and de Broglie wave mechanics. This is illustrated by detailed application to the hydrogenic atom and to the theory of radiation. The compression of such a survey of wave mechanics into 40 pages naturally presupposes a good knowledge of mathematics. Part III is devoted to further applications and to molecular, atomic and nuclear radiations. Each part ends with a short summary, and an appendix gives a simple derivation of the leading results of relativity theory as used in atomic physics.

The author's aim is stated to be "to help the reader to gain a clear idea of the essential simplicity of atomic phenomena, and to see in their proper perspective the new principles which modern investigations have brought into being". There can be little doubt that this aim has been very satisfactorily fulfilled so far as the more advanced reader is concerned; in addition, there has been compressed into an easily accessible and digestible form a vast amount of modern experimental and theoretical work.

N. M. B.

Albert Einstein:

a Picture of his Life and his Conception of the World. By David Reichinstein. Pp. 255. (Prague: Stella Publishing House, Ltd.; London: Edward Goldston, Ltd., 1934.) 12*s*. net.

As an intimate friend of Einstein, the author of this work is in a position to reveal some interesting details of Einstein's life and mental outlook. The great scientific work of the founder of general relativity is thus placed in its proper setting as an aspect of the remarkable development of its author. The liberal spirit of Prof. Einstein is stressed; and in giving an account of his clashes with Prussianism and Nazism, Prof. Reichinstein shows much feeling for the persecutions to which Einstein has been subjected by his fellow-countrymen. There is little doubt that this book is a valuable source of information for any future biography of Einstein. T. G.

Potlatch and Totem: and the Recollections of an Indian Agent

By W. M. Halliday. Pp. xvi+240+24 plates. (London and Toronto: J. M. Dent and Sons, Ltd., 1935.) 15*s*. net.

MR. HALLIDAY has a personal experience of the Indians of British Columbia which goes back to 1873. He has been in personal contact with them for thirty-eight years, of which twenty-six were spent in charge of the Canadian Government Indian Agency of the Kwawkewlth (Kwakiutl), of Vancouver. His reminiscences of Indian custom fall into two parts. In the first, he describes an imaginary potlatch ceremony, that remarkable custom by which position and prestige was made to depend upon the lavishness with which gifts were distributed by the head of a clan at a feast; and in the second he records such of his experiences among, and impressions of the Indians, while acting as a Government official, as will serve to throw light on Indian character and mentality as expressed in religious belief, attitude to law and authority, and achievement under the white man's system of education. Mr. Halliday's views on racial origins are not to be taken seriously.

The author's outlook is that of a sympathetic official, whose duties and views of Indian character and custom coincide. Thus the potlatch, now forbidden by law, is regarded as detrimental to the interests of the Indian, because, involving a return with interest, often so high as two hundred per cent, it reduced the individual and his immediate group to penury, and was an increasing burden on the community. His account of the institution, however, is sufficiently objective to make it obvious that the potlach was the integrating factor in the community, and its abolition the death knell of Indian tribal society. The Indians themselves, or at least the younger men, being shrewd and progressive, welcomed a change which set them free from tribal obligations. The tribal disintegration which has followed is a typical example of the results of the application of White philanthropic and moral ideas to the administration of the affairs of a non-European culture. That the results in this instance have not been universally unfortunate is to be attributed to a sympathetic administration, as well as to the abilities and character of the Indians themselves, though the author is inclined to assign their achievement to the infusion of white blood.

Law and the Social Sciences

By Huntington Cairns. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xiv+279. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., 1935.) 12*s*. 6*d*. net.

WHAT comes out clearly in Mr. Cairns's study of the relations of jurisprudence to anthropology, psychology, political theory, economics and sociology is that law, regarded more especially as the judicial process, has become increasingly sociologically minded, and that if it is to achieve full power in ordering human society, "it must join with the other

social sciences in a united effort to solve the problems common to all". These are not novel conclusions, and yet the task the author set himself was well worth doing. For it is often forgotten that only as late as the sixteenth century did jurisprudence escape from theology, philosophy and ethics, and became a separate discipline. This emancipation was undoubtedly necessary at the time. But once achieved, it became even more necessary, with the growing complexity and interconnectedness of society, to bring law back into the totality of social life. Society is one, and each of the social sciences, including law, studies and attempts to manipulate but one aspect of it. They cannot therefore remain isolated from each other if they are to be useful instruments for theoretical understanding and practical manipulation.

Every topic here touched upon would require a separate volume for full treatment, and it says much for the author's wide reading and large equipment that he has been able to concentrate so much in such a narrow compass. At the same time, a certain discursiveness and lack of criticalness (see, for example, the discussion on intelligence tests and criminal responsibility) are evident, and no doubt the author would be the last person to claim that he has exhausted the field. The book is a pioneer work, and from that angle deserves close study.

J. R.

The Dorset Coast: a Geological Guide

By G. M. Davies. Pp. vii+126+8 plates. (London: Thomas Murby and Co., n.d.) 6*s*. net.

PRACTICALLY the whole of the Dorset rock consists of formations of Mesozoic age, and it has, moreover, a wonderfully extensive and various catalogue of fossils. Whereas one may traverse the greater part of Cornwall without finding fossils at all, here in Dorset one cannot go into any little bay or cove without finding an abundant and extensive fauna. Few portions of our Jurassic rocks can be studied in such detail and admirable sequence as the Dorset coast line, which forms a very distinct opposite to the neighbouring coast of Devon.

The numbers of photographs in this book, and the meticulous care with which these have been chosen, and the care with which various details have been picked out, all add immensely to the value of the book.

We regret that so little has been said about the Chesil Bank, which still remains a problem. The Palæozoic pebbles are by no means so few as Mr. Davies suggests, and their persistent appearance has yet to be explained. For even supposing these erratics to have travelled all the way from their home in the St. Just cliffs, just around the Land's End, it still remains a problem as to why they should be piled up here, and yet why the beaches of Cornwall and South Devon contain so few.

We heartily congratulate Mr. Davies on having produced a book the clearness and simplicity of which make it a pleasure to read. Not only the tyro in geology but also many a professional geologist will take this with him when he travels the Dorset coast.

F. J. STEPHENS.

A World Production Order

By Dr. F. M. Wibaut. Translated from the Dutch by R. W. Roame. Pp. 240. (London: George Allen and Unwin, Ltd., 1935.) 6*s*. net.

THERE is much in this unpretentious book to commend it to the attention of the scientific reader. Its indictment of our present system of production and distribution as obsolete and inadequate, leading to a chronic condition of chaos in which unemployment on a large scale is endemic, is characterised by common sense and moderation. No less noteworthy for the complete absence of denunciation and class hatred or bitterness is its condemnation of the private monopolies which are the inevitable result of the present system and which control, in their own interest only, prices of the necessities of life. Its resolute attempt at fundamental thinking on the situation and to secure the economic conditions which will enable the scientific and technical triumphs of mankind to benefit the whole race has a sure claim on the sympathy of scientific opinion, and this claim is reinforced by the many years of administrative experience in Amsterdam from which Dr. Wibaut is able to speak.

Dr. Wibaut sketches for his readers no Utopia, nor does he make the mistake at this stage of outlining ways and means too closely. He defines with some certainty a fundamental change in the world's organisation and the improvements required to effect that change. He indicates too that in the League of Nations and the International Labour Organisation there already exist the germ of international and national councils and institutes required for building up ordered production on the basis of democracy. He is most concerned, however, to provoke thought, above all creative thought, through which alone can be worked out the details of a new production system based on the collective satisfaction of human needs.

The Geographic Pattern of Mankind

By John E. Pomfret. Pp. xv+428+22 plates. (New York and London: D. Appleton-Century Co., Inc., 1935.) 15*s*. net.

DR. POMFRET views his 'geographic pattern' as an essential background for the comprehension of economics, politics, history and the other social sciences; and in surveying the modern world as composed of areas each exhibiting a preponderant type of climate or physiographic influence, he consistently maintains this point of view. His aim is to show in detail how this main factor has determined the social organisation, utilisation of resources, character of industries and type of occupation, incidentally bringing out with no little point and emphasis the differences in character and achievement of regional forms of culture which have developed under these varying influences. The differentiation, social and psychological, of China and Japan, or the characterisation of South America, with particular reference to its economic and political development, may perhaps be regarded as particularly successful examples of his understanding of the interplay of the forces involved.

The Deep-Water Circulation of the Indian Ocean

By A. J. Clowes and G. E. R. Deacon

UNTIL very recently, it has been generally assumed that the deep-water circulation in the Indian Ocean was very similar to that of the Atlantic ; in certain features, such as the Antarctic bottom current and the Antarctic intermediate current, the close resemblance between the two *Gauss* also showed that there was a highly saline warm deep layer in the Antarctic and sub-Antarctic regions ; and since the data from the intervening part of the ocean were very scanty, it was reasonable to suppose that the warm deep layer found in the south was a continuation of the deep current

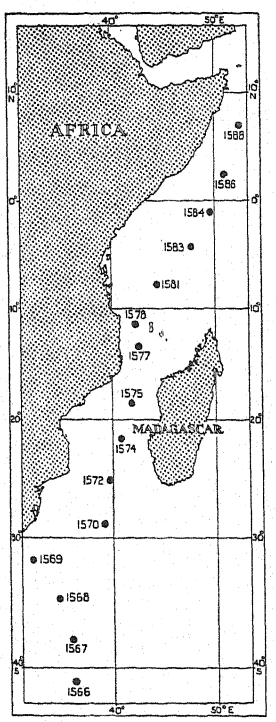

FIG. 1. Chart showing positions of hydrological stations made by the R.R.S. *Discovery II* in April 1935.

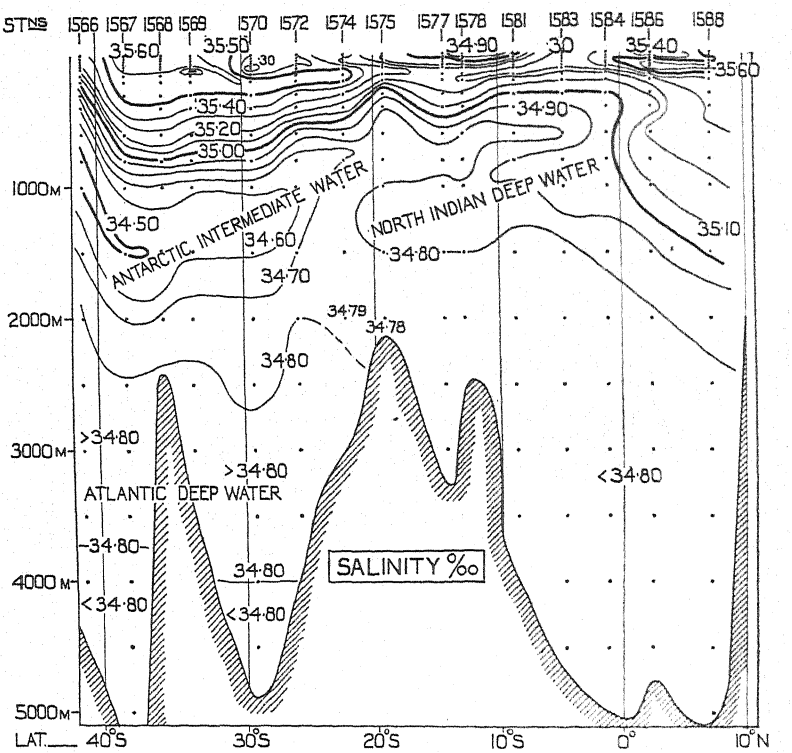

FIG. 2. Salinity at the stations shown in Fig. 1.

oceans is still undisputed. It has, however, been suggested that the north Atlantic deep current—the highly saline deep current which Merz and Wüst (1922, p. 23) showed to flow southwards between the intermediate and bottom currents in the Atlantic Ocean—has no parallel in the southern part of the Indian Ocean.

The existence of a southward deep current of highly saline water in the northern part of the Indian Ocean was demonstrated very clearly by Schott (1926), Matthews (1927) and Möller (1929), and it was found to be composed of highly saline surface water sinking from the coastal regions of the Arabian Sea and the neighbouring gulfs, particularly from the Red Sea. The observations made by the *Challenger*, *Valdivia*, *Planet* and which spreads southwards from the north. It was therefore assumed by L. Möller (1929, p. 37) that the north Indian deep current filled the deep layer in the western part of the Ocean with water of salinity more than 34·80 per mille almost as far as the Atlantic-Indian cross ridge in about 50° S.

Thomsen (1933) has, however, used the observations made by the *Dana* (1932), and the *Willebrord Snellius* (1932) in the southern tropical and subtropical parts of the ocean to show that the assumption that the highly saline deep layer in the south was a continuation of the deep current in the north was, after all, not justified. He found that the north Indian Ocean deep current did not carry water with a salinity greater than 34·80 per mille south of a line from the northern end of

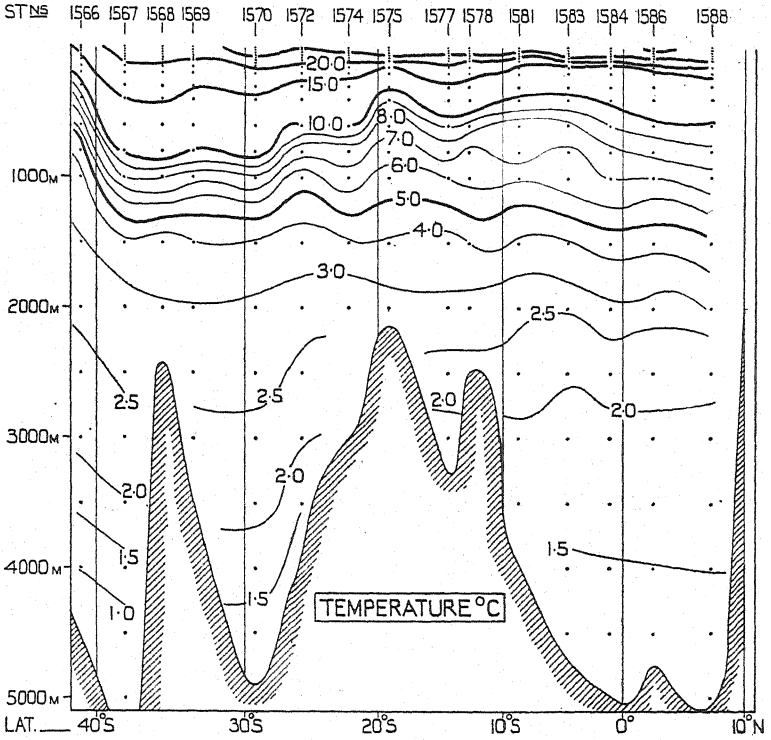

FIG. 3. Temperatures at the stations shown in Fig. 1.

Madagascar to Ceylon. L. Möller (1933) was not convinced that the new data which Thomsen used justified at present a reversal of her former conclusions. In a later paper, Thomsen (1935, p. 299) states that at stations on a line between Ceylon and Cape Delgado he found no traces of a deep current between 2000 m. and 3000 m., but that it is possible that a rudimentary, southerly-directed current exists with a nucleus at about 800 m. in the north and about 1200 m. in the south.

Further light has been thrown upon the problem by a series of observations made by the R.R.S. *Discovery II* in her recent voyage from the Antarctic in 1935 on a line from Marion Island through the Mozambique Channel to the Gulf of Aden. The positions of the stations and preliminary salinity, temperature and oxygen content sections are shown in Figs. 1–4. The north Indian deep water is clearly distinguished at the northern end of the sections by its high temperature and high salinity, and low oxygen content. The salinity section (Fig. 2) shows that it has a salinity of 34·80 per mille as far as 20° S. approximately. South of this latitude there is a second body of highly saline water with a salinity of more than 34·80 per mille, but it is clear from the salinity, temperature and oxygen content that this second body of highly saline water is not merely a continuation of the north Indian deep current. It is approximately 2° C. colder and 2 c.c. per litre richer in oxygen, and is therefore derived partly from another source, plainly from an eastward current of Atlantic deep water. The existence of such a current is in fact generally agreed upon. It was inferred by Merz and Wüst (1922, p. 23) from the temperature chart for 1500 fathoms given by Buchan (1895) in the *Challenger* reports, and also recognised by Wüst (1926, p. 250) and Möller (1929, p. 37).

Although there is this body of Atlantic deep-water in the southern part of the sections, our observations suggest that the north Indian deep current does not come to a sudden termination in 20° S. The oxygen

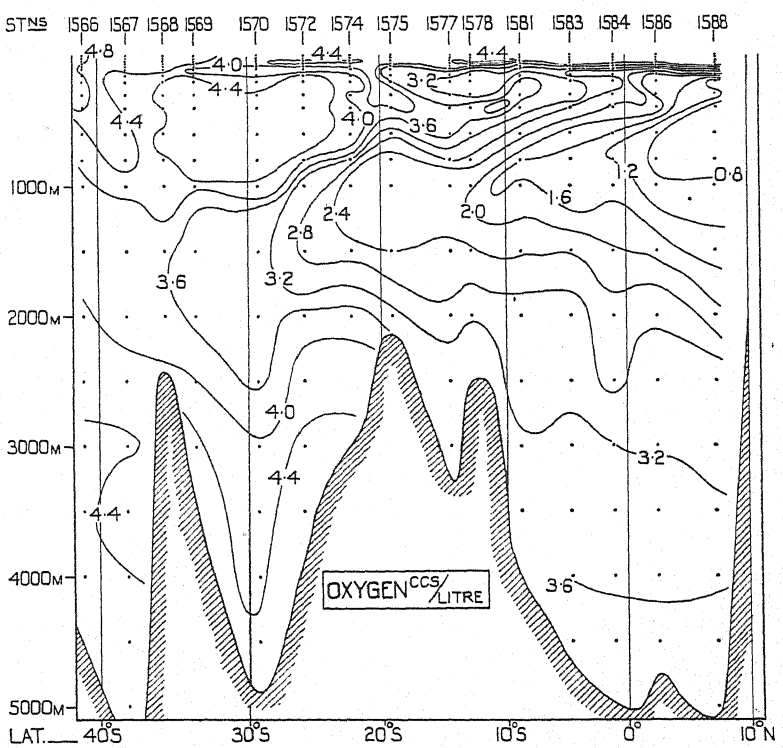

FIG. 4. Oxygen content at the stations shown in Fig. 1.

distribution, especially, suggests that the north Indian deep water flows much farther south in the upper stratum of the warm deep layer, sandwiched between the Antarctic intermediate current and the Atlantic water. A chart of the oxygen distribution in the warm deep layer in the southern part of the Indian ocean, to be published in a forthcoming report by one of us (G.E.R.D.), shows that south of Africa the oxygen content of the deep layer falls rapidly towards the east, indicating that the Atlantic water is joined by a southward movement of water containing less oxygen from the northern part of the Indian Ocean.

A comparison of our section with that of Möller (her Mozambique section is along almost the same line as ours) suggests that the volume and salinity of the north Indian deep current are subject to large variation, probably related to the changes of salinity in the coastal regions and to the current differences brought about by the changes of the monsoon winds and variation in the south Equatorial current. The observations of the *Valdivia* and the *Ormonde* used by Möller show that the deep current fills the northern part of the Ocean with water of 35·00 per mille salinity as far as 8° S. and to a depth of 2000–2500 metres, while our section (Fig. 2) shows that this isohaline is not found south of the equator or deeper than 1500 metres. A strict comparison cannot be made between Thomsen's and our section, since his is much farther east than ours, but the volume of the deep current seems to have been less when his observations were made, since he did not find the 34·80 per mille isohaline south of a line from Ceylon to Cape Delgado (1933, p. 78), whereas we found it to extend as far as 20° S.

Thus, as a result of the recent observations of the R.R.S. *Discovery II*, the extent of the southward flow of the north Indian deep current appears to be a compromise between the views of Möller and Thomsen. Oxygen observations in particular show (Fig. 4) that this current can be traced southwards as a tongue of poorly oxygenated water sandwiched between Antarctic intermediate water and an eastward current of north Atlantic deep water.

A Century of Botany*

1835—1885—1935

By Prof. F. O. Bower, F.R.S.

IN 1835 Glasgow already possessed a botanic garden, which had been established in 1818 by Royal Charter. In this same year, the regius chair had also been founded. It was occupied in 1835 by its greatest tenant, Sir William Hooker, who after holding it for twenty years became, in 1841, the first director of the Royal Botanic Gardens at Kew. He was succeeded in that office by his son, Sir Joseph Hooker, who had been educated in this University. Thus Glasgow may be held as the cradle of the national establishment. Under the care of the professor, the Royal Botanic Garden of Glasgow had become a centre of high horticulture, and of the distribution of rare plants, many of them new to science. But there was in 1835 no Department of Botany in the old College. There were no laboratory, botanical museum, herbarium, or library, beyond what Hooker himself possessed, which was accommodated in his own private house. So when he was appointed as the first Director of Kew in 1841 he naturally took his collections with him, leaving the University wholly denuded; though Kew itself absorbed thus the finest private collections in the country.

A brief survey may be made of the state of botanical science in the world at large in 1835, when Sir William Hooker was in his fifteenth year of office at Glasgow, and in the full plenitude of his powers as a man of fifty. Nothing can be more revealing of the time than that while it was pre-evolutionary, it was also pre-protoplasmic. Though plant anatomy was well advanced, with

* From an address delivered on November 8 in the University of Glasgow by invitation, in celebration of the jubilee of Prof. Bower's appointment as regius professor of botany (April 1, 1885) and of Prof. Bower's eightieth birthday (November 4, 1935).

its foundations securely laid by Hooke and Grew in the seventeenth century, and though their observations had been extended in the eighteenth by the phytotomists of the Continent, it was only the scaffold of cell-walls that they knew: the vital body which those walls enclosed was almost wholly missed. Before 1835, sporadic allusions had already been made to a transparent slimy substance contained within the cell-walls. Interest had been taken in the movements of granules within it, and suggestions made of vital motion. But it was only in 1831 that the nucleus was first recognised by Robert Brown as a body of general occurrence in the cells of plants: while the structural correspondence of the cell contents with the sarcode of animals was first published by Schwann in 1839. Finally, it was not until 1846 that the word 'protoplasm' was introduced by von Mohl, to connote that "viscid fluid—of white colour—which occupies the cell-cavity". Thus the year 1835 fell within that short nascent period when the physical basis of life was emerging from obscurity towards definite visualisation, making modern physiology for the first time possible.

On the other hand, 1835 fell within the heroic age of scientific exploration: and Glasgow, through Sir William Hooker's son Joseph, took her full share. We may well hold the years from 1831 when the *Beagle* sailed with Darwin on board, or 1839 when Ross, with Joseph Hooker as a young medical officer, penetrated the Antarctic with the *Erebus and Terror*, to 1851 when Joseph Hooker completed his Indian journey—or better still 1852 when Wallace returned from the Amazon —as its golden period. Discovery was then in the air, with its handmaids collection and record. It opened with a tacit acceptance of the fixity of species, but it bore within the germ of evolutionary theory. Sir Joseph, in working out his circumpolar collections into the Antarctic flora, gave in 1859 expression to his belief in the mutability of species. This was the year of publication of Darwin's "Origin of Species". Sir Joseph was in fact the first of the great group who stood round him. Thus not only did 1835 fall within the nascent period of evolution, but also an alumnus of Glasgow, son of the some-time professor of botany, was himself deeply involved.

Sir William, however, belonged to a prior age. He never publicly committed himself to the later view of the mutability of species. He was essentially an old-fashioned systematist, with a particular leaning towards the mosses and ferns. He had already published his "British Jungermanniaceæ" in 1816, as well as important memoirs on mosses. But it was during the period in Glasgow that he produced with Greville the sumptuous "Icones Filicum" (1851), and with the artist Ferdinand Bauer the preparatory work was being done there for the "Genera Filicum" (1842). Later came the "Species Filicum" (1846–64), a work which was finally condensed into the "Synopsis Filicum" (1865). These and other of his writings established Sir William's position as the leading systematic authority of his time on the Archegoniatæ. But he was also a general botanist, whose personal influence moulded the scientific establishment at Kew. Robert Brown still reigned at the British Museum. The effect of their work spread to the universities, with the result that between 1835 and 1885 descriptive and systematic botany held the field in Britain.

My second date, 1885, also marks a nascent period, but the conditions were very different from those of 1835. The intervening half century had brought in Britain, as the result of foreign travel, great accessions to its herbaria. The systematic treatment of these, particularly as published in floras of the British possessions, had occupied the time and capacities of our professional botanists to such a degree as almost to paralyse efforts in other branches of the science. Not only Kew and the British Museum, but the universities as well, were drawn into the floristic vortex. In Glasgow itself a notable result was the "Flora Indiae Orientalis", in which Prof. Walker Arnott described the rich Indian collections made by Wight. It was published in their joint names. But, meanwhile, on the Continent, and particularly in Germany where imperial demands were not so pressing, laboratories private and public were opening. The branches of minute anatomy, physiology and development of plants were advancing rapidly. In particular, Schleiden, Hofmeister, Naegeli and Pringsheim were laying afresh the foundations of morphology, broadly based upon the study of anatomy and developmental life-histories. Physiology was rejuvenated under the genius of Sachs. Tulasne and De Bary were meanwhile establishing a new cult of mycology, while Bornet and Thuret were doing the like among the algæ. Our own universities, however, concentrated their botanical teaching in the 'sixties and 'seventies upon the classes for medical students. The professors based their rather limited syllabus not on the biological side of the science so much as on the floristic and pharmaceutical. The idea of tropical forests and desert islands, of Crusoe and the Swiss Family Robinson hovered in the background. There were before 1870 no botanical laboratories in the British universities. Floristic and systematic botany, with dashes of pharmacy, morphology and economics made up the usual fare offered to the student. The individual professor might take what

special branch of study he pleased: but this rarely filtered through, as a private act of grace, to the individual pupil. In point of fact, Britain had fallen behind in all branches excepting systematic botany, in which she excelled.

The revival of biology, and of its branches of zoology and botany, was initiated in Britain by Huxley, Michael Foster and Thiselton-Dyer: but an important preliminary step was taken by Dean Farrar, himself at the time a public-school master. He advocated the teaching of science in schools, at the British Association meeting at Nottingham in 1866, with Huxley in the chair. Little result followed at first in the old public schools or in the universities. It was, in fact, through the national schools that the revival began. If science was to be taught there, the teachers must themselves be taught first. This led to the classes for teachers at South Kensington, organised under Huxley from 1871 onwards. The essential feature of his method was a daily preparatory lecture, followed by personal observation by each student. Thiselton-Dyer undertook the botanical side and Vines, originally a medical student in London, assisted him: by his election as a scholar of Christ's College, Vines formed the connecting link with Cambridge. Marshall Ward soon stood out among the early pupils at South Kensington, and later he also was entered as a scholar of Christ's. He and I, as fellow students at Cambridge under Vines, soon found places on the demonstrating staff to the summer classes at South Kensington.

This revival in the 'seventies spread with varying success to the English universities: but Huxley's methods caught on less readily in Scotland. The northern lag was, however, made up in Glasgow by the appointment of Bayley Balfour, fresh from foreign travel and visits to German laboratories, as professor of botany there in 1879. When I succeeded him in 1885, also having experience of foreign universities, and after three years' experience as lecturer at South Kensington, elementary practical classes of Huxley's type were already in being in London and elsewhere for the study of the 'New Botany': my duty was to develop them in Glasgow.

All this sounds very easy now: but the revival that spread from South Kensington found opposition like any other missionary effort. "The Cause", as Marshall Ward used to call it, involved a change over from the dead to the living plant: from the herbarium, supported by study in the garden and field, to observation at the laboratory table by each student himself. Structure, function, development and life-history were to be examined, and that not only in flowering plants, but in the cryptogams as well.

In 1885 there were in the Scottish universities no faculties or degrees in science: nor were there any advanced classes under ordinance. In Glasgow, botany was studied officially only in the summer. Not only was the time then devoted to botany in Glasgow limited, but also the space available for its study. The Department in 1885 consisted of two small rooms used as voluntary laboratories, and dusty attics for the herbarium. There was no lecture room, but such as could be borrowed from another department. I paid my own assistant and laboratory attendant. There was no official staff, not indeed any department at all in the modern sense. In theory this was corrected under the Act of 1889: nevertheless, for sixteen years after my appointment the accommodation remained the same. It was not until 1901 that the new building was opened.

Great as were these official and material defects in Glasgow in 1885, that date again fell within a nascent period in the history of botany in Britain. The first English edition of Sachs's "Textbook" had been published in 1875: the translation of De Bary's "Anatomy" followed in 1884, and that of Sachs's "Lectures on Physiology" in 1887. Thus the student of the British revival was supplied with fresh textbooks. His observational work was also vivified by the experience of teachers who had studied personally under these great men. Beyond this, many new starts were already in the air. Tangl had demonstrated in 1880 the continuity of protoplasm from cell to cell, and Gardiner extended these results so that Sachs found himself able in 1882 to state that "every plant, however highly organised, is fundamentally a protoplasmic body forming a connected whole".

On the other hand, in 1874, Schwendener had given a new aspect to anatomy by demonstrating the mechanical principles that underlie structure: while Haberlandt further stimulated the functional study of tissues by his "Physiologische Pflanzenanatomie" of 1884. At the same time, from the Buitenzorg garden, Treub was revealing the wonders of Lycopod embryology, with their bearing upon the morphology of the Archegoniatæ. At Bonn, Strasburger had already laid the foundation for cytology by his inquiry into the minute details of nuclear division. The third edition of his "Zellbildung und Zelltheilung" had appeared in 1880, while statistical hybridisation, the experimental correlative of nuclear division, had already been initiated by Mendel in 1865, though the world did not know of his results until 1900. Finally, it was in 1885 that Weismann's pronouncement on germplasm was published. Thus at our second period many new lines of advance were being opened up.

Such was the developmental phase of the science of botany when I accepted the Glasgow chair in 1885. Botany was no longer a valley of dry bones: a progressive and living aspect had been given to it. But at Kew and the British Museum great systematists still upheld the old classificatory traditions: and there appeared to be some danger of British botanists separating into two camps—as systematists or as physiologists. On the Continent, however, an ameliorating influence sprang from the work of Warming, who combined under the name of ecology the records of function and of distribution: thus presenting to systematists a living aspect of their study. Here at home Sir Joseph Hooker was the Colossus who had a foot down in both camps. It was, in fact, a forecast of ecology that he had practised in the Antarctic. But he was never a teacher, nor did Kew compete with the colleges, which had drifted off with a dangerous and almost exclusive bias towards the 'New Botany'.

(To be continued.)

Progress of Food Investigation

AS in previous years, the report of the Food Investigation Board for 1934* describes the researches carried out at the various research stations of the Board by the members of the food investigation staff and emphasises the ways in which laboratory results have been applied commercially. Sir Frank Smith was appointed chairman of the Board, in succession to Sir Joseph Broodbank, who resigned; Mr. E. Barnard was appointed director of food investigation and Dr. Franklin Kidd superintendent of the Low Temperature Research Station, in succession to the late Sir William Hardy. That the work of the Board is of value to all parts of the Empire has been signally recognised by the contributions made by Dominion Governments, which amount to nearly £10,000 a year, and show the wide extent to which Imperial co-operation in this field of research has already grown.

The discovery that beef can be stored in the chilled state for 60–70 days when the atmosphere contains 10 per cent of carbon dioxide has quickly led to the importation of considerable amounts of chilled beef from Australia and New Zealand; during 1934, no less than 4,400 tons were imported in gas storage from these two Dominions, and it is now practicable to secure the necessary gas-tightness in the holds. At the same time, the careful preparation of the meat and the hygiene of the slaughterhouse floor are probably of even more importance than control over the conditions of transport.

A number of problems, however, remain for solution, including the correct storage to prevent chafing, and the proper conditions as regards cooling, humidity and air circulation for the preservation to the fullest extent of the natural appearance or bloom of the meat. Loss of bloom is largely due to the oxidation of hæmoglobin to methæmoglobin; the reaction is monomolecular with respect to the concentration of reduced hæmoglobin and roughly monomolecular with respect to the partial pressure of oxygen; the rate is maximal at a partial pressure of about 23 mm. of carbon dioxide. The results show that 10 per cent of carbon dioxide in the atmosphere has a negligible effect, but with this concentration that of oxygen must be increased to more than 60 per cent if the production of methæmoglobin is to be appreciably retarded.

Important developments have taken place during the year in the application of refrigeration to the herring industry. Experiments had shown that herring, although containing much more fat than white fish, could be brine frozen at the usual temperature of −5° F., and would make good kippers after at least five months' storage at that temperature. 800 tons of herrings were then frozen in one of the East Coast factory ships with the view of using them for kippering, for canning and for consumption fresh during the early months of this year (1935) when home-caught herrings are not normally available.

The gas-storage of home-grown fruit has gone on apace. During 1934 the number of commercial gas-stores in Great Britain increased from 12 to 40, and the number has probably doubled in the course of the succeeding twelve months. It has been found that the winter temperatures of English warehouses are too low for the satisfactory ripening of several varieties of imported pears and plums. Conditioning for a brief period at a temperature of 70° F., however, greatly improved the quality of South African and Australian William pears and of South African Kelsey plums. The best conditions for commercial conditioning have yet to be ascertained, but there is little doubt that conditioning will soon be considered essential for the successful marketing of certain varieties of imported pears and plums.

* Department of Scientific and Industrial Research. Report of the Food Investigation Board for the year 1934. Pp. 261+x. (London: H.M. Stationery Office, 1935.) 4*s*. net.

The use of wrappers treated with a solution of iodine in potassium iodide has been found to retard the development of fungal rotting in grapes, tomatoes and oranges. Brown rot of plums and peaches has also been reduced by iodised wraps. The appearance and flavour of the fruit are not impaired, nor is ripening hastened. On the other hand, certain varieties of plums and peaches are adversely affected; they fail to ripen properly or may even turn black. When iodine is successful, it is because spores and young mycelium at the critical stage of infection are far more susceptible to its action than are old mycelium and the tissues of the fruit; it can thus be used in concentrations sufficient to retard the development of moulds without causing damage to the fruit.

Further results of interest have been obtained from the continued study of the critical changes occurring in the apple at the climacteric, the most important of which is the identification of the active substance which is given off by apples at their climacteric change, and which itself stimulates this change in other apples. It was identified by absorbing it in bromine at −65° C., afterwards preparing a crystalline derivative identified as diphenylethylenediamine. The suggestion that the active substance is ethylene was, therefore, confirmed. About 1 c.c. is apparently given off during the whole of an apple's senescence.

An accidental discovery of great practical interest was made in the course of gas-storage trials of the 1934 season; a set of ripe, strongly-smelling, post-climacteric apples was included in some of the experimental cabinets among several other varieties in the pre-climacteric condition. The ripe fruit caused a considerable amount of physiological damage to the rest of the fruit in the form of spotting round the lenticels.

Progress is recorded in the study of two common diseases of stored apples, namely, scald and low temperature breakdown. Scald is produced by changes in the tissues of the fruit occurring weeks or months before the injury becomes apparent; prevention by oiled paper wrappers is chiefly efficient during these early predisposing changes. Scald was also almost completely prevented in Newton Wonders stored at 3° C. by brief intermittent warming of the fruit at 15° C. Scald is probably due to an excessive accumulation in the superficial tissues of the fruit of some volatile substance.

Among other points in the report to which attention may be directed is the investigation into the stability of synthetic vitamin C (ascorbic acid) during canning. It was added to runner beans, which do not naturally contain much vitamin C, to spinach and to apples and apple jelly; in no case was the loss greater than 25 per cent during the canning.

This brief summary of some of the investigations described in the report will give some idea of the range of the researches carried out by the Board, and their importance for the nation's food supply.

Obituary

Dr. Griffith Evans

DR. GRIFFITH EVANS, whose death on December 7 we regret to announce, was a pioneer in the study of protozoology in connexion with infections, and the first man to associate trypanosomes with the production of disease. He was born at Tymawr, near Towyn, Merionethshire, on August 7, 1835. After studying medicine for a short time with a medical practitioner at Towyn and Aberdovey, he entered the Royal Veterinary College, London, where he qualified as M.R.C.V.S., and later passed into the Royal Artillery, with which regiment he served in Canada during the American Civil War. During his years of service in Montreal he registered in the Medical Faculty of McGill University, and graduated M.D., C.M. in 1864.

On his return to England in 1871, Evans was transferred to the Army Service Corps and continued his medical studies at King's College, London, and elsewhere until 1877, when he was sent to India. It was there that his great work on blood parasites was carried out. Microscopy had been his hobby since his earliest student days, and an important part of the equipment which accompanied him to India was a portable microstand, the best lenses which he could obtain up to 1/12th immersion, a suitable condenser, etc.

On arrival in India, Evans was appointed to investigate an endemic disease which for many years had been fatal to cavalry and artillery horses; by microscopic examination of the blood, which revealed the specific bacillus in the blood of every patient, Evans at once proved the disease to be anthrax fever. What surprised him most in his investigations was the fact that the first change in the blood seen under the microscope was a great increase in the number of the large white corpuscles before the bacillus could be seen; moreover, when the bacilli came, they appeared to be closer to the white corpuscles than to the red. He reported his conviction that the large

granular corpuscles had an important relationship to the bacilli, though he was unable to prove what that relationship might be. This was in 1878, six years before Metchnikoff discovered them to be phagocytes, and at a time when Evans himself did not know even how to fix and stain microbes in the blood for microscopic observation.

In 1880 Evans began his work on surra. He was requested to proceed to Dera Ismael Khan, where surra had been fatal to horses and camels for many years; and upon studying the reports which had already been made upon the disease he at once reached the opinion that it was due to a parasite of the blood —an opinion which had never before been formed. After much opposition, he gained permission to carry out his investigations with a free hand, to make what experiments he wished upon sick and healthy animals, and to kill the animals at any stage of the disease. His first act was to examine microscopically the blood of a surra patient: it was swarming with parasites. Though Koch had not yet made his classical postulates, and though Evans did not know the nature of the microbes revealed to him, he immediately associated them with the production of the disease. They were the parasites which, at first called *Trichomonas evansi*, are now known as *Trypanosoma evansi*.

Evans at once took steps to show his newly-discovered microbes to Dr. Timothy Lewis, the discoverer of the parasite in the blood of the brown sewer rat—now called *Trypanosoma lewisi*. Without hesitation Lewis declared that the two parasites were, with some slight difference, morphologically alike; but he emphatically denied that they were pathogenic. His rats were, in his opinion, healthy, and he did not believe that Evans's microbes were the cause of surra. Nevertheless, Evans continued his investigations eagerly, seeking to prove that a definite relationship existed between the variable number of the parasites present in the blood and the course of the symptoms. Official opinion was strongly against him. In fact, in Evans's own words, the Surgeon-General, the Chief Sanitary Officer and all the senior medical officers "sat upon me heavily", but the Government printed his reports, and he had the gratification of knowing that his statements spurred on a number of younger men to continue investigations along lines which he had laid down.

Evans returned to England in 1885, and after further work in Crookshank's laboratory, King's College, London, retired from the army in 1890. In 1917 he was awarded the Mary Kingsley Medal by the Liverpool School of Tropical Medicine, in recognition of his distinguished scientific work, and on that occasion he wrote a short autobiographical memoir, which was published in vol. 12 of the *Annals of Tropical Medicine and Parasitology*. A year later the Royal College of Veterinary Surgeons awarded him its John Steel Medal.

Dr. Griffith Evans celebrated his hundredth birthday in August last, when he was the recipient of a presentation scroll from the Royal Veterinary College and of many congratulatory messages (see NATURE, August 3, p. 173 and August 17, p. 251).

Dr. J. H. Breasted

WE regret to record the death of Dr. J. H. Breasted, the well-known Egyptologist, founder and director of the Oriental Institute of the University of Chicago, which took place on December 2, in the Medical Center Hospital, New York, at the age of seventy years. Dr. Breasted, who had returned to the United States from Italy only a few days previously, was thought to be suffering from an attack of the tropical malaria to which he had been subject for some years; but his illness proved to be due to hæmolytic streptococci, and terminated fatally.

James Henry Breasted was born on August 27, 1865, and was educated at the Chicago Theological Seminary and the University of Berlin. At the latter, he devoted himself particularly to Egyptological studies; and, indeed, the abiding influence of the Berlin school of thought was apparent throughout his work. In 1894, he became assistant in Egyptology in the University of Chicago, and in 1901 was made director of the Haskell Oriental Museum. Among other university appointments, he occupied the professorial chair in Egyptology from 1905 until 1933. His more important activities outside the University included a mission to the museums of Europe in 1900 to prepare documents for the Imperial Egyptian Dictionary for a commission of the Royal Academies of Germany, and the direction in the field of the expedition of the University of Chicago to Nubia in 1905–7.

By the close of the first decade of the present century, Breasted's international reputation as an Egyptologist and an ancient historian stood high, owing in no small measure to his attractive, and at the same time scholarly, "History of Ancient Egypt" (1905), and his excerpts from original documents of the Egyptian historical records, of which he had published five volumes. His strength, however, as was proved by his later activities, was even greater in the organisation of research than in his quality as a research worker. His interests had transcended the bounds of Egyptology and at a comparatively early stage of his career he had begun to formulate plans for a scheme of research into the origins and growth of civilisation on a grand scale, the theatre for its operation—the ancient East—being determined by the fact that here the lengthy span and the continuity of man's existence as a member of organised society could be investigated on archæological sites with a wealth of detail that was impossible in any other part of the world.

These plans did not attain fruition until after the Great War. As the result of an expedition of reconnaissance through the Near East in 1919–20, Breasted mapped out a plan of campaign for research in the field which covered all the main historical, geographical and chronological strategic points in Egypt and Western Asia, extending from the time of palæolithic man in the Nile Valley and Mesopotamia down to the days of the Persian Empire. As a necessary complement and accompaniment was an institute for the interpretation of results and further research at headquarters in Chicago, which so far as library and laboratory work were concerned was to be duplicated on a reduced scale at headquarters

in the field. Thanks to the generous assistance of Mr. J. D. Rockefeller, Jr., who accompanied Breasted on a tour of the chief pivotal sites of his scheme, it became possible to put the plan into operation; and it took material form as the Oriental Institute, which, as Breasted stated, at the time of the formal dedication of its own building in December 1931, in addition to its activities in Chicago, had no less than eleven expeditions at work in the field at one time. The placing of these expeditions in reference to the respective phases of historical and cultural research which Breasted anticipated that each would elucidate, showed a masterly grasp of the essential movements of ancient history, a quality conspicuous in what are perhaps his best known works "The Development of Religion and Thought in Ancient Egypt" (1912) and "A Survey of an Ancient World", "Ancient Times: a Survey of the Early World" (1916), and "The Dawn of Conscience" (1933).

WE regret to announce the following deaths:

Prof. J. S. Mackenzie, emeritus professor of logic and philosophy in the University College of South Wales and Monmouthshire, Cardiff, on December 6, aged seventy-five years.

Prof. Charles Richet, professor of physiology in the Faculty of Medicine, University of Paris, on December 4, aged eighty-five years.

Sir Alfred Sharpe, K.C.M.G., C.B., formerly governor of Nyasaland, who was well known as a traveller and big-game hunter, author of "The Backbone of Africa" (1921), on December 10, aged eighty-two years.

Lieutenant-Colonel E. W. White, C.B.E., emeritus professor of psychological medicine in King's College, London, on November 28, aged eighty-four years.

News and Views

The Ultimate Value of Science

IN a recent address on "Ultimate Values of Science" before the Commonwealth Club of San Francisco, Dr. J. C. Merriam, president of the Carnegie Institution of Washington, discussed the question whether, by reason of science or research, the world has been made a better place in which to live, or life has become more worth while. Referring first to the way in which better use is being made through science of natural resources, Dr. Merriam pointed out that though we have still a long way to go in learning to control the living world, the way has been marked out, and mankind may be expected to follow it. Moreover, organisation of society has made possible the transmission of knowledge from one generation to another, and science in particular has made possible the recording and continuous development of knowledge in a way which no one generation could achieve alone. The whole capacity for constructive work has been increased, and science is gradually giving us a new outlook over the universe, with ampler opportunity for appreciation of life and a new attitude towards its problems. The scientific point of view and the humanistic point of view require adjustment, if the full value of science, art, philosophy and religion is to be secured for mankind.

DR. MERRIAM urged that science, by reducing the uncertainties of life, increasing the assurance of progress and broadening the possibilities of achievement, has increased the opportunity for constructive living and thus favoured the development of the individual. He insisted that the problem of leisure should be considered primarily in terms of opportunity, and that it is essential to guard against a narrow vision in facing this and other problems of citizenship. The direct facing of the issues, the honest use of all the knowledge gained, is the surest way to recovery, and the wide acceptance of an attitude of mind illustrated by the pattern of scientific thought with its persistent search for facts upon which to base judgment and its broad vision over the world of things and events is an urgent need. The building of a better world depends upon the quality of intelligence used and upon clarity of vision, as much as upon thorough investigation and correlation of the facts.

Romanticism and the Modern World

AT the Royal Institution on December 6, Mr. F. L. Lucas, fellow and librarian of King's College, Cambridge, delivered a discourse on this subject. Romanticism, he said, may perhaps be called the literature of intoxication and dream. Freud has pictured the human ego as living a harassed life between the conflicting claims of the instinctive, animal 'id', the 'super-ego' or sense of social obligation, and the 'reality-principle' or sense of fact. Eighteenth-century classicism shows above all a too tyrannical control, by the two last, of the dreams and impulses that rise from the less conscious depths of personality. The Romantic revival was a revolt of dreamers against those twin sleepless dragons—'good sense' and 'good taste'. Though the Romantic Empire declined and fell, at its heart remains an eternal city. Romance is not dead. The science of the nineteenth century seemed to expel her with a brandished test-tube; the science of the twentieth re-opens the door to her with a bow. Yet this should not be exaggerated. The recently expressed view that poetry is independent of truth, a mere alcohol to stimulate 'emotional attitudes', is in its turn

a mystical excess. The world about us grows, it is true, more and more a dance of phantom formulæ on the points of dial-needles—the very stuff of dreams. Yet there are dreams and dreams. Some cohere and work; others do not. Incoherence was the weakness in the romanticism of Shelley or Victor Hugo; it is the romanticism of Homer or Hardy that is more enduring. Though dreaming, they imposed order and consistency even on their fantasies. Classicism, realism, romanticism, are all extremes—the three points of a triangle within which lies inscribed the magic circle where walk the greatest masters.

Parliamentary Science Committee

AT the annual meeting of the Parliamentary Science Committee held at the House of Commons under the presidency of Sir Arnold Wilson on December 5, the following officers were elected: *President*, The Right Hon. the Earl of Dudley; *Chairman*, Sir Arnold Wilson, M.P.; *Vice-Chairman*, Prof. B. W. Holman; *Deputy-Chairman*, Mr. Alan E. L. Chorlton, M.P.; *Hon. Secretary and Treasurer*, Mr. H. W. J. Stone. The honorary secretary's annual report discloses that representative scientific and technical institutions continue to affiliate to the Committee. During the 1934–35 session, questions were asked in Parliament concerning agricultural and horticultural research, interchangeability of water supplies, the International Locust Conference, milk pasteurisation, aeronautical engines (output), the gas grid scheme, the possibility of constructing earthquake-proof buildings in India, the research powers of the agricultural marketing boards, technical education and grants for industrial and agricultural research. Members of the Committee took an active part in the debates on the Herring Industry Bill and the Metropolitan Water Board General Powers Bill. Looking to the future, the Committee contemplates consideration in the near future among other things of such widely diverse subjects as the endowment of research, the finance of industrial research, income tax exemption on industrial research, patent legislation reform and the remission of death duties on bequests for research. The Committee compiles from Hansard and other sources a monthly summary of all scientific and technical matters considered in Parliament. The third volume of "Science in Parliament" has just been completed, and issued with a cross-reference index. Owing to the coming demolition of the Adelphi, the Committee is moving to Granville House, Arundel Street, Strand, W.C.2, on January 1.

The Imperial Cancer Research Fund

AT a meeting of the General Committee of the Imperial Cancer Research Fund held on December 4, the Duke of Bedford presiding, the thirty-third annual report of the Fund, dated 1934–35, was presented. A tribute was paid to Dr. J. A. Murray, who retired on October 1 after holding the directorship of the Fund since 1915, and who is succeeded by Dr. W. E. Gye. Dr. Gye in his report surveyed the scientific activities of the Fund since its inception, and referred to the work now in progress. The bearing of the researches upon tar cancers of mammals, and of the malignant sarcoma of fowls, the virus of which is a filterable one, on problems of human cancer was discussed, and Prof. J. McIntosh's experiments upon tar cancers of the fowl were summarised. The last-named tumours can at first be transmitted only by transplantation of a portion of the growth, but after transmission by this method for a few generations, it appears possible to transmit them by means of cell-free filtrates, that is, the virus becomes a filterable one comparable to that of the fowl sarcoma. The honorary treasurer, Sir H. J. Waring, reported that the Fund had a surplus of £7,568 for the year, and that legacies, donations and subscriptions all showed an increase over 1934. At the same time, the work is expanding, and expenses are likely to increase in the future, and he, therefore, made an appeal for additional contributions to the Fund. Dr. Gye, in summarising the present position of cancer research, said: "So far from there being any justification for pessimism, laboratory workers can all feel hopeful that the rapid progress now being made will lead to the solution of the primary problems of cancer".

Minerals and their Utilisation

SIR THOMAS HOLLAND, principal and vice-chancellor of the University of Edinburgh, propounded some very pertinent questions in proposing the toast of the profession of chemistry at the Ramsay Chemical Dinner held in Glasgow on December 6. Sir Thomas said that some of the problems which have been baffling geologists for a long time are really problems for the chemist. In the early days, geologists were content with a knowledge of the principal constituents of minerals, and based their classifications on these. But it has become evident that, in some cases, it is the smaller constituents of a mineral which are the most important. With civilisation has grown the desire for the use of metals, and this desire has increased and will continue to increase until the supply of metals has been exhausted. What the geologist is most interested in and what he wants the help of the chemist to solve are, therefore, the laws which control natural deposits. These reactions of Nature have gone on for countless ages of time, and have produced local concentrations of minerals. We produce annually about 50,000 tons of nickel and 1,500,000 tons of copper, and yet the crust of the earth contains about twice as much nickel as copper. Our production of lead is about the same as that of copper, and the available supplies of lead are only one fifth of those of copper and therefore one tenth of those of nickel. Zinc, of which we produce more than 100,000 tons a year, is only half as abundant as copper, and we use three times as much tin as nickel, though the supplies of nickel are 50–100 times those of tin. There is surely something wrong in this relationship. The different habits of rocks in showing that varying tendency towards rearrangement of their constituents open up problems in physical chemistry which are still largely obscure.

Physics in Industry in the United States

THE Advisory Council on Applied Physics of the American Institute of Physics met at the University Club, Pittsburgh, Pa., on November 16. This was the inaugural meeting of this Council, the purpose of which is to stimulate the application of physics by recommending suitable actions and policies to the Institute and the founder societies. Dr. Paul D. Foote, executive vice-president of the Gulf Research and Development Corporation, presided during the morning session and Dr. Lyman J. Briggs, director of the Bureau of Standards, during the afternoon. A discussion was held on the university education and training of men whose careers are to lie in industrial research. This discussion was opened with reports by Dr. Saul Dushman (presented by Dr. A. W. Hull) of the General Electric Co. and Prof. George H. Harrison of the Massachusetts Institute of Technology. Further discussion was devoted to the services which are rendered by the founder societies and the Institute to physicists employed in industrial laboratories. Reports on this topic were presented by Dr. L. O. Grondahl, director of research, Union Switch and Signal Co., and Prof. John T. Tate, of the University of Minnesota. In this connexion, the Council passed a resolution encouraging the formation by such physicists of a division on applied physics of the Physical Society. It is strongly felt that, while the Optical Society, the Acoustical Society and the Society of Rheology furnish splendid facilities for meetings and publications in their fields, other general applications of physics are neglected. The opinion of the Council is opposed to the formation of new specialised societies, since only through close integration with the Physical Society can the community of interest and interchange of ideas between the general applications and the basic fundamentals of physics be conserved.

South Indian Bronzes at South Kensington

BRONZE figures of the members of the Hindu Pantheon in their various manifestations are a conspicuous feature in the art of southern India. Of these, there is a large collection in the Madras Government Museum, which is perhaps not so widely known in detail as it deserves. The iconographic value of these bronzes is great: they are an important source of information for Hindu religious and cosmological conceptions; but, as a rule, their artistic merit is not high. It is now announced that, by a bequest of the late Lord Ampthill, formerly Governor of the Madras Presidency, the Victoria and Albert Museum, South Kensington, has acquired five of these bronzes, which are both of high artistic merit and of interest for their religious significance. Of these the most important is a figure of Siva as the Cosmic Dancer, which expresses the idea that the god himself is both performer and audience, while the universe is his theatre. The figure is four-armed, and appears in a dancing attitude in an encircling flaming nimbus. In its upper hands are a drum and fire as the symbols of creation and destruction respectively, while the lower hands are in the conventional attitudes of protection and assurance. The headdress includes a crescent moon, a human skull, cobras and flowers. The male and female principles are signified by a man's ear-ring in the right ear and a woman's ear-ring in the left ear. With this figure is shown one of his consort Parvati, in the manifestation of Gauri. These figures were found buried near a temple in the Tinevally District of the Madras Presidency. They were made by the *cire perdue* process; and from their stylistic affinities it is concluded that they belong to the late tenth or early eleventh century of our era. Lord Ampthill's bequest, part of which had previously been on loan in the museum, includes, in addition to the five bronzes, a number of other objects of great interest, illustrative of Brahmanical and Buddhist beliefs.

Vision in Optical Instruments

IN his Thomas Young Oration of the Physical Society on December 6, Prof. Charles Fabry discussed "Vision in Optical Instruments". Classical theory gives the *resolving power* of an optical instrument as determined by diffraction phenomena, but the result so obtained takes no account of the properties of the eye. Consequently, it does not indicate exactly what will actually be perceived with an instrument. What can actually be seen with such an instrument depends considerably on the brightness of the object examined, and on the degree of contrast between its parts and between the object and the background. In order to examine these questions, it is necessary to commence with the properties of the eye, and in particular, its ability to distinguish objects, not under the ideal conditions reached in the laboratory, but under conditions similar to those met with during observations. The effect of brightness is particularly large: for the greatest brightness the limit of resolution is about 1′, whilst it is 250 times as large (about 4°) for barely perceptible brightness. Contrast also has a very large effect. With these data, it becomes possible to determine what the eye will really see in a given instrument, assumed to be of perfect geometrical construction. The optimum size of exit-pupil can be calculated, and is found to be 0·7 mm. for the highest illumination, in agreement with experience. For an instrument with geometrical imperfections, an efficiency can be defined characterising the qualities of this instrument as compared with those of a perfect instrument. Stray light (fog) is another cause of inferiority in instruments, and the effect of this factor was discussed by Prof. Fabry.

Automatic Fire and Burglar Alarms

A DEVICE, invented in France, which can be used either as a fire alarm which will give automatically a telephone message to the fire brigade, or as a burglar alarm which will summon the police, is described in *The Times* of December 7. The apparatus is called a 'signaphone', and is already installed in about forty buildings in Paris. When used as a fire alarm, the device is operated either by thermostats fixed near the ceiling, or by push buttons so that a watchman has only to press the nearest button. The thermostats are operated by hot air rising to the

ceiling when fire breaks out. This breaks a closed electric circuit, and an electrical relay at once starts a clockwork motor. The motor drives a small dialling drum, the small metal discs on which correspond to the letters and figures of the telephone number of the nearest fire station. The station is thus called up and a gramophone record then comes into action giving, in a verbal message, the location of the fire and all essential details. This message is repeated continuously for 3½ minutes. If necessary, also, it can be made to ring up a second number—for example, that of the owner of the building—and repeat its message. When used as a burglar alarm, the signaphone is connected with an electric circuit in the building. In this case, a burglar who opens a door or window, takes down a picture or tries to open a safe or desk, without knowing it thereby summons the police, who learn from the the gramophone message what is happening. Anyone who desires to have both a fire and burglar alarm must have two signaphones installed. The Post Office has given permission for these devices to be attached to telephones on automatic exchanges. It has also met with the approval of the Metropolitan Police, to whom it has been demonstrated.

Equalising Supply and Demand

IN the first number of *Trends—A Monthly Graphical Review of Business Movements* (H. Whitehead and Staff, 20 Buckingham Gate, S.W.1, October 1935), Mr. Harold Macmillan contributes an interesting article on "Equalising Supply and Demand" in which he emphasises the importance of planning an adjustment of productive effort, so as to ensure the production of all goods and services in the quantities which will enable them to exchange for one another at prices covering their production costs. The regulation of production in relation to demand for the products of each industry requires that some common policy should be pursued by all the units collectively, for example, in regard to scientific research, observance of standard wages and conditions, maintenance of standards of quality or standardisation of the range of patterns. But as things are, a common policy must depend on voluntary agreements, and in the great majority of cases voluntary agreements break down because, when they have created conditions of stability and profitability, other producers are attracted who can exploit the market by the old methods. Mr. Macmillan therefore urges that it is necessary to give industry legal powers to enforce upon a recalcitrant minority decisions which have been approved by a large majority of the producers and have been sanctioned by Parliament. It is essential, however, that there should be adequate safeguards to defend the general public interest and the special interests of consumers and workers affected in each case.

Despotic and Democratic Governments

THE question as to whether parliamentary democracy can survive its present crisis and whether the rise of dictatorships in Italy, Germany and Russia does not indicate the decline of a long epoch of parliamentary government, is discussed by Mr. Herbert W. Stewart in an article in the *Hibbert Journal* (April, 1935). Mr. Stewart definitely rejects the modern scepticism, although he is far from denying many of the difficulties and real dangers involved in the parliamentary system, such as party intrigues, the corruption of the free but corruptible Press, the demagogic misuse of public institutions under parliamentary control. The unavoidable dilemma of this system seems to be that current affairs are run either by expert commissions, more or less on account of the initiative of the electorate and its parliamentary representatives—or by the masses themselves, and this involves the danger of delicate political matters becoming dependent on the issue of demagogical party activities and political bargainings.

COMPARING these dangers with those of Fascist States, however, Mr. Stewart concludes that Fascist State policy is apt to replace a comparative evil by a much more radical one; for an oligarchy controlling the key positions of the State is worse than the personal power of local cliques under parliamentary government. Parliamentary corruption is the smaller evil as compared with the possible and hidden corruption under a despotic government. The disadvantages of democratic governments should not be over-stressed. In the United States, Canada and Great Britain, after all, the individual voter does not feel that the electoral victory of any one of the existing parties might jeopardise the country. Parliamentary institutions are capable of adapting themselves to new circumstances and of modifying themselves. In the long run, the masses do not wish to be without these means of self-expression.

Solar Activity and Radio Transmission

RECENTLY, Dr. J. H. Dellinger, head of the radio section of the Bureau of Standards at Washington, suggested that a close watch should be kept to see whether there was a fade-out of radio transmissions at any time between October 21 and 25. He was led to make this suggestion by the discovery of severe fading occurring on March 20, May 12, July 6 and August 30, which indicate a 54-day cycle. According to a report issued by Science Service, Washington, D.C., certain short wave-lengths were wiped out by eruptions of the sun for the single day October 24. This fade-out sheds new light on the difficult problem of the connexion between radio transmission, sunspots and magnetic storms. Ordinary transmissions having wave-lengths approximately the same as those used in domestic broadcasting were not affected; but experimental radio transmission was completely wiped out, and the sending of commercial and amateur radiograms was greatly hampered.

THE Bureau of Standards describes the occurrence on October 24 as a wiping out of radio transmission above a certain frequency. It is also stated that there was probably some eruption in the sun much more sudden than the growth of a sunspot, and that this abruptly changed the rate at which the sun

sent certain waves or particles into the earth's atmosphere. Previously there has been no way of identifying the magnetic disturbances associated with such eruptions. As the radio effects are easily identified, it is hoped to get a closer insight into the connexion between them and solar disturbances. In a later report by Prof. H. G. Gale of Mount Wilson Observatory, it is stated that on the morning of October 24 a group of dark granular flocculi was observed on the sun's disk. This group was observed frequently during the day, and at its maximum it was the largest object on the sun's surface as observed by the hydrogen spectroheliograph. The increased solar activity paralleled the strange radio fade-out. Technical details are given in the November 15 issue of the *Physical Review*.

Science and Vegetable Production

MR. F. A. SECRETT lectured before the Royal Society of Arts on November 27, the subject of the discourse being "Modern Methods of Vegetable Production and Marketing". Mr. Secrett, as the owner of Holly Lodge Farm, Walton-on-Thames, is well qualified to speak on this topic (see NATURE, May 25, p. 866). Mr. Secrett's outlook combines the enthusiasm of the amateur with business acumen and scientific discrimination. One of the problems of intensive culture is to obtain sufficient humus for the soil. Sewage waste and town refuse may possibly fill the need, but Mr. Secrett insisted that fresh or green manure has a denitrifying effect on the soil. The technique of irrigation by overhead sprays, and of heating the soil by hot water pipes laid in troughs of water below the soil, were described in detail, for Mr. Secrett is an authoritative exponent and pioneer in the application of these practices. Particular attention was given to methods of aerating the irrigation water, and of incorporating soluble fertilisers. The section on marketing dealt with the use of non-returnable packages, the reorganisation of commission sales, and the revision of railway rates. Much criticism of the work of marketing boards was given, and Mr. Secrett showed, by reasoned argument and without caustic remark, that the unvaried edict of bureaucratic control is often opposed to the best interests of a dynamic and changeable industry such as vegetable growing.

Mount Everest Expedition

IN preparation for the new Mount Everest expedition of 1936, a reconnaissance party was at work last year. At the Royal Geographical Society on December 2, Mr. E. E. Shipton gave an account of this expedition. The main objects were to investigate snow conditions at high altitudes and decide on the best season for the attempt on the summit, to examine the possibility of alternative routes either by the north-west ridge from the head of the Central Rongbuk glacier or by the unknown Western Cwm, and to test equipment. An exploration of the western approaches to Mount Everest revealed no possible way of approach to the summit. Moreover, it was found that the ice slopes of the North Col were in a very dangerous condition during the whole of the monsoon, and always liable to be swept by avalanches the occurrence of which it was impossible to foretell. The expedition scaled numerous hitherto unclimbed peaks in the district in the course of its work.

Housing and Overcrowding

THE Ministry of Health has recently issued several circulars dealing with the subjects of housing and overcrowding, all published by H.M. Stationery Office. "Housing" (2*d*. net) summarises the principal provisions of the Housing and Public Health Acts in relation to maintenance of dwellings in a reasonably fit condition. "Housing, England" (Statutory Rules and Orders 1935 No. 1115. 1*d*. net) relates to the appointment of a committee, to be called the Central Housing Advisory Committee, for the purpose of advising the Minister on questions relating to overcrowding. "Circular 1507" deals with Section 1, Housing Act, 1935, and fixes dates for (1) the completion of inspection—April 1, 1936, (2) submission of report—June 1, 1936, and (3) submission of proposals—August 1, 1936. "Statutory Rules and Orders 1935 No. 1086" (3*d*. net) makes regulations applying to polls of local government electors in connexion with the promotion of bills by councils other than councils of metropolitan boroughs. The Central Housing Advisory Committee appointed by Sir Kingsley Wood includes among other prominent members the names of Lord Balfour of Burleigh, the Earl of Crawford and Balcarres and the Earl of Dudley, the Bishop of Winchester, Miss Megan Lloyd George, Sir Francis Fremantle, Dr. Greenwood Wilson and Mr. Silkin.

A Long Barrow in East Anglia

IT has been supposed that no long barrows exist in Norfolk and Suffolk, and various theories have been put forward to account for the absence of the long-barrow culture in these counties. Some have supposed that it never existed in these areas, while others have thought that the non-existence of the burial mounds is to be accounted for by their removal through ploughing or other agricultural operations. It now seems that the latter is the more likely explanation as, recently, Mr. J. E. Sainty, of The Hedges, West Runton, near Cromer, and his friend Mr. A. Q. Watson, of Holt, have discovered, in west Norfolk, what has every appearance of being a long barrow, surrounded by a ditch. This is a noteworthy find and the discoverers hope to be able to excavate the site in the near future.

Science in the Public Press

WE are glad to direct attention to a series of eight articles on scientific problems of particular human interest now being contributed to the *Evening Standard* by competent authorities on the subjects with which they deal. The first article, by Prof. H. Levy, in the issue of December 9, presents a philosophic picture of the universe. Succeeding articles in the series are "What is Death?", Prof. J. B. S.

Haldane; "Is There an After-life ?", the Bishop of Birmingham; "Can We Create Life ?", Prof. F. G. Donnan; "Is There Life on the Planets ?", Dr. H. Spencer Jones; "Why Do I Dream ?", Prof. Cyril Burt; "Can We Harness the Atom ?", Prof. E. N. da C. Andrade; and "What Is My Conscience ?", Prof. J. C. Flügel.

New Research Laboratory of the L.M.S.

ON December 10, Lord Rutherford opened the new L.M.S. Railway research laboratory at Derby in the presence of many well-known scientific workers and industrialists. Before the special train left St. Pancras, Pat Rutherford, grandson of Lord Rutherford, had the honour of naming the new Crewe-built engine of the special train. Sir Josiah Stamp first introduced him to the leading guests and then lifted him on to the running-plate of the engine. A purple cloth covered the name-plate. Pat pulled the cord to unveil the plate and called out, "I name this engine 'Lord Rutherford of Nelson' ". We propose to print an account of the speeches made at the opening of the new laboratory at Derby in our next issue.

The 200-inch Disk for the Mount Wilson Observatory

ACCORDING to the New York correspondent of *The Times*, the second two hundred inch pyrex glass disk which has been made at the Corning Works for the California Institute of Technology has been accepted as satisfactory by the scientific representatives of that institution. The disk has been annealing for twelve months, and it is expected that the process of grinding and figuring, which will take place at Pasadena, Cal., will occupy five years. There are said to be some flaws on the surface of the disk: these were caused through the floods of this summer, which shut off the heating apparatus for forty-eight hours, but they will be removed during the grinding process. Astronomers and others on the east of the Atlantic who have followed the not uneventful history of the manufacture of the mirror for the two hundred inch telescope with great interest, will be glad to hear that the present disk is satisfactory, and will wish their American colleagues a little luck, of which perhaps they have not yet had their share, in their delicate and long-continued operations on this large disk.

Announcements

THE honorary membership of the Royal Asiatic Society has been conferred upon Prof. Wilhelm Geiger, of the University of Munich, in recognition of his eminent services to Indian and Iranian philology.

THE following appointments have recently been made by the Secretary of State for the Colonies: Mr. J. C. Cater, to be assistant conservator of forests, Trinidad; Mr. H. E. C. Lewys-Lloyd, stock inspector, Tanganyika, to be assistant live stock officer, Uganda.

DR. WILBUR A. SAWYER has been appointed director of the Division of International Health of the Rockefeller Institute, New York.

THE fourth International Congress of Cytology will be held in Copenhagen in 1936. The exact date has not yet been fixed, but the Congress will probably take place in August. Further information can be obtained from the General Secretary, Nassaustrasse 17, Berlin-Wilmersdorf.

THE Iron and Steel Institute is offering a number of grants from the research fund founded by Mr. Andrew Carnegie in aid of metallurgical research. Candidates for grants must be less than thirty-five years of age. Applications should be made before January 10 to the Secretary, Iron and Steel Institute, 28 Victoria Street, London, S.W.1.

THE first International Congress of Criminal Anthropology and Psychiatry will be held in Rome next April, when the following subjects will be discussed: etiology, diagnosis and prognosis of criminality in minors; prophylaxis of crime in relation to penal laws; fundamental conception of criminal biology; and prophylaxis of crime and criminal anthropology. Visits will be paid to the various Italian institutions for the prevention of criminality and re-education of delinquents in Rome, Naples, Orvieto and elsewhere. Further information can be obtained from the general secretary, Prof. B. di Tullio, via Giulia 52, Rome.

A PRACTICAL brochure entitled "Instructions for Collectors: No. 4—Insects", published by the British Museum (Natural History), has recently appeared in its eighth edition. It gives instructions, intended chiefly for persons travelling abroad, as regards the best methods for collecting insects and the essential apparatus. It is obtainable from the Museum or through booksellers, price 3*d*. (postage 1*d*).

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A part-time lecturer in practical mathematics in East Ham Technical College—The Secretary for Education, Town Hall, East Ham, E.6 (Dec. 17).

A scientific officer at the Building Research Station, Garston—The Establishment Officer, Department of Scientific and Industrial Research, 16 Old Queen Street, Westminster, S.W.1 (Dec. 19).

An assistant instructor in dairying to the Wilts County Council—The Clerk of the Council, County Offices, Trowbridge (Dec. 19).

Pharmacist-inspectors to the Pharmaceutical Society of Great Britain—The Secretary of the Society, 17 Bloomsbury Square, W.C.1 (Jan. 1).

A professor of mathematical physics in the Indian Institute of Science, Bangalore—The Director (Jan. 15).

A professor of physiology in the University of Queensland—The Secretary, Universities Bureau, 88A Gower Street, W.C.1 (Jan. 25).

An assistant lecturer in mathematical physics in University College, Hull—The Registrar.

An assistant lecturer in chemistry in the Huddersfield Technical College—The Director of Education, Education Offices, Peel Street, Huddersfield.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 956.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Chemical Detection of Artificial Transmutation of Elements

IT has been our aim for years to prove the result of transmutation experiments by chemical analysis, and in a brief report[1] we have described our failure to find chemical evidence for the production of hydrogen or neon by bombardment with α-rays. In the meantime, many new ways of artificial transmutation have been found, and the discovery of artificial radio-elements has enabled Curie and Joliot[2] to use the methods of radio-chemistry, that is, the combination of radioactive measurement with chemical operations, for the investigation of the chemical character of products of artificial transmutation. This line of work has been extended by Fermi and his collaborators and by many others. The quantity of newly formed matter has in general been much too small for any attempt at a purely chemical detection; the claim[3] of having separated and spectroscopically observed helium of atomic weight 3, made from heavy hydrogen, has been disproved by later work[4].

At present, for various experimental reasons, the best choice for the chemical detection of an artificially-produced element seemed to be helium originating from boron according to the reaction[5]

$$_5B^{10} + {}_0n^1 = {}_3Li^7 + {}_2He^4.$$

In a closed copper vessel we bombarded the methyl ester of boron with neutrons. These were produced near the centre of the spherical vessel by the decay of radon, mixed with beryllium, and were slowed down by the hydrogen atoms of the ester and of the water surrounding the metal flask. In a first experiment, by the decay of 450 mC. of radon, sufficient helium was produced for a spectroscopic observation. During a second experiment, lasting seven weeks, we procured enough radon to allow 2,200 mC. of it to decay in our apparatus. This time we were able not only to observe spectroscopically the helium produced but also to measure it; we found, to an accuracy of about 20 per cent, $1{\cdot}3 \times 10^{-7}$ c.c. helium. A blank test run afterwards for nine weeks under exactly the same conditions, but without radon-beryllium tubes, showed not the slightest sign of helium production.

The copper vessel was a sphere of only 7·5 cm. radius; it is unlikely that more than half of the neutrons formed in the beryllium tubes were caught by the boron inside the vessel. A new experiment, making use of a larger flask, is in progress; but it can already be concluded from our preliminary figures (as one helium atom, according to the above equation, needs for its production one neutron) that a millicurie of radon, mixed with beryllium, produces more than 3,000 neutrons a second[6].

In this experiment—for the first time, so far as we are aware—an artificially produced element has been separated, spectroscopically observed, and measured. We presume that the old alchemistical goal can be achieved to-day in other cases also.

We wish to express our sincere thanks to Prof. F. L. Hopwood, director of the Radium Department, St. Bartholomew's Hospital, London, to Prof. S. Russ, director of the Radium Department, Middlesex Hospital, London, and to Prof. Stefan Meyer, director of the Institute for Radium Research in Vienna, for kindly supplying the radon-beryllium tubes; and also to Dr. E. Glückauf for assistance in the experiments.

[6] The ordinarily assumed yield of neutrons under these conditions is 1,000 neutrons per sec. (See, for example, E. Fermi and collaborators, *Proc. Roy. Soc.*, A, **146**, 483; 1934.) According to R. Jaeckel's observations (*Z. Phys.*, **91**, 493; 1934) the value 10,000 neutrons per sec. is more likely.

Absorption of Residual Neutrons

AMALDI, D'Agostino, Fermi, Pontecorvo, Rasetti and Segrè have discovered that certain elements strongly absorb neutrons which have been slowed down by paraffin wax[1]. They report, for example, that thin sheets of cadmium or indium of 0·013 gm./cm.² and 0·3 gm./cm.² thickness respectively cut down the intensity of a beam of slow neutrons to half its value and find for iodine a half-value thickness of 4 gm./cm.².

Thick sheets of a strongly absorbing element, such as cadmium, will, however, still transmit an appreciable fraction of the incident heterogeneous beam, and in these circumstances it appeared to be of interest to investigate the absorption of such residual neutrons in some elements.

In one set of experiments, I filtered slow neutrons by a sheet of cadmium, 1·6 mm. (1·4 gm./cm.²) thick, and determined the absorption of the residual neutrons in several elements, using radioactivity induced in indium (54 min. period) as an indicator of the neutron intensity. The residual neutrons from the thick cadmium filter are scarcely absorbed by cadmium itself—a 0·5 mm. thick cadmium absorber will absorb perhaps less than 10 per cent of the residual neutrons. Yet I find that these residual neutrons are strongly absorbed by some elements—for example, a thin indium absorber of less than

0·3 gm./cm.² (0·4 mm.) thickness absorbs more than two thirds of the intensity.

Cadmium absorbs the bulk of the unfiltered beam much more strongly than indium, but as we see, it is transparent for some component of the unfiltered beam which in its turn is strongly absorbed by indium. This fact is in contradiction to the current conclusions drawn from the theory of radiative capture.

Fermi *et al.*, Bethe, Perrin and Elsasser attempted to explain the observed large absorbing cross-sections of elements such as cadmium without assuming long-range forces of the nucleus. They have assumed that the range of these forces is small compared with the wave-length λ of the slow neutron and that the neutron is captured in a deep energy level of the nucleus, the excess energy of several million volts being carried away by an emitted photon. They have demonstrated that large effective absorbing cross-sections result if resonance occurs, and it can be shown that the degree of this resonance will not change appreciably with the neutron energy between thermal energies and some 10,000 electron volts. Consequently, if an element has an absorbing cross-section larger than another element for one particular neutron energy, it should not have a smaller absorbing cross-section for any other energy within this energy range.

The present observation on indium contradicts this conclusion. It cannot be argued in defence of the theory that the observed effect might be due to neutrons of energies higher than some 10,000 volts, since the observed very large absorbing cross-section of the indium atom for the residual neutrons would then have to exceed λ^2/π—the limit set by the theory.

In our experiments, use was made of the fact that slow neutrons will diffuse through a paraffin wax tube in much the same way as a gas will diffuse through a tube, if the mean free path in the gas is large compared with the diameter of the tube. The neutrons were led from a radon-beryllium source of about 200 mC. through a paraffin wax tube of 13 cm. inner diameter and 20–40 cm. in length to filter, absorber and indicator sheets and passed only once through these sheets.

Control experiments show that the observed absorption is not due to reflection (back scattering) from the indium absorber. Reversal of the position of cadmium filter and indium absorber produces no change in the transmitted intensity, and this fact indicates that the observed highly absorbable residual neutrons are not produced in our cadmium filter but form part of the unfiltered beam. We are thus led to the conclusion that we have to deal in these experiments with types of absorption spectra for which the present form of the theory cannot account.

There were earlier observations[2], especially those reported some time ago by Moon and Tillman, which did not seem to fit in with the theory. Tillman and Moon showed that the absorption of slow neutrons in an element appears to be different if different elements are used as indicators, and that it often appears to be comparatively high, if the same element is used as absorber and indicator.

In the present experiments, the residual neutrons from cadmium show such selective absorption effects with some combinations of indium, silver and iodine, and show them much more markedly than the unfiltered beam. Moreover, some elements show, if one and the same element is used as absorber and indicator, a larger absorption for the residual neutrons than for the unfiltered neutrons; for example, less than 1 gm./cm.² of iodine absorbs more than half of the residual neutrons if iodine is used as indicator. It would therefore seem that some elements have fairly sharp regions of strong absorption in an energy region for which cadmium is transparent.

It would be interesting to know the energy values which correspond to these absorbing regions. An attempt is now being made to determine them by studying the absorption in boron and lithium of the 'highly absorbable' components of the residual beam.

The observed strong absorption of residual neutrons makes it possible to construct efficient slits or shutters for the purpose of stopping out a well defined beam.

The Slowing Down of Neutrons by Collisions with Protons

FERMI and others[1] showed that neutrons, passing through substances containing hydrogen, loose their energy by collisions with protons. It is of interest to discuss this process of slowing down somewhat further. So long as the energy of the neutron is higher than the energy with which the protons are bound in the molecules of the substance through which the neutrons pass, it seems evident that the latter give, on the average, half their energy to the proton at every collision. But when the neutrons are slowed down below this binding energy, they must excite rotation and oscillation of the hydrogen atom in the molecule in order to lose energy.

It is not certain whether the cross-section of protons for neutrons is a uniform function of the velocity of the neutrons, or if it shows discontinuities for energies comparable with the molecular bindings. In the latter case, it is possible that two substances, containing hydrogen held by different linkages, would show differences in slowing down the neutrons. We have carried out some experiments which indicate the existence of such differences.

Spheres with different radii (5–15 cm.) were alternately filled with water (0·11 gm. H/cm.³), ethyl alcohol (0·10 gm. H/cm.³), benzene (0·067 gm. H/cm.³) and a liquid paraffin (0·14 gm. H/cm.³). In the centre of the sphere a neutron source (radon+beryllium) was placed. The activation of a silver plate, which was fixed on the surface of the spheres and exposed for five minutes to irradiation, served as a measure of the intensity of slow neutrons.

Fig. 1 shows the number of slow neutrons per unit of the solid angle plotted against $r\,d$, where r is the radius of the sphere and d the quantity of hydrogen contained by 1 cm.³ of the liquid in question. The general aspect of these curves is already known. For small radii a rapid increase of the intensity with increasing radius is observed, due to the slowing down of neutrons by collisions with protons. After a certain point, an increase of the radius causes a reduction of the intensity. This clearly shows that not all neutrons which pass the surface of a sphere are reaching the next bigger sphere. The vanishing of slow neutrons must be ascribed to absorption.

The absorption of slow neutrons by paraffin and other substances containing hydrogen has been studied in detail by Bjerge and Westcott[2], who found that the number of slow neutrons is reduced to a half after diffusion through 1·6 cm. of water. By a different method we obtained the value of 2·5 cm. for paraffin in a preliminary experiment. A source of neutrons was placed in the centre of a paraffin wax cube of 14 cm. side. Five plates of paraffin wax, each 1 cm. thick, and finally a small silver plate were placed upon this cube. A screen of cadmium was interposed between the paraffin plates at different distances from the silver plate. The activity of the silver, obtained for equal times of irradiation, increased when the distance between the silver and the cadmium was increased. A curve was obtained which showed that influence of the absorption of the cadmium decreased to a half when the distance between the silver plate and the absorber was increased by 2·5 cm.

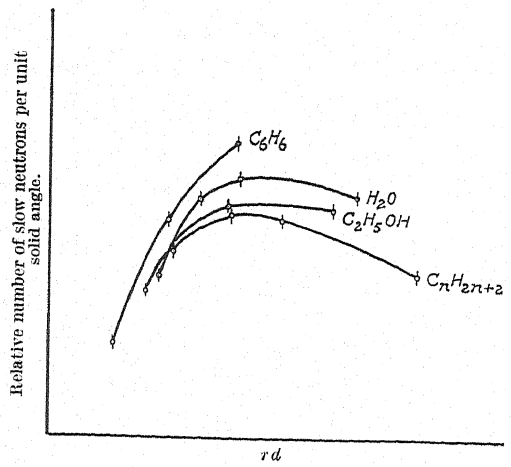

FIG. 1.

Fig. 1 shows that the maximum values of intensity are different for different liquids; these differences cannot be ascribed to the quantities of hydrogen contained by the liquids alone. Also, it is not possible to explain these results by absorption of slow neutrons by oxygen or carbon nuclei. A neutron has, for the same number of collisions with protons, passed twice the number of carbon atoms in benzene as in the liquid paraffin, and we see that the maximum value for the latter is much lower than for benzene, where the maximum seems to be just reached with the biggest sphere.

The differences in the influence of the four liquids examined, on the intensity of slow neutrons, cannot be ascribed to differences in the quantities of hydrogen, carbon or oxygen these liquids contain. Other differences between these liquids depend upon their molecular structure. Thus different probabilities for the slowing down of neutrons by excitation of rotation and oscillation of the hydrogen atoms in the different molecules may account for the discrepancies observed.

Quantised Field Theory and the Mass of the Proton

THE new theory of the electromagnetic field which I have proposed[1] seemed to allow an interpretation of the spin of the electron as a real electromagnetic angular momentum. Prof. W. Pauli was so kind to direct my attention to the fact that the quantisation of the field equations determines the total electromagnetic angular momentum as an integral multiple of $\hbar$; hence this interpretation is impossible.

My collaborator, Mr. M. H. L. Pryce[2], has, therefore, proposed a modification of the quantised field theory, in which there is ascribed to each singularity a spin, represented by non-commuting matrices of the Dirac type. Pryce remarked that this assumption may explain the existence of two different kinds of charged particles, electrons and protons, both with the spin $\frac{1}{2}$. For the electromagnetic angular momentum can have the values $j = 0, 1, 2, \ldots$ (in units $\hbar$). As the spin with the momentum $s = \frac{1}{2}$ may be parallel or anti-parallel to the electromagnetic moment, its component in this direction being $\sigma = +\frac{1}{2}$ or $\sigma = -\frac{1}{2}$, there exist two states with the total momentum $\frac{1}{2}$, namely, $j = 0$, $\sigma = \frac{1}{2}$, and $j = 1, \sigma = -\frac{1}{2}$. Pryce suggested that the latter state might have a much higher energy than the first one.

This conjecture of Pryce is strongly confirmed by an estimate of the relation of the energies or masses. The necessary formulæ have already been given by Schrödinger and myself in a note in NATURE[3]. There we started from the assumption (which I now consider as wrong) that the spin is the electromagnetic momentum; then the principal part of the energy of the electron would not be electrostatic but electromagnetic, and we showed that this would make the radius of the electron about 10 times larger than is usually assumed. Now I apply the same method for an estimate of the mass of the proton.

I assume that the chief part of the energy of the state $j = 1$, $\sigma = -\frac{1}{2}$ is electromagnetic and can be represented by $\frac{1}{2}\mu^2/r_0^3$, where $r_0 = e^2/mc^2$ is the conventional radius of the electron and $\mu = er_0/2\alpha$ the Bohr magneton ($\alpha = e^2/\hbar c = 1/137$).

Putting $Mc^2 = \mu^2/2r_0^3$, one gets by introducing the value of μ:

$$M = \frac{e^2}{r_0 c^2} \times \frac{1}{8\alpha^2}.$$

In the non-rotating state $j = 0$, $s = \frac{1}{2}$, one has

$$m = \frac{e^2}{r_0 c^2}.$$

Therefore

$$\frac{M}{m} = \frac{1}{8\alpha^2} = \frac{18{,}770}{8} = 2{,}400,$$

in sufficient agreement with the experimental value 1,840.

The use of the Bohr magneton μ for calculating the energy does not imply the assumption that the total magnetic moment is μ, which would contradict the facts. The spin contributes to the magnetic moment just a Bohr magneton of the opposite direction, and the resultant ought to be zero if the compensation were complete. It seems not surprising that there is a non-compensating part of the order $\mu/1{,}000$, as the experiments show.

If it is true that a proton and a positron (or a negative proton and an electron) are different states of the same system, there should be transitions from one to the other, for example, a transformation of a

proton into a positron under emission of light quanta of the order of magnitude $Mc^2 \sim 2{,}000\ mc^2$ or 1,000 millions of electron volts, as are actually found in cosmic rays.

Frequency of Collision of Electrons in the Ionosphere

MESSRS. FARMER and Ratcliffe[1] criticise my results on this subject[2] on the ground that I have neglected the effect of a possible variation of the E layer attenuation during the three-quarters of an hour or so in which the observations were taken. Such a variation of E layer attenuation would involve a spurious contribution to the slope of the log ρ, P' curve, which would invalidate the calculation of the collision frequency. But where the reflection coefficient ρ decreases to a minimum and rises again (as in all cases observed), there are two branches to the log ρ, P' curve, one corresponding to ρ decreasing and the other to ρ increasing, and the effect of a continuous variation of E layer attenuation would be to increase the slope of one branch and decrease that of the other by the same amount. The effect of the variation of E layer attenuation is therefore automatically eliminated in taking the mean of the slopes of the two branches.

In actual results obtained where both branches are clearly defined, there is no significant difference between the slopes of the two branches (so far as the accuracy of the observation allows) so that the effect of the variation of E layer attenuation is certainly small.

Prof. Appleton's criticisms[3] are more fundamental, for he considers the formula from which the collision frequency is derived to be unjustified. My formula $\log \rho = \frac{-\nu_c}{2c} P'$ is contrasted with the more accurate formula $\log \rho = \frac{-\nu_c}{2c}(P'-P)$, and Prof. Appleton considers that the neglect of P may introduce considerable error, especially when P is of the same order of magnitude as P'.

It should be noted, however, that in the application to the determination of ν_c by my method, I am not so much concerned with the total reflection coefficient or equivalent path P', as with the changes $\delta \log \rho$ and $\delta P'$ occasioned by alterations in the layer as the maximum critical frequency ν_m approaches the frequency ν of transmission. As ν_m approaches ν, P' rapidly increases, if not to an infinite value at least to a very large value, while P tends to a definite limit. It follows that in the limit, as the critical frequency is approached, $\delta P'$ tends to a large value compared with δP, and the relation $\delta \log \rho = \frac{-\nu_c}{2c} \delta P'$ is accurately satisfied for the ordinary ray, while $\delta \log \rho = \frac{-\nu_c}{2c} \frac{\delta P'}{1-\tau/2}$ for the extraordinary ray. Thus the slope of the log ρ, P' curve gives ν_c quite accurately.

In order to test the accuracy of this relation, some examples have been worked out in which no approximation is made other than that involved in the assumption that $\alpha = \frac{\nu_c}{\beta\pi\nu}$ is small. The attenuation and group time derived from the real and imaginary parts of the refractive index were integrated by quadratures, and the relation between log ρ and P' was determined. The distributions of electronic concentrations in the layer considered were those which start from zero, reach a maximum at a height z_0, and then decrease. A typical example is shown in Fig. 1, in which $\log \rho \Big/ \frac{2\tau\alpha z_0}{\lambda}$ is plotted against $\frac{P'}{2z_0}$. In accordance with relation (1) the curve should, for large values of P', tend to a straight line the slope of which is unity for the ordinary ray and $1/(1-\tau/2)$ for the extraordinary ray.

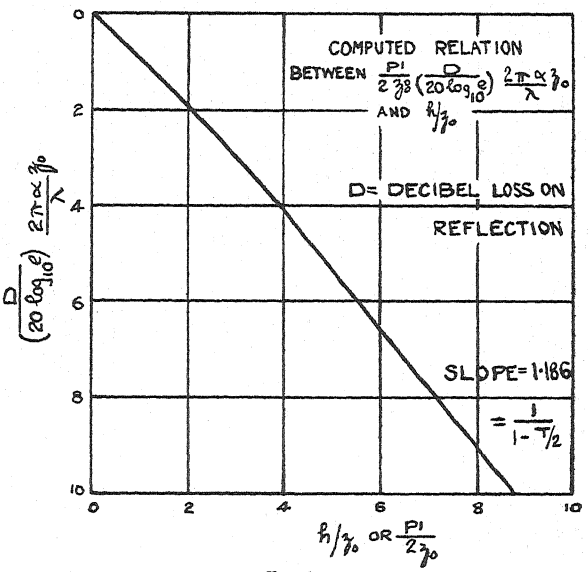

FIG. 1.

This is actually the case for the curve, which is calculated for the extraordinary ray with $\tau^2 = 0{\cdot}1$. The slope of the curve is constant for values of $P'/2z_0 > 4$ and agrees with $1/(1-\tau/2) = 1{\cdot}187$ within the errors of the graphical representation.

This general theoretical reasoning, backed by numerical examples, demonstrates clearly that the method given is quite accurate for the purpose of determining the collision frequency.

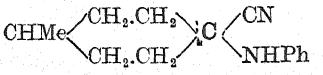
Multiplanar Cyclohexane Rings

THE claim of Dr. Qudrat-i-Khuda[1] to the isolation of the four stereoisomeric forms of 1-carboxy-4-methyl*cyclo*hexane-1-acetic acid required by the Sasche-Mohr hypothesis which it has not been possible to substantiate in this laboratory[2] led us to search for further possible examples of this

phenomenon in reactions involving the methyl*cyclo*hexanones. Attention was directed, therefore, to the condensation of the cyanhydrins of methyl*cyclo*hexanones with arylamines, by an extension of the method used by Walther and Hubner in the case of the simple *cyclo*hexanone[3].

If, for example, 4-methyl*cyclo*hexanone were to react with potassium cyanide and aniline in the stabilised strainless forms, the production of four isomeric 1-cyano-1-anilino-4-methyl*cyclo*hexanes



would be anticipated. This reaction was actually studied by Betts and Plant some years ago, from quite another point of view[4]. Fractional crystallisation of the condensation product led, however, to the isolation of a more easily fusible isomer in addition to the 1-cyano-1-anilino-4-methyl*cyclo*hexane described by these authors.

The condensation of 4-methyl*cyclo*hexanone with *p*-bromoaniline, *o*-, *m*-, and *p*-toluidines, and the α- and β-naphthylamines led, with the exception of the case of *o*-toluidine, to the formation of pairs of isomeric cyanoarylaminomethyl*cyclo*hexanes. 3-Methyl*cyclo*hexanone behaved similarly towards aniline and gave rise to two isomeric forms of 1-cyano-1-anilino-3-methyl*cyclo*hexane, but with *o*- and *p*-toluidines and with the naphthylamines, the presence of only one individual could be detected. The cyanhydrin of 2-methyl*cyclo*hexanone also gave rise to pairs of isomerides on condensation with aniline and with β-naphthylamine. In the reactions with *o*-, *m*- and *p*-toluidines, and with α-naphthylamine, however, only one product was isolated.

In all the three methyl*cyclo*hexanones, therefore, the formation of two, but of never more than two, isomeric cyanoarylaminomethyl*cyclo*hexanes was observed in certain cases. A full report of these experiments will be published elsewhere.

Breeding in Captivity of the South American Lung-fish

IN view of the advantages of the South American lung-fish, *Lepidosiren paradoxa*, as a laboratory animal on account of the large size of its cells and of its vitality, the first record, so far as I am aware, of a successful attempt to breed the fish is of general interest.

At the suggestion of Professor Graham Kerr, a double tank was installed in this Department in 1929, having a wooden lining fitted to float in a large outer tank of galvanised iron. The latter, erected over gas burners, serves as a water-jacket by means of which the temperature of the water in the inner wooden tank is maintained at 20° C. The inner tank, 9 ft. × 2 ft. 9 in. × 4 ft. 3 in., contains water to the depth of 1 ft. 8 in., and in addition about 30 cwt. of mud which was collected from a nearby loch. The mud is piled on an inclined plane diminishing in depth from 2 ft. 6 in. to 1 ft. It forms a narrow platform above the water-level on which an extensive growth of ferns has developed in the last eight months, and the water-surface itself supports a carpet of *Salvinia*. The temperature of the mud increases with depth, reaching a maximum of 26° C. at the bottom of the tank.

An adult female *Lepidosiren* has lived in this tank for the past six years. Until the spring of this year, she had as partner a male specimen which showed breeding signs from time to time; for example, enlargement of the filaments on the posterior appendages, burrowing and taking down vegetation to support the burrow walls. Young, however, were not forthcoming. This male died and was replaced in August by another adult which had lived in a separate tank in the Department for several years. Disturbance of the fish was reduced to a minimum. Maintenance of the water-level by means of two large shower sprays permanently mounted over the tank and connected to the main water supply was permitted, and also the regular introduction of food in the form of sliced beef every second day. No other disturbances were allowed and breeding must have begun very soon after the second male had been placed in the tank. On October 21–22, twenty-two post-larval young (that is, older than stage 36[1]) appeared at the surface amongst the *Salvinia* and were collected.

The *p*H of the water is 6·6 and the oxygen content at the surface 2·3 c.c. per litre, diminishing to 2·0 c.c. per litre at the bottom of the tank.

I am indebted to Mr. H. H. Brown for the oxygen estimations.

The Species Problem

MAY I add a few words as a contribution to the species concept discussion which was touched upon in a recent article[1] in NATURE? The ideal species definition has not yet been given, and probably never will be given, the problem being of too complex a nature to be condensed into a single definition.

There is, however, one aspect of the theoretical problem, which I discussed some years ago[2], to which I wish to direct attention here, as I think that special point has not been sufficiently emphasised. Accepting the evolution theory, as we do to-day, we have definitely precluded the possibility of treating the species as the basal unit of taxonomy. The unit must be the different *lines of evolution*. I defined a line of evolution thus: "A taxonomical-phylogenetic line of evolution is a sequence of generations, the individuals of which descend from the individuals of the preceding generation and within each generation group themselves according to the law of probability with regard to all essential features, and further, form a closed sphere of combinations, reacting avitally or incompatibly with all other spheres of combinations with which it comes into contact". The species is the momentary realisation of such a line.

The great advantage of this view is that all demands for *constancy* are omitted from the species definition,

where they are, in reality, absolutely antagonistic to the theory of evolution. By regarding the species as an expression of the line of evolution, and only in that way, can we keep our species concept in conformity with the demands of the theory of evolution.

The curve of variation according to which the values of characters group themselves may change, but so long as it remains *one curve*, we really have the same species, as it is the realisation of the same line of evolution, even if the characters have changed. But if two (or more) different populations of a species change in different ways, so that the curves of variation are no longer congruent, two (or more) species arise from the old one. The line of evolution has divided into new ones, which manifest themselves as different species, none of which is identical with the old one, even if one of them might show to a certain extent the same exterior qualities. For the further consequences of my view I may refer to the original paper; I may add that the problem has recently been touched upon by Hiitonen[3].

"The University of London Council for Psychical Investigation"

IN September last the "University of London Council for Psychical Investigation" issued an invitation to an exhibition of fire-walking. Much attention was given to the subject in the daily Press, and an account of the demonstration was contributed by Mr. C. R. Darling to NATURE of September 28, p. 521. From the reports it is not clear what 'psychical investigation' had to do with the heat-resisting properties of the soles (? souls) of the feet; but what was more important was the interest apparently taken by the University of London in an unusual method of studying thermal conductivity. On inquiring, indeed, of the Principal, I was told that the 'University of London Council for Psychical Investigation' had no connexion with the University of London: if it had none with psychical investigation either, that might explain the matter. Since then, however, the "Honorary Secretary of the University of London for Psychical Research" has given an exclusive film interview, which was advertised recently in the programme of the Gaumont-British Movietone News Theatre. "Psychical Research", in spite of the Principal, has clearly come into its own.

It is to be hoped that other learned bodies will follow suit: for example, The Royal (Spook) Society of London; The Marine Biological Association (for the Study of Sea Serpents); The Institution of Fire (-walking) Engineers; The (Psychical) Research Defence Society. My only personal fear is that the Anti-Vivisectionists may seize their opportunity and announce themselves as A.V. Societies.

Kelvin's 'As if' in Physics

IN a letter appearing in the issue of NATURE for November 9, headed "Kelvin and the Age of the Sun", attention is very needfully directed to an instance of a complete misrepresentation of Kelvin's attitude towards a special problem.

A still more lamentable instance was given in a comparatively recent statement, by a leading worker, in which scorn was poured on Kelvin for his support of the so-called elastic-solid theory of the ether. One can scarcely avoid the conclusion that the worker had never read the "Baltimore Lectures", which deals with investigations as great and mind-satisfying as any of the truly great investigations of the present day. For, on p. 9 of the "Lectures", Kelvin says:

"The luminiferous ether we must imagine to be a substance which *so far as luminiferous vibrations are concerned* moves *as if* it were an elastic solid. I do *not* say it *is* an elastic solid". (I have added the italics.) And, on p. 17, he says: "There is no way in which that can be explained by the rigidity of an elastic solid".

It is greatly to be desired that the "as if" of Kelvin were freely interspersed throughout many of the unqualified statements made regarding the conclusions to be drawn from the theory of relativity. An apt illustration of the need for this occurs in the letter, by Dr. Lanchester, which appears in the same issue of NATURE.

It cannot be said that we are without indications, for example, in connexion with Miller's work on ether drift, that it may yet be found necessary to return to, and develop, Kelvin's methods. The necessary "as if" is as safe in them as it is in an unillustrated equation. Co-ordinates ignored in an equation may actually be the most fundamentally active.

The idea that relativity first told us that, possibly, physical "things are not as they seem to be" is inconsistent with the history of natural philosophy.

A New Technique in Cookery

THE authorities on cooking understand the effects of time and temperature[1] better than one might be led to suppose from Mr. Dufton's comments in his letter[2] under the above title.

The new technique is interesting, and has some obvious advantages over normal roasting, which demands experience, personal attention and a knowledge of cuts, but the meat is really *stewed* in its own juices for a very long time. It would be a tough joint indeed that resisted fifteen hours cooking at 212° F., if evaporation was prevented. Stews can be delicious, and are generally made from inexpensive meats.

In *roasting*, the centre of the joint never reaches 212° F.; for 'well done' meat the maximum recommended is 180° F. to 185° F. Hence only cuts which do not require prolonged hydrolysis can be roasted successfully. Tough meat has to be stewed or boiled for some hours because more drastic hydrolysis of the tissues is needed to secure a tender result. To do this in the ordinary oven, water must be added on account of evaporation; but the smaller the excess, the more flavoursome the meat: a large excess yields tasteless meat, but good broth.

Although fully appreciating Mr. (and Mrs.) Dufton's contribution to the economics and technique of stewing, we would point out that :

(1) high temperature ovens are required for other dishes ;

(2) the cooking of meat and, incidentally, of other foods, has been studied scientifically, though not exhaustively ;

(3) many people consider the appearance and flavour of outside cuts to be worth the trouble and expense of roasting.

Food and the Nation

I WAS disappointed not to find in the article under this heading in NATURE of November 18 any reference to the change that has taken place during the last half century in the manufacture of white bread.

In my young days, flour was produced by grinding wheat between millstones, whereby the skin of the grain (not the husk) was preserved in the flour. A notion having got abroad that the excellence of bread is in proportion to its whiteness, steel rollers were made to replace the millstones, whereby the grain was stripped of its dusky skin, with its valuable vitamin contents, and the baker was enabled to produce a whiter loaf.

Simultaneously with this change has grown the manufacture of margarine, coloured and flavoured to resemble butter, but with little, if any, of its nutritive quality. It is distressing to see children in our large cities fed chiefly on white bread and margarine.

In India, rice—the staple food of millions—is now milled in the same drastic way as wheat is in Europe, resulting in widespread mortality from beriberi.

Stone-ground flour is still produced in Great Britain. My own household is supplied with it from a mill in Horsham, and the bread baked from it is more agreeable in taste than the baker's ultra-white.

HERBERT MAXWELL.

Monreith,
Whauphill,
Wigtownshire.

WHAT Sir Herbert Maxwell says with regard to the loss of nutritional value through the widespread use of white bread and margarine is no doubt true enough ; but omission of reference to this point does not affect the economic relationship between food-production and consumption, with which the article was particularly concerned.

Editor, NATURE.

Points from Foregoing Letters

Helium produced from boron by neutron bombardment has been purified, observed spectroscopically, and measured by Prof. F. A. Paneth and H. Loleit. This seems to be the first case where an artificially produced element has been detected spectroscopically and measured by other than radioactive methods.

Dr. L. Szilard states that slow neutrons filtered by thick sheets of a strongly absorbing element like cadmium are strongly absorbed by thin sheets of indium and some other elements, though cadmium itself is transparent for such residual neutrons from cadmium. This is in contradiction to the conclusions usually drawn from current theory. The residual neutrons from cadmium show strong selective absorption effects, and are in some elements more absorbable than the unfiltered beam.

Dr. Hans von Halban, Jr., and Dr. Peter Preiswerk have determined the degree of activation produced in a silver plate by neutrons (from a radon-beryllium source) slowed down by passing through various thicknesses of water, alcohol, benzene and liquid paraffin. The difference in the effects observed suggests that the molecular structure of those compounds may affect the amount by which the velocity of the neutrons is reduced. The authors believe that the neutrons part with some of their energy in order to excite rotation and oscillation of the hydrogen atoms in those compounds.

A modification of Born's theory of the electromagnetic field has been suggested by M. H. L. Pryce to explain the existence of two different kinds of charged particles, electrons and protons, both with the spin $\frac{1}{2}$. Dr. Max Born calculates the mass of the proton by means of formulæ derived from that theory ; he arrives at the value 2,400, which is of the right order of magnitude. He points out that the theory allows for the transformation of a proton into a positron, with emission of radiation quanta of one thousand million electron volts, such as are found in cosmic rays.

T. L. Eckersley maintains that, notwithstanding the criticisms of Farmer and Ratcliffe and of Prof. Appleton, his previously suggested formula for the calculation of the frequency of collision of electrons in the upper atmosphere gives sufficiently accurate results.

Dr. R. D. Desai and Prof. R. F. Hunter state that they have carried out further experiments with methyl*cyclo*hexanones in order to test the Sasche-Mohr hypothesis, according to which four isomeric forms of certain derivatives of these compounds should exist ; but so far, they have been unable to obtain more than two isomeric cyanoarylamino derivatives.

C. W. Parsons reports that a pair of South American lung-fishes, living in a wooden tank containing mud and partly filled with water, maintained at 20° C., have bred after a period of some months during which they have been disturbed as little as possible. Twenty-two young fish (just post-larval) have appeared at the surface, representing the brood. This seems to be the first record of this fish breeding in captivity.

Knut Fægri states that, in dealing with biological classification, it is preferable to speak of "lines of evolution" rather than species. A line of evolution is a sequence of generations, the individuals of each generation grouping themselves according to the law of probability with regard to all essential features. Only by regarding the species as a momentary expression of the line of evolution, Mr. Fægri states, can the species concept be kept in conformity with the theory of evolution.

Research Items

Venezuelan Archæology

THREE new archæological sites in the State of Falcón, Coro, El Mámon and La Maravilla, in the important but little explored coastal area of northern Venezuela, have been described by Gladys Ayer Nomland (*Ibero-Americana*, 11). They are situated in the midst of shifting sand dunes in the flat coastal strip at the edge of the plain, which lies between the inland range of mountains and the present coast line, and was left by the retreat of the sea with which it was covered in Pleistocene times to a distance of twelve kilometres inland. This flat strip must have served as a cultural highway between central and eastern South America. The location of the sites, excepting the hill-top site of El Mámon, was determined by the seasonal presence of dammed water in the gullies. The inhabitants lived by hunting and fishing. The absence of any signs of European contacts is strong presumptive evidence of a pre-Columbian dating. Notwithstanding the fragmentary condition of both pottery and skeletal remains, it is evident that the inhabitants practised urn burial, presumably as a secondary interment, judging from the size of the mortuary vessels, which could not have held a corpse entire. The artefacts from the sites consisted of pottery, implements of black and green stone, and ornaments of shell, pottery and stone. The pottery comprises a grey-brown ware, painted ware and a red ware. The ornament is geometric. In the Venezuelan fictile art, which is of a high degree of excellence, the plain red and grey-brown ware appear to form the basic substrata from which the more complex painted ware was developed. Certain groups can be differentiated, but phylogenetic relations are to be traced. The site of Coro, however, stands apart, the red ware diverging from the orderly progression into the highly complex incised group and not in the direction of the painted ware as elsewhere. This may be due to chronological difference, Coro probably being the earliest and La Maravilla, with its rich development of painted wares, the latest; but this is mere conjecture. The groups cannot be affiliated with any other datable groups.

Courtship of Manakins

THE manakins (not to be confounded with the fashionable variety!) are small passerine birds (family Pipridæ) inhabiting the tropical and sub-tropical regions of America, exclusive of the Antilles. They show courtship behaviour which in some species is complex, co-operative and well organised, and the existence of fundamentally similar habits among widely distributed and strongly differentiated members of the same family suggests that these are rooted in the origin of the family itself and are as much part of its evolution as is form. Frank M. Chapman has made a particular study of the courtship of Gould's manakin (*Manacus vitellinus vitellinus*) on Barro Colorado Island (*Bull. Amer. Mus. Nat. Hist.*, 68, 471, Sept. 1935). About a fortnight before courtship activities begin, the males commence to gather at an established *lek* or courting ground in the forest. The arrival of the breeding season is marked by the making of a 'court' from which the male removes all loose material, and into which the chief object of its existence is now to induce a female to enter. The courting ground generally contains from five to seven courts, thirty to forty feet from each other. Since the males have limited vocal powers, they announce their presence by making snapping and whirring sounds with their wing-feathers. When a female has once entered a court, there is no further competition for her favours by other males. The courting site has no immediate connexion with the nesting site, for the nest is built in a forked branch a short distance off the ground (twenty inches to five feet) usually a hundred yards or more from the nearest court.

Evolution of the Human Foot

HERBERT ELFTMAN and John Manter (*J. Anat.*, 70, Part 1, Oct. 1935) state that the fundamental similarity in architecture of the foot of the chimpanzee and that of man leaves no doubt as to the evolution of the human foot from that of an ape. Superimposed upon this structural similarity are important differences, considered in some detail, which the foot has undergone in evolution. The authors state that although the gorilla resembles man more closely than does the chimpanzee in the relative shortness of the lateral digits of the foot, it shows no indication of the more fundamental changes which are essential for the development of the human condition. "The fact that the human foot, adapted as it is for walking on the ground, bears a closer resemblance to the ape foot as used in arboreal than in terrestrial locomotion, may be regarded as another evidence of man's arboreal ancestry. It would also suggest that the essential features of man's foot were acquired at an early stage of his terrestrial existence, rather than after long apprenticeship on the ground."

Crustacea of Jehol

IN the report of the first scientific expedition to Manchoukuo under the leadership of Shigeyasu Tokunaga, June–October 1933 (Sect. 5, Div. 1, Part 2) various crustacea are described by Masuzô Uéno (Phyllopoda), Tune Sakai (Decapoda-Brachyura) and Hajime Uchida (terrestrial Isopoda and freshwater Amphipoda). Most of the text is in Japanese, but there are descriptions of species and bibliography in English, and all the papers are beautifully illustrated, some in colour. *Apus numidicus* was found in a swamp of alkaline water in the northern part of Jehol. It is a form typically inhabiting water of warm and arid regions of Africa and the south-western parts of Asia. The extension of its distribution into Manchoukuo from these western regions is probably due to the similarity of ecological conditions in both countries. Only one crab was collected by the expedition, *Eriocheir sinensis*, the mitten crab, which has now become notorious from its having been accidentally imported from China into Germany and settling there. It is now difficult to eradicate. Of terrestrial Isopoda, only one species was found, a new one, *Porcellio jehoensis*; and one new species of Amphipod, *Gammarus nekkensis*, inhabiting a cold spring, 1,000 metres above sea-level.

Plankton Production in the Southern Hemisphere

THE yearly cycle of events in the production of marine plankton has been followed for many years and in many places in the northern hemisphere. Similar observations are, however, to a large extent lacking from coastal waters in the southern hemisphere. It is therefore worthy of note that the yearly sequence has been followed in Australian waters off Sydney (Dakin, W. J., and Colefax, A., "The Marine Plankton of the Coastal Waters of New South Wales (1)", *Proc. Linn. Soc. N. S. Wales*, **58**, Parts 3–4, 186–222; 1935). Collections made at fortnightly intervals throughout the year showed that in its main essentials the seasonal cycle is similar to that known for northern waters. The phytoplankton production shows two peaks, one in early spring and a smaller one in late summer. The spring outburst is not so markedly great as in northern seas; but it is of interest to find that the similarity extends also partially to the sequence of species, in that *Rhizosolenia* species follow those of *Chætoceros*. The zooplankton appears also to show two maxima, occurring respectively just after the two phytoplankton maxima. Tables are given for all the plankton catches, the organisms being identified to species so far as possible. This work forms a valuable foundation for further research on the plankton of Australian waters.

Primitive Colour-Pattern of Insect Wings

MR. HEMMING LEMCHE, of the Zoological Laboratory of the Royal Veterinary and Agricultural College, Copenhagen, discusses this subject in a recent paper (*Vidensk. Medd. fra Dansk naturh. Foren.*, **99**, 45–64; 1935). His chief contention is that there exists in insect wings a primary colour-pattern, which can be traced back to an archaic pattern common to all insect groups. This archaic pattern comprises a number of cross-bands (most probably seven) separated by hyaline interspaces. He further points out that these archaic cross-bands traverse the wing in such a way that the bifurcations of the veins lie at the inner edge of the bands. It follows from this contention that the primary vein-forks cannot have been scattered irregularly over the wing, but have been located in cross-lines represented by the inner edges of the bands. The theory, it is claimed, is supported by evidence afforded by the most primitive fossil insects. Traces of the primitive banding are also retained among generalised Lepidoptera, in Mecoptera and in Acridiidæ among living forms. The present paper, it is stated, will be followed by more detailed studies which will form the subject of a later contribution.

Leaf and Scale Types in *Pinus*

WITHIN this single genus, indeed upon a single tree, are found four distinct types of branch system, long shoot, dwarf shoot, staminate cone axis and ovulate cone axis, and the generally accepted theories of this last cone would add yet another, the axis of the seed scales. Upon these varying branch systems are found no less than eleven types of foliar structures which include some leaf types, many scale types and the sporophylls. A most instructive analysis of these different foliar and branch types, of their development and structure and of their homologies, has been prepared by Dr. C. C. Doak (*Illinois Biol. Mon.*, **13**, No. 3, August 1935). Evidence for reduction of leaf number both in the fascicles of the short shoots and in the number of simple leaves or cotyledons in the seedlings thus emerges very convincingly, whilst the influence of the closely knit surrounding bud scales upon the shape and growth of the meristematic basal regions of the needles growing within is very clearly brought out. Alike in its extensive and clearly recorded observations upon some thirty-five species of pines and in its extensive and critical survey of the relevant literature, this monograph will have permanent value as a contribution to some of the most intriguing problems of shoot morphology.

Asparagus Cultivation

A SHORT note by Mr. A. N. Rawes (*J. Roy. Hort. Soc.*, Oct. 1935) gives some very useful information about the cropping of *Asparagus*. Several series of beds containing all male plants were compared with beds planted with female crowns. The result showed that in every case the male plants yielded about 60 per cent more saleable stems than the females. The series covered a variety of planting methods and differing cultivation, but the superiority of the males was obvious in every case. Very little difference in the relative grades of produce was, however, demonstrable between the two sexes. The paper reports a continuation of previous experiments made at the Wisley gardens, with confirmation of the earlier results, and also discusses the merits of close and wide planting.

Antarctic Moraines

IN his presidential address to the Australian and New Zealand Association for the Advancement of Science, 1935, now reprinted in pamphlet form, Sir Douglas Mawson gave a lengthy review of the unveiling of Antarctica, and discussed several of the problems which that continent presents. He stressed the evidence of the former much more extensive glaciation and noted particularly the recent recognition of terminal moraines on the sea floor often fifty to one hundred miles beyond the real coast line. These moraines are frequently hundreds of feet in height. Off Adelie Land the height of the chief off-shore moraine is about three thousand feet. It is the occurrence of these submarine banks that has much to do with the ice-obstruction that prevents access to certain coasts of Antarctica. Huge icebergs become grounded in 600–1,000 ft. of water and hold up floating pack, and thus coastal waters are blockaded. It is noticeable that where the sea floor is down-faulted, as on the west of the Ross Sea or the east of the Weddell Sea, deep water prevents these moraines acting as barriers to moving ice. Such shores are relatively accessible. It is only the action of periodic super-tides as described by O. Pettersen that moves the more securely anchored ice obstructions.

Earthquakes and Rainfall

MR. J. F. BRENNAN, Government meteorologist in Jamaica, has recently made an interesting comparison between the mean monthly frequency of earthquakes and the mean monthly rainfall in Jamaica (*Earth. Notes, East. Sect. Seis. Soc. America*, **7**, 25–26; 1935). During the years 1908–34, 480 earthquakes were recorded. The curve representing the mean monthly frequency shows two maxima, in February (60 earthquakes) and July (46), both months of minimum rainfall, and two minima in May (25) and

October (31), months of maximum rainfall. The author suggests that the greater frequency of earthquakes during the dry seasons may be due to the withdrawal of water from underground water-courses, which may thus facilitate the fall of large masses of rock.

Irrigation Research

THE Punjab Irrigation Research Institute has issued two further reports of its work. In "Protection below Khanki Weir" (2, No. 8, Nov. 1934), Mr. J. P. Gunn gives an account of the experiments made, by means of models, to determine an effective and simple method of preventing scour at the reconstructed portions of the Khanki Weir, which is built on a sand foundation. The arrangement adopted and incorporated in the new works consisted of three rows of 'arrows' pointing upstream, followed by several rows of control blocks, as it had been found that this gave a low velocity of flow at the bottom without local turbulence and had the effect also of raising the level at which maximum velocity occurred sufficiently near the surface of the water to stabilise the scour. The results in practice are so far reported as satisfactory, but a complete investigation could not be made until the fall of the river. In the second of these reports, entitled "Influence of an Upstream Sheet Pile on the Uplift Pressure on a Floor" (2, No. 9, Jan. 1935), Dr. N. K. Bose, mathematical officer, and H. L. Uppal, assistant research officer, present the results of one of a series of experiments directed towards ascertaining the influence of different arrangements of sheet piling on the distribution of floor pressure. The work has involved extensive observation and mathematical analysis of the data obtained, and from it two general conclusions are drawn: namely, that, length for length, a long sheet pile is less effective than a short one, and that the longer the sheet pile the less effective is the floor. As the investigation proceeds, it is hoped to be able to determine data for safe and economical dimensions under varying working heads.

Solar Radiation and Weather Studies

IN "Solar Radiation and Weather Studies" by C. G. Abbot (*Smithsonian Miscellaneous Collections*, 94, No. 10) an account is given of an investigation begun by Dr. S. P. Langley, formerly secretary of the Smithsonian Institution, into the dependence of weather on variations in the radiation emitted by the sun. While few physicists or meteorologists are likely to dispute the probability of a connexion between the two, some may doubt whether the problem of measuring the solar radiation, which involves various assumptions about the relation between its intensity outside the earth's atmosphere and at the point where measurement is made, has been solved, and may regard any apparent variations of the intensity, after due allowance has been made for the varying distance between the earth and the sun, as mere errors of measurement and computation. Such doubts may perhaps be dispelled by the generally close resemblance found between graphs representing the day to day values of the solar 'constant' obtained by measurements made at places so far apart as Montezuma (Chile), Table Mountain (California) and Mount Brukkaros (South West Africa) illustrated in this work. The solar variations on which the comparisons in this discussion are mainly dependent are those revealed by ten-day means of the solar 'constant' for the period 1920–34. A number of periodicities ranging from 7 months to 68 months were revealed by a variant of the periodogram method of analysis, and these suggested the existence of a well-marked 23-year period. For tracing the connexion between these and weather, use has been made of long meteorological records collected together in an earlier Smithsonian Publication—"World Weather Records". Considerable success is claimed in this, and practical application of the results was made in long-period forecasts for 1934, 1935 and 1936; it is stated that these were fairly well verified for temperature and precipitation in 1934.

Vibration of an Incomplete Circular Ring

FINDING that Lamb's method of treatment is applicable only to relatively small arcs of rings, Mr. T. Ikebe has investigated, by means of a mathematical analysis, the frequency and form of vibration of a ring having a very small air gap ("On the Vibration of an Incomplete Circular Ring", *Sci. Pap. Inst. Phys. and Chem. Res., Tokyo*, 27, No. 589). His investigation is based on equations given by Prescott in "Applied Elasticity", and proceeds by the application of Ritz's method and of an integral equation to determine values of the frequency of a ring of negligible cross-sectional dimensions. Comparison of these results with those obtained experimentally reveals marked discrepancies, which are considered to be due to the effect of rotational energy in the test ring, the radial thickness of which cannot be regarded as negligible. A further investigation, giving effect to the influence of rotational energy, yields more comparable results; but as the experiments were carried out on a magnetised ring and in a magnetic field, some doubt is expressed as to the effective value of Young's modulus and as to the condition of free oscillation.

A Method of Improving the Radio Beacon

IN 1929, the Air Ministry erected an improved rotating beacon at Orfordness, Suffolk, for direct navigational use in the North Sea. Mr. H. A. Thomas has discussed the possible errors of this method when the navigator uses it to find the direction of the beacon from the ship (*J. Inst. Elec. Eng.*, 77, 285). An analysis of the records of bearings taken on this beacon by ships at sea shows that within a range of 100 miles, about 80 per cent of the bearings obtained were correct within 2°, whether taken by day or by night. At greater distances the day observations showed reasonable consistency up to 250 miles, but the night observations gave evidence of the well-known 'night effect' errors. These effects are known to be due to interference at the receiver on the ship between the ground ray and other rays which have travelled through the upper atmosphere. These produce false bearings owing to the lack of definiteness of the minimum points. With the operating frequency 288·5 kilocycles (1,040 metres) at present allocated to rotating beacons, it is necessary to use a large aerial system, and rotating this produces mechanical difficulties. In the system described by Mr. Thomas, there are two pairs of spaced aerials supplied by two power amplifiers. These amplifiers, automatically controlled, provide the necessary voltage variations. Experiments show that a controller of this type can advantageously fulfil the function of an excitation apparatus. It is concluded that the system would be suitable for incorporation in a full-sized rotating radio beacon for marine navigational purposes.

British Institute of Radiology: Annual Congress and Exhibition

THE ninth Annual Congress and Exhibition of the British Institute of Radiology was held in the Central Hall, Westminster, on December 4–6. As usual, one session was devoted to the reading of papers on the physical and technical aspects of X-rays as applied to medicine.

Dr. J. Read, of the Radium Institute, gave a lecture on "High Voltage X-ray Tubes in the U.S.A.", in which he traced the development of continuously evacuated tubes for voltages up to one million volts. The first tube of this type, constructed by Lauritzen at the Kellog Laboratory, Pasadena, in 1927, was successfully operated at 600 k.v. peak supplied by an alternating current generator comprising four transformers in series. The tube, which was self-rectifying, had a glass envelope some nine feet long and an earthed anode. A later tube of the same type has a central earthed discharge-chamber and a balanced arrangement of electrodes, one at 500 k.v. positive potential to earth and the other at 500 k.v. negative potential to earth, so that the peak potential difference between the electrodes is 1000 k.v. Whereas the earlier tube made use of the 'cold emission' of electrons, the later tube has a shielded hot filament. Special vacuum pumps, first of the mercury vapour type with liquid-air traps and later of the oil vapour type, were designed. The latest pump has a pumping speed of 2,000 litres per second.

A somewhat similar X-ray tube excited by alternating voltages up to 100 k.v. peak has been installed at the Soiland Institute. In this tube, the glass envelope is replaced by a porcelain one consisting of a large transformer bushing insulator, this permitting a considerably smaller over-all length. At Lincoln (Illinois) and at the Harper Hospital, Detroit, similar tubes are operated by constant voltage generators. Rather different types of tubes and generators are installed at Seattle and at Chicago. In these installations, the high-tension generators consist of two Villard generators connected in series, and the tubes are built in a cascade arrangement so that the electrons are subjected to successive accelerations. This design reduces the cold emission of electrons, but requires a considerably better vacuum than the Lauritzen design. A further difficulty in operating such tubes arises from the fact that, owing to the long electron path (some 10 feet) the electron beam is deflected by magnetic fields to a serious extent. The effect of the earth's field may be balanced out by suitably disposed magnets, but even so the focus is apt to wander.

Dr. Read also described an ingenious arrangement devised by Sloan at the San Francisco hospital. In this outfit, the high-tension generator consists of an oscillator generating high-frequency waves of 6 metres wave-length, coupled as in a Tesla transformer to a tuned secondary. The transformer is mounted in an evacuated tank, and the high-potential end of the secondary carries the target of the X-ray tube, the filament being mounted in the side of the tank. The high-tension transformer and X-ray tube are thus mounted in the same vessel, and the complete outfit is considerably smaller than those previously considered. Some difficulties are experienced owing to mechanical vibrations of the high-tension coil, and the efficiency of the generator is rather low, an input power of about 100 k.w. being required to give a reasonably powerful X-ray beam.

Dr. L. H. Gray, of the Mount Vernon Hospital, gave a paper on "The Ionisation Method of Gamma Ray Energy Measurement", in which he showed theoretically that the degree of ionisation produced in light elements can be related to the energy of the radiation, and measured by ionisation in air. The possibility of measuring gamma ray energies by ionisation depends on two factors: (1) The energy required to produce an ion pair in air must be independent of the velocity of the ionising electrons; and (2), the ratio of the stopping powers of air and other materials for electrons must be independent of the velocity of the electrons. Reviewing the experimental evidence, he is of opinion that both these conditions are fulfilled. In the case of heavy elements, the degree of ionisation is relatively higher, due to the fact that the absorption process is not wholly one of scattering, but is partly photo-electric. In aluminium the ionisation is some 10 per cent higher than in carbon, and in lead more than four times as great.

The eighteenth Silvanus Thompson Memorial Lecture was given by Dr. G. W. C. Kaye, of the National Physical Laboratory, on "Forty Years of Radiology (1895–1935): A Review and Some Reminiscences". Observing that, almost to the day, forty years have passed since Röntgen's discovery of the radiation that bears his name, Dr. Kaye reviewed in a fascinating manner the history of the subject, starting from the early gas X-ray tubes excited by induction coils, passing on to Coolidge's invention of the hot cathode tube (1913), Bouwer's development of the self-protected tube and the recent advances of various types of shock-proof equipment. High-tension generators, he said, beginning as induction coils and made by instrument makers, have become more and more powerful, and modern equipment follows closely the lines of other branches of electrical engineering. Apart from everyday apparatus in use in all hospitals, there is a tendency, particularly in the United States, to experiment with much higher voltages, and generators and tubes operating at one million volts have been described. In Great Britain, X-ray treatment with 400 kilovolt X-rays is being carried out in several hospitals in London, Leeds, Manchester and Birmingham.

Reviewing the question of dosage, Dr. Kaye stated that the ionisation unit of X-ray quantity, the röntgen, has practically replaced the older arbitrary standards such as the pastille dose. Recent research, he said, appears to show that the röntgen will also serve as a unit of gamma-ray dose. Touching briefly on radium therapy, Dr. Kaye remarked that since 1913 the National Physical Laboratory has measured about a quarter of a pound of radium, of value more than a million pounds, the bulk of this radium being the property of the National Radium Trust. Mention was also made of the industrial and physical applications of X-rays in the radiographic and fluoroscopic examination of objects and the study of the solid state of matter by crystal analysis.

Lightning Stroke Currents

RECENT laboratory researches on impulsive rushes of electricity produced by high-voltage discharges of condensers have proved of great value by leading to improvements in the methods used in protecting buildings and overhead wires from damage by lightning strokes. The discharge in the laboratory is very similar to the lightning stroke in Nature. The sound produced, although the arc is only a few feet long, is uncomfortable and often painful to the ear. Anyone taken unawares by a laboratory discharge occurring a few feet away might be seriously affected by the blinding light and the deafening noise produced.

In a paper read at the Pacific Coast Convention of the American Institute of Electrical Engineers, Seattle, Mr. P. L. Bellaschi gives definite and interesting information about lightning strokes. Statistics prove that most of them are single discharges. The number of multiple discharge strokes is about 20 per cent, and the number of oscillations is very seldom greater than four. Field observations show that multiple discharges sometimes strike the ground at appreciable distances apart. Hundreds of cases are known where bronze conductors, used in telephone circuits, which are about 2 square millimetres in cross-section have been fused by lightning. A case has been reported where lightning has vaporised a 3·34 sq. mm. copper conductor. Several thousands of wood poles used for telegraphs and protected by 21 sq. mm. steel wires connected to the earth have been kept under observation for several years. None of the wires was found fused and none of the poles was damaged, although previously to being protected they were often found shattered.

Assuming that an ordinary lightning stroke fuses a 2 sq. mm. bronze conductor, and that it consists of a single discharge, then on the basis of a duration of 40 microseconds, the maximum value of the current produced by the stroke would be of the order of 100,000 amperes. On the basis of a 100 millionths of a second duration, the current would be of the order of 65,000 amperes. The data available show that currents as high as 200,000 amperes would be very rare.

Photographs are shown of copper tubes that have been crushed inwards by lightning discharges. In one case a hollow copper rod 1·47 cm. inside diameter and 6·675 mm. thick was crushed by lightning. From the incipient fusion shown in several places, the rod was obviously raised to a high temperature. The crushing force was calculated to be 400 lb. per sq. inch of tube surface. An oscillatory discharge would considerably increase this crushing force.

Lightning strokes to guy wires have blasted the rock, cement, etc., in which the wires were embedded. The shattering of poles and trees is a familiar occurrence. Parts of shattered objects have been thrown distances of more than a hundred feet. Metal pipes have been cracked and broken open by lightning. Experiments are quoted which show that the diameter of the lightning stroke channel generally lies between one and two centimetres.

Aluminium in Food

STATEMENTS appear from time to time incriminating the use of aluminium cooking utensils as dangerous to health, the small amounts of the metal that are dissolved by the food being considered responsible for the occurrence of various human ailments. As often as such allegations have been made they have been denied, and the question is not yet settled. There is no doubt that the ingestion of relatively large amounts of aluminium produces toxic symptoms, but it is not so simple to prove the toxicity to human beings of the minute amounts which are non-toxic to animals. In any event, knowledge of the amounts of the metal likely to be met with in cooked foods and of the amounts producing symptoms in animals is a prerequisite to a discussion on the subject. Such information is provided in a recent review by Monier-Williams*.

Alum itself has in the past been used as the acid ingredient of commercial baking powder and is still so used in some countries: bread made with such a baking powder may contain as much as 0·05 per cent of aluminium, or 500 parts in a million. The amount found in foodstuffs is much less and a large part of that found in plants is probably adventitious in origin, due to contamination with soil and dust. Probably the amount consumed daily with food is of the order of 5–10 parts, or less, per million. In animal organs the quantities are of the order of 1–2 parts in a million.

The accurate determination of aluminium in food and biological material is a difficult matter. Monier-Williams describes a method in which 8-hydroxyquinoline is used as a precipitating agent for aluminium. It has the advantage that the compound with aluminium contains only 5·9 per cent aluminium, so that small amounts can be determined with great accuracy; the precipitate can be weighed or titrated with bromine.

The amount of aluminium taken up by food during cooking varies greatly with its nature, especially its acidity, and the conditions of cooking as well as with the particular utensils used: the purer the metal employed in the latter the more resistant is it to corrosion. Probably less than 10 parts in a million

* Ministry of Health. Reports on Public Health and Medical Subjects, No. 78: Aluminium in Food. By Dr. G. W. Monier-Williams. Pp. 34. (London: H.M. Stationery Office, 1935.) 9*d*. net.

is usually the amount occurring in food cooked in aluminium vessels. It appears that a considerable proportion of the metal taken into the stomach is soluble, but the actual amount dissolved varies greatly with the circumstances. Only minute amounts, however, appear to be absorbed into the body, from determinations of the quantity in the blood, tissues or urine. The presence of relatively large amounts of the metal in the digestive tract may interfere with the digestive processes, alum especially producing gastro-intestinal irritation and loss of appetite in both animals and man.

Neither these experiments nor those which show the harmlessness of the ingestion of small amounts of aluminium are necessarily conclusive, since it is possible that there may be individuals who are susceptible to even such small doses of the metal as may be derived from aluminium utensils. Monier-Williams concludes that there is no convincing evidence that these small amounts have a harmful effect upon the ordinary consumer, but that it is undesirable to admit the entry of aluminium into food in the relatively large amounts in which it may be employed as a constituent of baking powders or self-raising flour.

Phytoplankton and Herrings*

THE concentration of phytoplankton organisms at times in dense patches in various parts of the sea is a phenomenon, which was recognised by early observers (see also NATURE, Dec. 7, p. 897). These brownish or greenish patches in the North Sea, usually formed of the diatoms *Rhizosolenia* or the colonial flagellate *Phæocystis* and accompanied by a slime which clogs the nets are well known to the fishermen, who call such discoloured water 'stinking water', 'weedy water', 'Dutchman's baccy juice', etc., regarding it as a bad sign for the fishing. The present authors analyse the herring fishery of the southern North Sea together with the occurrence of these phytoplankton patches, the object of the work being "to give an account of our knowledge of the distribution and movement of any dense phytoplankton concentrations in the southern North Sea from 1921 to 1932 (excepting years 1928 and 1929) at such times as might affect the herring fishing, and by examining the official reports and statistics of the fisheries from year to year to see whether or not the existence of these patches, either on the fishing grounds themselves, or lying in the path of incoming shoals of fish, can be regarded as a probable cause of some of the fluctuations in the herring landings over this period."

It has been found again and again that where large zones of phytoplankton occur the herrings avoid them, sometimes making extensive detours rather than penetrate them, and that these patches form definite barriers to the oncoming shoals.

At the time of the great herring shoaling in the southern North Sea, *Rhizosolenia styliformis* and *Phæocystis* are the outstanding features of the plankton in this area, and when the fish have been plentiful and the fishing above the average, no instance is found of a concentration of plankton in such a position where it might be held to have an influence on the fishery, whereas on each occasion when the fishery has been below the average and the decrease cannot be attributed to weather or economic conditions, phytoplanktonic concentrations occurred. Four factors are considered as possibly influencing the fishery—the effect of the moon, year classes, gales and economic conditions; to these are now added the very probable and now almost certain factor of influence of phytoplankton.

The authors note further that since the present paper was being prepared for press another autumn season has come round, 1933, and this brings with it such striking evidence in favour of the phytoplankton hypothesis that they feel justified in regarding this as not only possible but even highly probable.

Educational Topics and Events

CAMBRIDGE.—N. G. Hentley, of St. John's College, has been appointed to the Benn W. Levy research studentship in biochemistry.

At Queens' College, Sir C. J. H. Thomas, Permanent Secretary of the Ministry of Agriculture and Fisheries, has been elected into an honorary fellowship.

Mr. C. W. Gilbert, of Christ's College, has been elected into a research fellowship at Jesus College.

An election to the Pinsent-Darwin studentship in mental pathology will be made in January 1936. The studentship is of the annual value of not less than £225, and is tenable for three years. The student must engage in original research into any problem having a bearing on mental defects, diseases or disorders, but may carry on educational or other work concurrently. Applications should be sent before January 1, 1936, to the Secretary, Pinsent-Darwin Studentship, Psychological Laboratory, Cambridge.

ELECTIONS to three Beit fellowships for scientific research will take place on or about July 10, 1936. A fellowship is of the annual value of £240, and is tenable for two years at the Imperial College of Science and Technology, South Kensington, London, S.W.7. Candidates must be less than twenty-five years of age. Further information can be obtained from the Rector of the College.

THE thirty-sixth annual meeting of the Science Masters' Association will be held in the Chemistry Department of the Imperial College of Science and Technology, South Kensington, London, S.W.7, on January 1–4, under the presidency of Sir William Bragg. The following lectures will be delivered during the meeting: Sir William Bragg, "School Science after School" (presidential address); Prof. J. C. Philip, "Chemical Fogs"; Prof. J. W. Munro, "Recent Advances in Economic Entomology"; Dr. H. J. T. Ellingham, "Primary Cells: their Nature and Action"; Dr. John Taylor, "The Doctor as Detective". There will also be a lecture-demonstration of biological films by H. R. Hewer. Among the discussions to be held is one on "Geometrical Optics—especially Sign Conventions" and another on "School Certificate Biology Syllabus". Further particulars can be obtained from the Annual Meeting Secretary, The Square, Repton, Derby.

Science News a Century Ago

Meeting of the [illegible]l Geographical Society

AN ordinary meeting of this Society was held on Monday, December 14, 1835, at its rooms in Regent Street. The president, Sir John Barrow, "announced that the Council had decided that His Majesty's annual premium should be awarded to Captain Back, on account of his recent discoveries, and particularly of a large river running beyond the Great Slave Lake a distance of 500 miles. He felt convinced that the south land seen by Captain Back was the coast of North America, and this convinced him of the possibility of a north-western passage. He was happy to state that the Council had decided in Captain Back's favour on no other authority than that of his simple and affecting narrative. So closely had he been within starvation that he had been compelled, on one occasion, to eat his own shoes; yet notwithstanding the great sufferings which he had undergone, he had come forward gratuitously to the assistance of his 600 fellow-countrymen who were now enclosed in the ice on the shores of Greenland with no other prospect before them than death. He was happy to announce that Captain James Ross had previously offered his aid to the Admiralty, which, he had every reason to believe, would be accepted." (*Courier*.)

Central Agricultural Society of Great Britain and Ireland

As the result of a largely attended meeting held on December 15, 1835, at the Freemasons' Tavern, Great Queen Street, a society called the Central Agricultural Society of Great Britain and Ireland came into existence. At the meeting, Mr. Ormsby Gore, M.P., was in the chair, while the Earl of Stanhope was the principal speaker. A few days later, on December 21, the Society published a notice in *The Times*, stating that at a meeting of the Committee held on December 16, at 448 West Strand, London, it was resolved that the objects of the Society "be exclusively national; directed to no theoretical purposes but formed solely with a view to procure the co-operation of the owners and occupiers of land in every practicable measure which can afford relief to the present distressed state of agriculture . . . and with a view to improvement in every branch of practical agriculture".

Manufacture of Machinery in Germany

ON December 18, 1835, *The Times* quoted the following extract from a Frankfort paper: "We have much cause to rejoice at the great advance which has been made in Prussia within these last few years in the manufacture of machinery. It is not very long ago, for almost every large machine, we required help from England, and had the greater part from that country. Now an entire change has taken place in this respect, and the great establishment of this kind in Berlin, furnishes the most complete and admirable machines at far lower prices than in England. These happy results we owe to the zeal of Privy Councillor Beuth, who, as President of the Mechanics' Institution and Director of the Department of the Interior, dees everything to favour and improve the construction of machines". Beuth was born at Cleve in 1781 and died in Berlin in 1853. A statue of him was erected in 1861.

Monument to Laplace

ON December 19, 1835, the *Athenæum* stated: "A monument has been raised to this great man at Beaumont, and placed on the site of the house where he was born. It is a building erected for the purposes of a primary school, and a hall for the mayoralty. Two tablets of marble are inserted in the front of the building, on one it is recorded that the corporation of Beaumont had erected their edifice to the memory of Laplace, born at Beaumont, the 22nd of March 1749 and died at Paris the 5th March 1827. On the other is inscribed:

'Sous un modeste toit, ici naquit Laplace,
Lui qui sut de Newton agrandir le compas,
Et, s'ouvrant un sillon dans les champs de l'espace
Y fit encore un nouveau pas.' "

Societies and Academies

DUBLIN

Royal Dublin Society, November 26. G. F. MITCHELL: A recent bog-flow in Co. Clare. On October 29, 1934, a mountain bog burst above an escarpment which interrupted the gentle slope of the hillside. The bank of well-drained peat overlooking the escarpment gave way, allowing the bog above that level to flow away violently. It is suggested that the heavy rainfall (more than 2 in.) in the vicinity in the preceding week had increased the weight of the bog, and caused the supporting bank to give way. E. J. SHEEHY: The mechanical aspect of the nutrition of farm stock. Insufficient recognition of the mechanical effect of foods explains the absence of uniformity sometimes occurring in the results of different laboratories, and also the frequent conflict of opinion between the scientific worker and the practical feeder. Certain foods have, in particular circumstances, a nutritive value in excess of their net energy value. G. CRUESS-CALLAGHAN: The application of the catalase test to butter. An analysis of the large number of results published by Knudsen (probably for butter made from ripened cream) yields a value about $-0{\cdot}4$ for the coefficient of correlation between the catalase figure and the quality of the butter, and about the same value for the coefficient for the catalase figure and the keeping property. Reasons are suggested for the varying coefficients, ranging from $-0{\cdot}191$ to $+0{\cdot}96$, put forward by other workers.

PARIS

Academy of Sciences, November 12 (*C.R.*, 201, 861–916). AUGUSTE BÉHAL: Scientific bibliography. EDGAR BATICLE: The problem of distribution. GÉZA KUNETZ: The conservation of the Spearman common factor in a linear substitution. NIL GLAGOLEFF: Axioms of appurtenance of Euclidian geometry. MARCEL VASSEUR: Tangential invariants relating to the conjugated network common to two applicable surfaces. FRÉDÉRIC ROGER: The relation between the tangential and metric properties of Cartesian ensembles. N. ARONSZAJN: The metric characterisation of Hilbert space, of vectorial spaces and of certain metric groups. EDOUARD CALLANDREAU: The variation of the influence round a point. PIERRE CHEVENARD and XAVIER WACHÉ: The acceleration of a structural reaction in a steel by the effect of a mechanical constraint. Experiments on a chrome-

vanadium-molybdenum steel. Tests on the steel under load at temperatures between 450° and 600° C. show important changes. As neither the measurements of resistance, expansion or magnetisation showed any appreciable physiochemical modification, the softening observed must be due to a structural modification of the alloy. It is pointed out that these facts must be taken into account when designing machines required to work at a high temperature. MARIUS AUBERT, PIERRE CLERGET and ROGER DUCHÊNE: The influence the addition of various substances on the combustion of gas oil in injection motors. Study of the effect of adding ethyl nitrate to the gas oil in regulating the combustion and suppressing detonation. HENRI CAMICHEL: The constants of the movement of the *F*-type stars. LÉON DUBAR: The internal and superficial conductivity of cuprous oxide. Cuprous oxide possesses a very high superficial conductivity, which is reduced by the adsorption of water vapour. MLLE. SUZANNE VEIL: An electrometric control of displacement reactions. GEORGES BRUHAT and LOUIS WEIL: The rotatory power of quartz for rays perpendicular to the optic axis and its dispersion between 2537 A. and 5780 A. In the whole of the interval of the spectrum studied the rotatory dispersion of quartz is the same for rays perpendicular and parallel to the axis. JEAN LAVAL: The diffusion of X-rays varies in a discontinuous manner with the angle of diffusion. EDMOND ROTHÉ and MME. A. HÉE: The radiometric exploration of a rhyolite *coulée*. The rhyolite near Welschbruch is strongly radioactive, and it has been found possible to map out the volcanic *coulées* by radiometric measurements. OSIAS BINDER: The hydrolysis of solutions of copper sulphate. VICTOR HENRI and PIERRE ANGENOT: The relation between the ultra-violet absorption spectrum and the Raman spectrum of pyridine. The analysis of the ultra-violet absorption spectrum of pyridine vapour proves the existence in the lower level of the molecule of five fundamental frequencies. These correspond with the Raman spectra of pyridine and benzene. JEAN TABUTEAU: The application of the Raman effect to the study of the *cis-trans* isomerism of the methylcyclohexanols. It has been proved that the Raman spectra of the *cis* and *trans* isomers are different and the variations are greatest for frequencies between 300 cm.$^{-1}$ and 900 cm.$^{-1}$. PIERRE CARRÉ and HENRI PASSEDOUET: The influence of an element or a negative group on the relative mobilities of alkyl radicals in their chloroformates. GEORGES LÉVY: The nitration of α-ethylnaphthalene. GEORGES DARZENS and ANDRÉ LÉVY: The preparation of 1, naphthyl-β-propionic, 2, naphthyl-β-propionic and 2, tetrahydronaphthyl-β-propionic acids. The synthesis of dihydrophenalone and of 5, 6-tetrahydrobenzo-1-indanone. ANDRÉ GUILLEMONAT: The oxidation of 3-methyl-2-pentene and of 2-methyl-2-pentene by means of selenious anhydride. MOSHEH AVNIMELECH: The Vindobonian in Palestine. FERNAND JACQUET and THÉODORE MONOD: The fossiliferous Primary of the south of Mauritanian Adrar. RENÉ SOUÈGES: The embryogeny of the Resedaceæ. The development of the embryo in *Reseda Luteola*. JEAN RÉGNIER and ANDRÉ QUEVAUVILLER: The concomitant variations of chronaxy and of nervous excitability under a pharmacodynamic influence (action on the motor nerve of *Rana esculenta* of cocaine and its substitutes). MLLE. CATHERINE VEIL: The mechanism of the colour change in fishes.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Saturday, December 14

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS, at 2.30.—Prof. G. Hickling: "William Hutton's Observations on Coal, 1833".

BRITISH PSYCHOLOGICAL SOCIETY, at 3.—Annual General Meeting.

Prof. J. Drever: "The Status and Qualifications of Professional Psychologists" (Presidential Address).

Sunday, December 15

BRITISH MUSEUM (NATURAL HISTORY), at 3 and 4.30.—Miss M. R. J. Edwards: "Pests".*

Monday, December 16

BRITISH MUSEUM (NATURAL HISTORY), at 11.30.—Capt. Guy Dollman: "Pouched Mammals".*

Wednesday, December 18

INSTITUTION OF CIVIL ENGINEERS, at 6.30.—Prof. A. H. Gibson: "Tidal and River Models" (Vernon-Harcourt Lecture).

Scientific Humanism

IN the preface of his admirable volume on the history of seventeenth century science, Prof. A. Wolf pleads for a new orientation in humanistic studies. The need for such a re-orientation, repeatedly urged in the columns of NATURE, is becoming more evident daily. On the Continent, reasonable persuasion and confidence in public education are increasingly regarded as exploded liberal superstitions. Blind obedience to leaders with supposedly exceptional gifts is more in keeping with the temper of the times, and if we record with gratitude the fact that Britain and the Scandinavian countries are least swayed by it up to date, it is all the more important to forestall a danger against which we have been amply forewarned. Men of science in Huxley's generation urged the claims of education with an assurance which is rarely voiced to-day. If we ask why this is so, one reason is not far to seek. The old tradition which exacted several years of classical study as the price of scientific education had at least one advantage. At the end of it, scientific worker and statesman had a common realm of discourse. In modern practice there is a complete dichotomy between an education which gives the statesman no prescience of the technical forces shaping the society in which he lives, and one which stimulates in the scientific worker little interest in the social impact of his own activities.

That there exists substantial reason for dissatisfaction with the exploits of contemporary statesmanship most scientific workers realise, and far-sighted leaders of scientific work like Sir Frederick Gowland Hopkins and Sir John Orr already recognise how the work of the man of science must inevitably suffer if society fails to make use of it. Sir Josiah Stamp's recent assault on the technocrats, in his Norman Lockyer Lecture before the British Science Guild on "The Calculus of Plenty", emphasises the absence of a common vocabulary to make the reasons for alarm rationally articulate. For the economist as such, plenty has little meaning aside from making what use we do make of our present resources with what social machinery we take for granted. The plenty of the scientific worker is a thermodynamic reality which resides in the balance sheet of human effort expended in securing available sources of power which could be applied to the satisfaction of our common mammalian requirements, if their use were rationally planned. The economist takes it as an axiom that people choose different things and does not concern himself with the fact that they have many common needs. The man of science sees society as an association of individuals with many basic requirements; and, since people have no instinct to recognise minimal quantities of ascorbic acid in their diet, he cannot assume that people necessarily choose what is best for them without a science of human nature to enlighten their choice.

The disruptive movements which have overwhelmed Germany and Italy have been, first and foremost, youth movements. Some explain this as a symptom of large-scale unemployment. In part it may be. Still, it is important to remember that, under existing conditions, it is nobody's business to take stock of what resources for human welfare are made available by progressive scientific knowledge. Consequently youth has some excuse for feeling that intelligent leadership in social affairs is not likely to come from present political parties. The existing curriculum of humanistic studies does little to arrest the retreat from reason Social history is a pageant of political controversy in which matters of sentiment play a larger part

than matters of fact, or a sequence of commercial enterprises solely controlled by the incentive of profit. What the expansion of maritime enterprise in the sixteenth century owed to rapid advances in nautical astronomy does not enter the picture. That witch-burning ceased almost as soon as the discovery that air has weight scattered the salamanders of alchemy, is shown to be more than a mere coincidence by the noteworthy experiment which Gassendi induced Colbert to witness. For purposes of history, as it is now taught, the general enlightenment of mankind proceeds with no acknowledgment of its debt to advancing knowledge of Nature.

At the end of the Great War, there was an articulate recognition of the danger of leaving the administration of a great country in the hands of civil servants trained in the tradition which prompted Mr. Gladstone's familiar query to Faraday. Pressure of informed opinion succeeded in securing a pivotal concession, when 'Everyday Science' was introduced as a compulsory subject in examinations for higher administrative posts of the Civil Service. The recent decision of the Commissioners to eliminate it will have deplorable consequences. Of late years there has been an encouraging sign of progress in the teaching of school science with more emphasis on its humanistic content. Many textbooks recently published show that more emphasis on the place of science in the education of the average citizen does not necessarily entail diffuse and vague courses of study conferring no knowledge which can be tested by customary examination standards. While the authors of such books deserve our gratitude, there is still ample scope for improvement, which will come, if teachers of science in the universities can be encouraged to co-operate with teachers of science in the school. In particular, there is need for more *extensive* as opposed to intensive teaching of isolated branches. With careful planning, and an enlightened social objective, this is not incompatible with examinable knowledge suitable for pupils of average intelligence.

The existence of the Civil Service examination in 'Everyday Science' acted as a catalyst. While it remained, it provided a unique opportunity for canalising the need for such co-operation by creating a demand for science courses in the universities suitable to students with a humanistic training. A beginning had been made under great difficulties with little appreciation from those who had been nurtured in the older tradition. If scientific men do not corporately influence the Commission to revise its decision, they will have forfeited an opportunity as well as a principle.

The Examination of Examinations

An Examination of Examinations: being a Summary of Investigations on the Comparison of Marks allotted to Examination Scripts by Independent Examiners and Boards of Examiners, together with a Section on a Viva Voce Examination. By Sir Philip Hartog and Dr. E. C. Rhodes. (International Institute Examinations Enquiry.) Pp. 81. (London: Macmillan and Co., Ltd., 1935.) 1*s*.

WHEN the late Prof. F. Y. Edgeworth made the startling discovery that twenty-eight experienced examiners could assign to the same piece of Latin prose marks varying from 45 to 100 per cent, he raised a doubt about the efficiency of public examinations which must have lingered ever since in the minds of persons concerned in their administration. No one questions that the major public examinations of Great Britain are conducted with scrupulous fairness, great pains being taken to secure by supervision and co-ordination of the examiners' work that the ultimate verdicts shall be as trustworthy as possible. The precautions worked out by Mr. David Mair when he was director of the Civil Service examinations are a noteworthy example of scientific efforts directed to this end; and the same thing may be said of the measures described by Dr. Crofts in his writings. Doubtless there are other authorities responsible for important examinations who approach the problems of administering them in the same scientific spirit; nevertheless, the results of inquiries which Prof. C. W. Valentine published in his book on the reliability of examinations showed only too clearly how doubtful an instrument for achieving its purpose an apparently well-administered examination may be.

The uneasiness stimulated by Prof. Valentine's book must be greatly increased by the pamphlet now written by Sir Philip Hartog and Dr. E. C.

Rhodes on behalf of the English Committee of the International Institute Examinations Enquiry. The committee, it should be understood, is a branch of a body enlisted under the auspices of the International Institute, Teachers College, Columbia University, and financed by the Carnegie Corporation and the Carnegie Foundation of New York. The object is an inquiry into the functions, methods of procedure and solid value of examinations in the more important countries of Europe and in the United States. The investigation is naturally taking different forms in the several countries, and in England has been devoted mainly, as the appearance of this pamphlet suggests, to "the examination of examinations" from the point of view of their efficiency. The chairman of the English committee is Sir Michael Sadler; Sir Philip Hartog is the director of the technical inquiries the committee has conducted, while Dr. Rhodes has served as the committee's statistical expert.

Several other publications have appeared or will appear under the authority of the Committee, but so far as the general public is concerned none is likely to excite so much interest as the present brief, cogent and admirably written memoir. It would be improper to regard it as an 'indictment' of our public examinations, if only because the inquiry it describes was facilitated, and indeed made possible, by the cordial co-operation of several important examination authorities, and by the willing collaboration of expert examiners who work for them. The validity of the results here set out depends, in short, largely upon the fact that the material investigated consisted entirely of scripts that had been written and assessed in connexion with some public examination of repute, and that the agents were experienced examiners working at a familiar task under conditions to which they are well accustomed.

These things premised, it must be admitted that the results of the inquiry establish beyond a doubt that chance plays a seriously large part in determining the verdicts passed upon candidates in examinations in which a student's career is very often determined by the kind of place he takes. One has always recognised the possibility that a question paper may or may not 'suit' a particular candidate. But what is now brought out is the degree to which the mark assigned by an examiner to a candidate's answers may depend not merely upon stable personal characteristics for which allowance could conceivably be made, but also upon tendencies which vary from time to time, and even upon such factors as his interest in the subject-matter of a particular question.

The examinations selected by the Committee for the purpose of the investigations were: (*a*) the 'school certificate' examinations taken in secondary schools by between 60,000 and 70,000 candidates every year; (*b*) the 'special place' examinations (taken by from 400,000 to 500,000 children annually, and of enormous social importance), by means of which children between the ages of ten and twelve years gain admittance from primary schools to central or secondary schools; (*c*) a college scholarship examination in English essay; (*d*) a university honours examination in mathematics; (*e*) a university honours examination in history.

Under heading (*a*) the plan adopted in investigating the marking of history and Latin was to select in one case 15 scripts, in the other case 15 couples of scripts, all of which had received the same 'middling' mark from the school certificate authorities concerned. In each case the scripts were re-marked in turn and independently by 15 examiners, who were asked to assign to them both numerical marks and also awards of failure, pass and credit. In the case of Latin the examiners were divided into two groups who, in accordance with their expressed preference, were guided in their detailed marking by schedules differing in a good many particulars, one of them containing a greater number of instructions to examiners than the other. As the outcome of this second examination, the fifteen history scripts originally considered to be of equal value received 43 different marks varying from 21 to 70 out of a maximum of 96. The fifteen couples of scripts in Latin received from the six examiners who worked under Scheme I, 24 different marks ranging from 28 to 55, and from their colleagues who used Scheme II, 28 marks ranging from 33 to 61. Even more striking, if not more significant, was the fact that when fourteen out of the original fifteen examiners marked the same fifteen history scripts after an interval of a year or more, not only did their numerical marks differ from those they had previously awarded (a difference of as many as 30 marks being made by one examiner), but the verdicts of failure, pass and credit were also varied in a very serious degree. On each occasion the examiners awarded a total of 210 verdicts to the fifteen candidates who had all originally received the same verdict (pass); and in 92 out of the 210 cases the verdict on the second occasion differed from the verdict delivered on the first.

The examinations of scripts in French and chemistry followed broadly the same lines with modifications, scripts of which the original marks corresponded to a normal frequency distribution being selected instead of scripts originally declared to be equal in value. In both subjects the same discrepancies in judgment on the part of the examiners came out. As a comparable investigation of school certificate English, the inquiry conducted on behalf of the Durham

University Examinations Board is quoted. It showed much the same discrepancies, the most serious from the point of view of the candidates being, once more, the lack of agreement among the examiners, not only about the mark deserved by a particular script but even about the verdict to be passed upon a candidate's performance. For example, out of 39 candidates awarded a failure mark by one or more examiners, 24 were awarded a credit, 8 special credit, and 3 distinction by one or more of their colleagues.

The scripts of 150 candidates in a 'special place' examination required more complex investigation, since they dealt with two subjects, English and arithmetic. The number made it possible for the committee to test divergent methods of marking; for example, the marking of English essays by general impression as distinguished from marking in accordance with a detailed schedule of items to be assessed. An unexpected result of these variations in method was the discovery—confirmed later when diverse methods of examining were applied in honours mathematics—that a detailed schedule, while it may bring about a certain degree of uniformity in the assessments of examiners, still leaves a dangerous amount of variation possible.

It is scarcely necessary to follow the Committee through its other investigations, the results of which confirm the conclusions already indicated. Another examination of a particularly interesting type must, however, be referred to: namely, the *viva voce* examination of 16 candidates of excellent academic standing, well recommended by their universities and attracted by a prize of £100. The object here was to make the examination conform as closely as possible with the *viva voce* examination of candidates for higher posts in the Home Civil Service, and the work was entrusted to two boards of distinguished and experienced men and women whose names are given. All 16 candidates were interviewed by the two boards. The members of each board were requested to assess independently upon a given scale a candidate's merits as revealed in the interview; and after interviewing him each board agreed upon a joint mark. While there was substantial agreement between the opinions of the members of the same board, the verdicts of the two boards differed in a quite remarkable degree. For example, the candidate who stood first in the estimation of Board I was placed thirteenth by Board II. As Sir Philip Hartog remarks, such glaring differences can only be accounted for by the luck of the interview. Board I happened to strike upon a subject which enabled the candidate to reveal his individuality, while Board II, although doing its utmost to explore the candidate's mind, did not happen to touch the revealing spring.

To the major section of the report which describes the investigations and their results is appended a briefer section dealing with the statistical aspect of the inquiry. Its purpose is to show how, from the verdicts given on a number of scripts by a number of examiners, one could determine: (*a*) the ideal mark which 'ought' to have been given to a script; and (*b*) a measure of the random variations in assessment to which a particular examiner is liable. The assumption made is that the mark actually given in a particular case differs from the ideal by a fixed amount characteristic of the examiner's general habit of marking, *plus* an independently varying amount dependent upon a characteristic distribution of random variations about his standard. A reassuring footnote on page 44 mentions a further difference between examiners: namely, a difference in the spread or standard deviation of the marks they would give in a particular examination even if their random variations could be eliminated. It is stated that the influence of these further differences has been estimated, and as far as the examinations considered in the pamphlet are concerned, has been found to be relatively slight. This conclusion may be true of examinations such as those for the school certificate, where definite levels of achievement with definite marks connected with them are familiar to the examiners. The reviewer's experience of one of the largest 'special place' examinations has, however, led him to attach much greater importance than the authors think should be given to differences in the standard deviations of examiners' marks. Setting this point aside, all that need be added is that it is shown how the standard deviation of each examiner's random marks can be calculated. It is then possible, on the principle that an examiner's 'weight' is inversely proportional to his liability to random variations, to obtain a simple ratio from which the ideal mark can be calculated.

It must not, however, be supposed that the method of calculation, interesting as it is, can be used to remove from the marks given in public examinations the serious element of doubt they at present contain; for it depends upon the assumption that a considerable number of examiners have marked each script independently under carefully prescribed rules, and that is a condition which no examining authority could afford to incorporate into its procedure.

The future publications announced by the committee include a treatise on the "Marks of Examiners" by the present authors, which will also contain a memorandum by Prof. Cyril Burt. Serious students of the subject will look forward to this work, which will presumably develop a good deal further the technical methods to which

reference has just been made. But it is not necessary to wait for the further publication before expressing the opinion that the Committee, by the well-conceived and carefully conducted researches described in this memoir, and Sir Philip Hartog and Dr. Rhodes by their lucid account of them, have conferred a very definite obligation upon the public.

The public may, however, ask—and not unreasonably—how the Committee would deal with the disquieting things which the inquiry has revealed. Would it end examinations, or mend them? And if it would mend them, then in what way? The Committee does not entirely ignore these questions, but it has not gone into them. It points out that the "new type" examinations are by their nature entirely free from the weaknesses of the ordinary type; nevertheless, it cannot bring itself to contemplate the abolition of the essay type of answer, which is the kind normally demanded of candidates in public examinations. If the latter attitude prevails—and it is supported in Great Britain by an enormous weight of tradition and prejudice—the problem of retaining the present mode of examinations while making them reliable assumes very great importance. In view of its difficulty—perhaps its final insolubility—it would seem desirable to explore simultaneously alternative methods of assessing progress and knowledge at least for pupils at school. Attention should therefore, we think, be given to carefully standardised methods of recording progress such as those now used by some of the county authorities in their primary schools and described in the 1935 issue of the "Year-Book of Education".

Dreams and Culture

The Dream in Primitive Cultures

By Dr. Jackson Steward Lincoln. Pp. xiii+359. (London: The Cresset Press, Ltd., 1935.) 18*s*. net.

AMONG primitive and superstitious people throughout the world, dreams have nearly always been estimated highly. It was perhaps inevitable that western science, in its endeavour to eschew fantasy and concentrate on verifiable fact, should have reversed the verdict and regarded the unruly figments of our sleeping minds with ill-disguised contempt. Nevertheless, the mere occurrence of dreaming remained a challenge to the psychologist, while the high value placed on dreams by primitives is in turn a fact which can be neglected by the anthropologist only at his own peril. It is true that Tylor had already attributed a very important role to dreams in his doctrine of animism. Nevertheless, the rehabilitation of dreams by Freud should have implied as a practical corollary a thorough reconsideration, in the light of new knowledge afforded by psycho-analysis, of the influence of dreams on primitive culture, and it is perhaps indicative of the over-departmentalisation of the human sciences that it is only now, thirty-five years after the publication of the "Traumdeutung", that there has appeared a serious attempt at a general treatment of this subject.

It has often been noticed that the savage, like the child, appears to distinguish less easily than we do between dream events and events in waking life. This apparent confusion is due, Dr. Lincoln argues in this book, not so much to a real inability to separate the two types of experience, but rather to the fact that dream experiences are given an equal, or even a higher, reality value; and are not, as with ourselves, considered to be meaningless or negligible. Thus, to take an example quoted from Raymond Firth, an Indian dreamt that W. B. Grubb had stolen things from his garden and after waking demanded that he should make amends. Argument showed that the dreamer realised that Grubb had not been there in person. Nevertheless, he maintained, "If you had been there, you would have taken them". Here (in virtue of the psychological mechanism of projection) "the dream is given reality value at the expense of actual experience, yet there is no confusion between the two kinds of experience" (p. 29).

Furthermore, there would seem to be two distinguishable attitudes towards dreams among primitive peoples. In some cultures, as among the extinct Huron and the Navajo, the manifest content is taken at its face value, while in others, as among the Ashanti and the Naga, there is a search for latent symbolic meanings which, when found, enable the dream to be interpreted. To judge from the examples given, however, some degree of interpretation at least seems to be very general.

Perhaps the most important distinction made in the book is that between unsought, spontaneous, individual, dreams on one hand, and induced, 'traditional', 'culture pattern' dreams upon the other. The system of seeking guidance in dreams induced by some special ritual is very widespread. Temple incubation was fashionable in classical times, while in existing or recent cultures procedures for inducing dreams are found in Australia,

Melanesia, Polynesia, Africa and, above all, in North America, where the author's own field work was carried out. Here, as among the Crow Indians, the vision quest may even be "the most important social event in tribal life". Many examples, both from Dr. Lincoln's own extensive collection and from the records of other workers, show the paramount influence of these sought dreams upon the whole subsequent life of the dreamer. They may dictate his name, his profession (especially if he is to be considered as endowed with magical or healing powers), his guardian spirit, his courtship, his prayers and sacrifices, his treatment in mental or physical disease, or even in a social sense his sex, for certain dreams may compel a man to adopt the clothes and duties of a woman.

Not only the life of the individual but also that of a whole society may be profoundly affected by dreams, sought or unsought: war, myths, traditional dances, totems, religious ceremonies and migrations, being sometimes thus determined.

So important is the right dream vision that dreams may sometimes be purchased, though often this process is considered as dangerous to the vendor and therefore tends to be concealed. A stickler for accuracy of psychological description might suggest that this tendency to concealment renders it probable that actual individual dreams of a culture pattern kind are rarer than is commonly asserted. This, however, makes little difference to the sociological importance of the dream in general.

In most induced dreams of cultural importance, the new item of culture is nearly always prescribed by a spirit figure, which, Dr. Lincoln maintains, can be regarded as a father-imago in the psycho-analytic sense—and this irrespective of whether the dreamer belongs to a patrilineal or matrilineal society. Evidence is presented to show that the prescribed item represents an attempt to surmount the difficulties of the Oedipus complex, which thus, as psycho-analysts have already maintained from a different angle, is a very potent factor in moulding culture generally. This suggestion opens up an interesting problem (not here dealt with) as to the relation between culture pattern dreams and initiation ceremonies, in which culture items are definitely handed down by direct instruction from the elders.

Furthermore, it is maintained that the widespread occurrence of dreams of this description shows the ever-present nature of the Oedipus complex, which appears to recur spontaneously in each succeeding generation. If this is so, we can accept Freud's explanation of many cultural institutions without "fruitless speculations as to first origins" or the assumption of innate ideas or racial memories.

Dr. Lincoln's book (which contains a preface by Prof. C. G. Seligman) undoubtedly deserves careful consideration by students of both anthropology and psychology, and is a happy example of fruitful fusion of these two disciplines.

The Boundaries of the Sciences

(1) A Comprehensive Treatise on Engineering Geology
By Dr. Cyril S. Fox. Pp. xv+392+18 plates. (London: The Technical Press, Ltd., 1935.) 35*s*. net.

(2) Géologie appliquée
Par Prof. E. Raguin. Pp. 403. (Paris: Masson et Cie, 1934.) 38 francs.

(3) Useful Aspects of Geology:
an Introduction to Geological Science for Engineers, Mining Men, Prospectors and all interested in the Mineral Industries. By Dr. S. J. Shand. Second edition, revised and amplified. Pp. x+183. (London: Thomas Murby and Co., 1934.) 6*s*. net.

WATERTIGHT compartments are obsolescent in modern scientific thought, so that an increasing number of partnerships are found as in biochemistry, biophysics, the use of X-rays in medicine, crystal structure and industry, and the application of physical chemistry to road and building problems. The dangers of the over-specialisation of the scientific worker, so often debated and deplored in the columns of NATURE, have been much to the fore in recent years; and the reviewer well remembers a remark made in his student days by the then Provost of University College, London, to a gathering of undergraduates, in which it was pointed out that the difficulties experienced by graduates in finding employment was largely caused by the fact that they had specialised in one branch of science only.

The applied science known under the broad term of engineering has suffered less from this disability than many of the pure sciences such as geology, which apart from its application to mining is still regarded by many as an excellent hobby study, but as otherwise of limited practical application. Chemistry has extended enormously into almost all branches of industry, physics is rapidly following suit, while botany and zoology

are also finding applications in agricultural, horticultural, animal and fishery problems.

There are, however, signs that geology is beginning to realise its potential value for the civil engineer and roadmaker ; and though much work both of an educational and of a research character still remains to be done before its application can be said to have been thoroughly explored, the small but persistent stream of scientific works is encouraging.

(1) The extremely readable treatise by Dr. Cyril Fox opens with theoretical considerations on such matters as the solar system and the age of the earth ; and these topics, from their purely scientific interest, might have been abbreviated or omitted with advantage, while the next chapter, which deals with the common rock-forming minerals, contains matter irrelevant to the main theme. It is thought that a series of carefully selected photomicrographs, on the lines of those given by H. G. Smith in "Minerals and the Microscope", accompanied by really full descriptions, would enhance greatly the value of the work. The physical characters of rocks and minerals, as affecting their industrial and commercial uses, have been the subject of research in Germany, the United States and Great Britain during the past twenty years, but the treatise takes little account of any such developments published since 1925, and the usefulness of Part 1 (Building Materials) is curtailed accordingly.

The full treatment accorded to such subjects as isostasy and earthquakes is doubtless due to the experiences of the author in so unstable a region of the earth's crust as the Himalayas, and forms the basis of much of Part 2 (Field Operations) ; and almost the only valid criticism of this portion is in respect of the omission of any reference to recent studies by civil engineers of the behaviour of shingle beaches as agents of coast erosion. Part 3 deals with water supply, and it may be questioned whether an engineer requiring information on the quality of water would make reference to a work of this kind, which omits to discuss recent work such as chlorination of drinking water obtained from rivers, while yet dealing with the general considerations affecting rainfall and the movements of terrestrial waters in an orthodox but attractive manner.

The question of the matter to be included in or excluded from such a treatise must always be difficult, and the points mentioned above do not detract seriously from its value for any but the specialist reader. Such spelling errors as occur are probably due to difficulties of proof reading as between an author resident in India and his publisher in London ; the style and method of publication are excellent.

(2) M. Raguin covers an even wider field, his first four chapters dealing with the evolution of the surface features of the earth, the mode of formation of solid rocks, the sequence of geological events and the nature of tectonic movements, while the succeeding nine chapters embrace such diverse matters as a brief outline of stratigraphical geology, materials of construction, the building of tunnels and barrages, the movement of underground waters, the combustible minerals such as coal and oil, the study of mineral veins and geophysical methods applied to prospecting.

Here again a readable style is combined with a series of very clear and evidently carefully prepared diagrams, the chapter on stratigraphical geology being interleaved with a series of photographs of common fossils characteristic of the various geological systems. One would perhaps have preferred to have seen a curtailment of this latter treatment, together with an expansion of the portions dealing with mineralogy and petrology, as likely to be of greater use to the majority of readers. The geological bias of the book is more apparent than in that by Dr. Fox, while the space accorded to such matters as overthrusting, klippen-structures and nappes, with all their complications, is only to be expected, having regard to the natural interest of French geologists in Alpine tectonics.

It is stated in the preface that the work is not intended for the specialist, but in spite of this proviso, it should prove of interest to many specialists requiring information on branches of the subject which are cognate to their own.

(3) As a purely introductory type of book, that by Prof. Shand is a most helpful work. It is many years since the elements of geological science have been set out in a manner so calculated to catch and to hold the interest of the non-technical reader. It is well known that one of the chief difficulties in this connexion is the avoidance of the use of scientific terms which are unfamiliar to the beginner, and Prof. Shand has succeeded admirably in his difficult task in this little volume. It is certain that geologists in Great Britain, often notoriously backward in attempting to popularise or to apply their science to the needs of the common man, will find it extremely difficult to cover so many really useful aspects of geology in so lucid a manner.

Emphasis is laid rightly on the importance of field and laboratory studies, and it would be an invidious task to point out minor omissions in a work covering so wide a field. It is to be hoped that the popular view of geology as a dry-as-dust subject will be still further dispelled by the appearance and wide use of still more books of the kinds noted above. B. H. KNIGHT.

Practical Quantum Mechanics

Introduction to Quantum Mechanics: with Applications to Chemistry
By Prof. Linus Pauling and Dr. E. Bright Wilson, Jr. Pp. xiii+468. (New York and London: McGraw-Hill Book Co., Inc., 1935.) 30*s*. net.

QUITE a number of books have been written on quantum mechanics with applications to problems of physics. Now, however, we have something new, a book on quantum mechanics with applications to chemistry. It is a field which for some time has needed ploughing; and the names of the authors guarantee that the job has been well done.

The logical development of the book is extremely good. After the usual introduction and decline and fall of the old quantum theory, it proceeds to show how the Schrödinger equation can be set up for a system of interacting particles. The rigorous solutions for the harmonic oscillator, the hydrogen atom, and the particle in the box are then worked out in considerable detail. By this time the reader is well prepared for solutions by approximations; and perturbation theory and variation methods follow quite naturally. So far, only one-electron systems have been discussed, and as an introduction to many-electron systems a whole chapter is devoted to the helium atom, mainly with the view of accustoming the reader to spin, Pauli principle and all the other jargon of atomic and molecular structure. The discussion of atoms is rounded off with a difficult chapter on Slater's theory of complex spectra and Hartree's method of the self-consistent field.

About half the book has now been covered. The remainder deals chiefly with molecules, beginning with the rotations and vibrations of diatomic and polyatomic molecules, together with a short account of the selection rules. Then comes a section on calculations of the energy of formation of molecules. Simplest is the hydrogen molecular ion, and next the hydrogen molecule. This section ends with a brief description of Slater's treatment of polyatomic molecules and a few pages on 'resonance'.

At this point the authors, seeing that they are far from home in spite of nearly 400 pages, decide that the pace must be quickened. They select four applications of quantum mechanics to miscellaneous problems and write a few cogent pages on each, bundling them together to make the penultimate chapter. The last chapter is on the same plan, but takes as its subject matter some of the more important methods and principles of general theory. There is an appendix which includes many useful facts, such as physical constants and normalising factors, and this concludes with a fitting tribute to the Greeks in the form of the Greek alphabet!

The book is primarily an introduction to quantum mechanics, and as such necessarily contains a fair amount of material already available elsewhere. For example, the theory of the harmonic oscillator and of the hydrogen atom have already been given in many other places. Perhaps for this very reason they are now dealt with at unusual length. Numerous diagrams are given of the wave functions, and with their help the reader should readily grasp the significance of what might otherwise have remained merely a mathematical formula.

The book is highly recommended as a textbook of practical quantum mechanics. It is well balanced and very readable; the diagrams are workmanlike and the index good. Each chapter includes about half a dozen problems, and many suggestions are made for further reading. Unfortunately the book, like many others from the United States, is rather expensive. W. G. P.

Physics for College Students:
an Introduction to the Study of the Physical Sciences. By Prof. A. A. Knowlton. Second edition. Pp. xxi+623. (New York and London: McGraw-Hill Book Co., Inc., 1935.) 21*s*. net.

THE author is to be congratulated on the production of an original and stimulating work which amply justifies the study of physics as a cultural subject. The treatment is based on the doctrine of energy, and, while it is quite elementary, making very little appeal to mathematics, it is closely reasoned, alive and in touch with reality, and calculated to keep the reader's mind constantly on the stretch. The fifty-seven chapters into which the book is divided cover very thoroughly the whole field of elementary physics, and at every step of his progress the reader may test his knowledge by means of well-selected quantitative examples and ingeniously devised topics for discussion.

A notable addition to the elementary literature of the subject. A. F.

Aufbau der zusammenhängenden Materie

Redigiert von A. Smekal. Pp. xiv+1203. ("Handbuch der Physik". Herausgegeben von H. Geiger und Karl Scheel. Zweite Auflage. Bd. 24, Teil 2.) (Berlin: Julius Springer, 1933.) 129 gold marks.

ONE hundred and twenty-nine gold marks may seem a very stiff price to pay for a scientific book even when advantage may be taken of the new facilities for purchasing German books at 25 per cent discount, but the present volume is exceptional in many ways. It contains some 1200 pages of excellently printed matter, and the subjects treated are such that it could not well have been inexpensively produced. It is well supplied with tables and diagrams, and little or no attempt has been made to save expense by undue curtailment of the mathematical treatment. One may legitimately look at the six chapters and ask oneself, in considering the cost, how much one would expect to pay for the excellent 300 page treatise on the electron theory of metals by Sommerfeld and Bethe, if it were issued in separate covers; or, again, what would be the market price of a book of 200 pages on atomic structure and chemistry, by Grimm and Wolff.

The plan followed is very satisfactory. Herzfeld writes on the size and structure of molecules, considers their electric properties, their band spectra and the forces between them in the various states of aggregation. Perhaps one may say that English readers will be surprised that he does not devote more space to viscosity formulæ in his comprehensive survey. Kronig deals with the relations between molecular attractions and the structure of crystals, and includes a neat account of the significance of the fine structure observed in the edges of X-ray absorption bands. Then follows the compact treatment of the electron theory of metals given by Sommerfeld and Bethe; it is doubtful whether some of the properties of metals here discussed have previously been described in so clear and concise a manner. The problems of the crystal lattice are examined by Born and Göppert-Mayer, Smekal deals with the factors which influence the properties of crystals, and the article by Grimm and Wolff completes the book.

It is an important contribution to the literature of modern physics and chemistry, and a work which will frequently be consulted by most research workers interested in modern theory. From this point of view it is a pity that the book is not issued in two or more separate parts. L. F. B.

Leçons d'algèbre et de géométrie à l'usage des étudiants des Facultés des Sciences

Par Prof. René Garnier. D'Après la rédaction de Badrig Guèndjian. Tome 1: Algèbre linéaire, homographie, équations tangentielles. Pp. viii+233. (Cours de la Faculté des Sciences de Paris.) (Paris: Gauthier-Villars, 1935.) 40 francs.

THIS book has been specially written by Prof. Garnier for mathematical students taking a course in the faculty of science at Paris. It is essentially a theoretical treatise embracing four chapters on linear algebra; two on the classic theorems of both plane and solid projective geometry and one on tangential equations. The treatment is wholly analytical and, as the author points out in the preface, the most general methods have been applied in establishing the fundamental propositions. Centres and diameters of conics, for example, are derived as special cases of poles and polars.

The text has been very clearly written, and it is difficult to discriminate between the excellence of the various chapters. Special mention, however, should be made of the brilliant analytical discussions on enharmonic ratios and envelopes. These, in spite of their generality, should not fail to stimulate a keen interest in the reader. If the book has a defect at all, it is that common to most French textbooks, for there are no exercises provided for the student's practice.

Toxikologische Mikroanalyse:

Qualitative Mikrochemie der Gifte u.a. gerichtlich-chemisch wichtiger Stoffe. Von Prof. Dr. L. Rosenthaler. Pp. viii+368. (Berlin: Gebrüder Borntraeger, 1935.) 25.50 gold marks.

THIS work may be regarded to a large extent as complementary to Dr. Rosenthaler's "Der Nachweis organischer Verbindungen" (Stuttgart, 1923), in which he treats of macro-analytical methods in organic chemistry. In the new volume he gives a comprehensive and reliable account of the many micro-methods which are now available for the detection of poisons, whether in traces or otherwise. As he points out, forensic chemistry offers a particularly favourable field for the application of micro-analytical methods.

The book gives a short general account (19 pp.) of micro-methods for sublimation, distillation, electro-analysis, spectro-analysis, crystallisation, etc., followed by descriptions of diagnostic tests for specific inorganic (76 pp.) and organic (259 pp.) substances.

The book is well printed, and there are numerous illustrations, chiefly of crystalline derivatives prepared in the various tests; it should prove of use to practical workers in forensic medicine and analytical chemistry in general. J. R.

Value and Existence

By Prof. N. O. Lossky and Prof. John S. Marshall, Pp. 223. (London: George Allen and Unwin, Ltd., 1935.) 7*s*. 6*d*. net.

AT a time when materialism appears to be at a discount, it is natural that discussions on the problem of values become more and more pressing. To such discussions, Prof. Lossky contributes an excellent monograph in which the notions of value and existence are interpreted in terms of a Neo-Platonism tempered by Christian ideals. Where true absolute concrete consubstantiality lies and how it is related to this world, are the two aspects of the problem dealt with in part 1 of the book. In the second part, which is contributed by Prof. Marshall, we find an explanation of some basic conceptions of Prof. Lossky's views. T. G.

The Phenomena of Spin in Detonation

CAMPBELL and Woodhead[1] discovered that in certain gaseous mixtures, when a detonating type of combustion flashed along a cylindrical tube, the flame front was not simply a disc-like or convex surface, but the detonation spun spiralwise along the tube, giving rise to a banded appearance in the photographs of the luminous products of combustion. Bone and Fraser[2] made a careful photographic investigation of the phenomenon, which showed that the initiation of detonation was almost

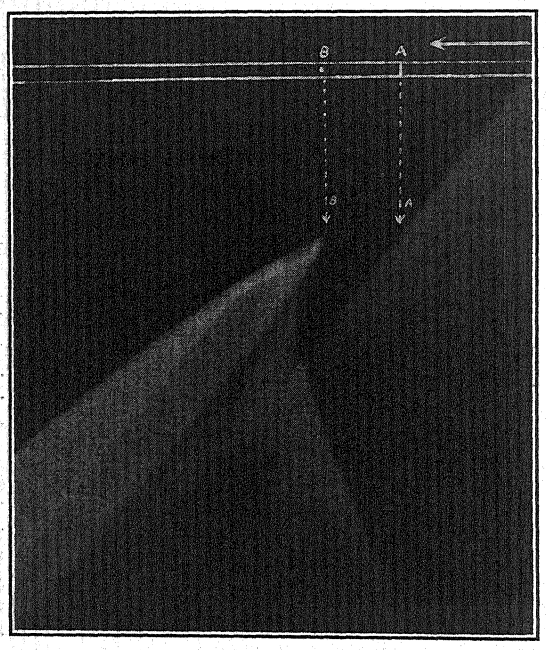

FIG. 1.

invariably associated with the spin of the 'head' of detonation but that in hydrogen mixtures it rapidly disappeared, whereas in certain mixtures it was visible in the ordinary flame before the detonating condition had been reached. They came to the conclusion that the frequency of the spin was fairly independent of the composition of the mixture, of its density and of the speed with which the detonation passed down the tube, but that it depended on the tube diameter such that the pitch of the rotation of the 'head' was about three times the tube diameter. Those results were obtained using a 9 in. duralumin drum rotating at 16,000 r.p.m. (equivalent to a film speed of 190 m./sec.). The extension of that investigation[3], which will be briefly described in this article, has been rendered possible by the use of a special camera whereby photographs could be taken at speeds which would be equivalent to using a film rotating on a drum at 1,000 metres a second, thus enabling events to be recorded which happen during a millionth of a second.

The apparatus consists essentially of a double-sided stainless steel mirror which is rotated at high speed, and flashes the image of the explosion formed by a suitable lens (Dallmeyer Pentac 12 in. focus) on to the surface of a circularly disposed stationary photographic film. In order to rotate the mirror at the high speed (30,000 r.p.m.), which is equivalent to a speed of rotation of the image of 1,000 per sec., the mounting has to be such that a vacuum can be maintained within the camera. The drive is by means of a 4 h.p. motor which can be maintained at any constant speed up to 6,000 r.p.m. by an auxiliary dynamo, the voltage output of which is controlled by altering the resistance in the shunt-field circuit; this, together with the friction drive off a spherical steel surface which is rotated by the motor, enables the most suitable speed to be chosen so as to provide the most accurate measurement of the flame. The explosive mixture is usually fired by a spark and travels down a 7 metre length of copper tube and then through a special tap into a glass tube 1·3 cm. diameter and $1\frac{1}{2}$ metres long which is placed in the field of view of the camera lens. Most of the experiments were made with $2CO + O_2$ mixtures.

It is only possible here to mention a few of the results of the investigation; the photographs provide detail of the phenomena of detonation never before attained. It has often been noticed[4], when the detonating type of combustion is initiated, that where this initiation occurs is somewhat ahead of the advancing flame front. The present investigation shows quite definitely that this is generally the case. The composite character of the setting up of the detonation is clearly shown in Fig. 1. The flame travels forward at 1,275 m./sec.; it so influences the combustible molecules in a compression wave ahead that ignition suddenly occurs at B, 6·3 cm. from the flame, which has reached position A, and from the position B a detonation wave travels forward at 3,260 m./sec. The velocity of this wave soon subsides, however, to 1,980 m./sec. A wave also starts in the backward direction from the seat of detonation through the gases with a resultant forward velocity of 350 m./sec., and gives rise on meeting the advancing flame to the 'retonation' wave travelling back through the products at 875 m./sec. Not only

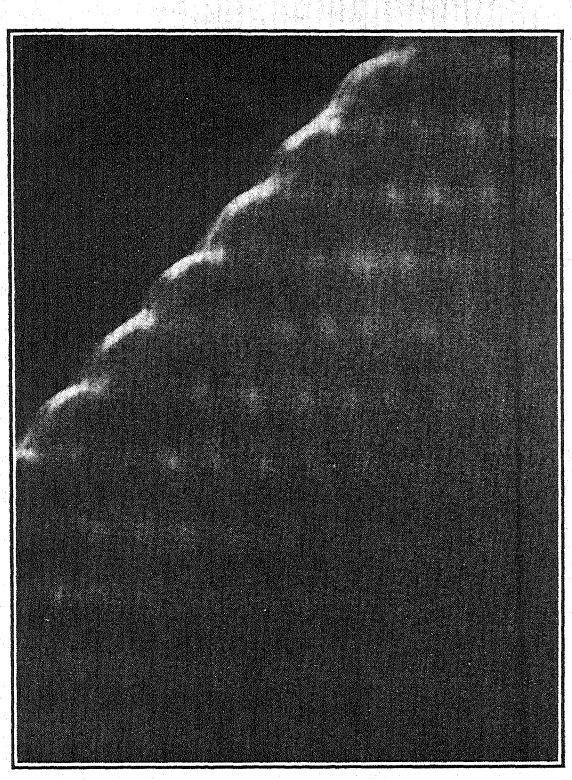

FIG. 2.

is a compression wave visible which travels out from the point of auto-ignition at 1,320 m./sec., but also, at the point where the initial rapid detonation in the forward direction subsides to the more normal velocity, a compression wave is visible which moves forward, also at 1,320 m./sec. The spin first makes its appearance at this point. The whole interval from the point when auto-ignition occurs to the point when the velocity subsides to 1,980 m./sec. is only about a ten thousandth of a second.

The spin is due to the spiral motion of the head of detonation down the tube, and the pitch appears to be governed mainly by the diameter of the tube, as was shown by causing a detonation to proceed down a tapered tube. It is possible to observe the phenomenon of spin and to maintain detonation in $2CO + O_2$ mixtures in tubes so small as 3·6 mm. diameter. In tubes of triangular or square section the pitch of the spin is nearly that which would occur in a tube of circular section of equal periphery; in a tube of oblong section the track is that in a tube of circular section the periphery of which corresponds to the shorter sides of the oblong.

The banded appearance of the after-flame which was obtained in former investigations is now shown by the higher resolution to be due to the criss-crossing of a set of waves or regions of high luminosity starting out from the spinning head twice during each rotation and proceeding at an angle of 22° to each other, one in the forward direction and the other slightly retrogressive (see Fig. 2).

The authors state that "whether or not a persistent spin develops in a detonation seems to depend on the requisite degree of excitation of the combustible gas. In cases (such as when hydrogen is involved) where this is easily attained, the initial close association between the forward moving compression wave and the burning medium in the front does not become attenuated and no persistent spin can be developed. On the other hand, a persistent spin develops whenever the requisite degree of excitation of the molecules of the combustible gas is such as to render the association between the forward moving front precarious so that an attenuated (cone-shaped) front develops". They also state that "it follows geometrically that at each half-rotation of the head a pocket of the unburnt gas will be enclosed on

FIG. 3.

three sides by the flame and thereby spontaneously ignited by its radiation", giving rise to the effects observed which accompany the spin.

The view that activated combustion must be associated with the compression wave in order to maintain detonation is supported by experiments in which a small ¼-in. nitrogen gap (obtained by means of the special tap) in the column of explosive gas causes the detonation and spin to be destroyed and only reinitiated when the flame front again catches up the compression wave. It is interesting to learn that, contrary to Dixon's results, the velocity and stability of the detonation wave is enhanced rather than diminished by intensively drying the carbon monoxide mixtures. Addition of hydrogen appears to give rise to a multiplicity of spinning heads, and more than 2 per cent of hydrogen tends to prevent the spin, though detonation is maintained.

The remainder of the present memoir relates to experiments on the effect of magnetic and electric fields on the propagation of detonation. Very strong magnetic fields were obtained by magnets of special design. A transverse field of 35,000 gauss had no appreciable effect on the detonation owing to the short time (0·005 sec.) the flame is within the field, but longitudinal fields of 22,000 gauss over a length of 58 cm., or of 35,000 gauss over 8 cm., caused an appreciable slowing down of the rate of travel of the detonation by about 50 m./sec. The effects of the magnetic field were not large. Strong electric fields (up to 5,000 volts per cm.), on the other hand, had a very marked effect, particularly when the flame travelled in the direction negative to positive potential; for example, when the detonation passed the negative electrode, both spin and detonation were suppressed, the flame speed decreasing to about 1,000 m./sec. by the time the positive electrode was reached and continuing to fall as it proceeded into the no-field region (see Fig. 3). For passage in the direction positive to negative there was a slight acceleration of the flame.

It is supposed that the positive CO^+ ions are important for the maintenance of activation in the detonation head, and that if these are drawn out of the flame front, the activation is not maintained and so the spin and eventually the detonation are destroyed by separating the region of activation from that of the region of high compression. This is borne out by the fact that in dry carbon monoxide mixtures or when hydrogen (0·3 per cent) is present, the 'damping' influence of the field on the detonation is counteracted. In methane mixtures, too, the spin and velocity were not influenced by the field.

There can be no doubt that these experiments form a highly interesting addition to information about the behaviour of the detonating type of explosive in gaseous mixtures. A. C. E.

A Century of Botany*

1835—1885—1935

By Prof. F. O. Bower, F.R.S.

UP to 1885, the whole field of botany was supposed to be covered by the professor himself. The elementary teaching might embrace the spirit of all its branches: but the science as a whole was then like a bomb with its pin drawn out, ready to burst into divergent lines for which neither personnel nor accommodation were prepared. Stimulating the time surely was, but exacting to the point of impossibility. The best course for the new professor in Glasgow was then to select some branch as his own special study, and by preference one cognate with local history. Personal experience gained elsewhere pointed to the mosses and ferns, a line of specialisation which would renew continuity with the Hookerian tradition. Moreover, the overcast skies of Glasgow gave conditions suitable for their culture. So after an interval of half a century, the special line of research followed there by Sir William Hooker was resumed.

With the new ordinances framed under the Act of 1889 came changes of organisation, which had the effect of levelling up the Scottish university system to that of England. The establishment of degrees in science stimulated higher courses in all the departments, and this led, of necessity, to their expansion both in staff and in equipment. Under the new ordinances, the differentiation of elementary and advanced classes involved an

* *Continued from p.* 941.

increased staff. The appointment of additional lecturers and assistants stimulated research, for which space was now available.

A group of botanical investigators was thus formed, who not only pursued the special study of the living Archegoniatæ, but also extended their comparisons to the cognate fossils. The co-operation of Lang and Gwynne-Vaughan with myself established that 'triumvirate', who worked happily and fruitfully together for twelve years. In close relation with us that remarkable palæophytologist, the late Dr. Robert Kidston, a prince of amateurs, was also associated. With his aid new problems of comparison between past and present vegetation were opened. As results it may suffice to quote the series of memoirs by Kidston and Gwynne-Vaughan on the fossil Osmundaceæ, and those by Kidston and Lang on the fossils of the Rhynie Chert, carried out after Dr. Lang had moved to Manchester. These show the value of the co-operation between Dr. Kidston's house at Stirling and the Glasgow Department. Happily, under his will all the type specimens of these classic works, together with others of untold value, are now in safe keeping in the Department. Thus Glasgow became once more a centre for study of the Archegoniatæ. A ready channel of publication was offered by the Royal Society of Edinburgh. Its resources, with financial aid from the Carnegie Trust, have made a stream of published work available from the Glasgow Department which, in scientific value and beauty of production, will bear comparison with any produced elsewhere.

Passing now to the present time, we may ask how botanical organisation in 1935 strikes one who can compare it by personal contact with that of the previous century. As we have seen, up to 1885 each aspirant to a chair in botany was assumed to possess a general knowledge of and sympathy with all branches of his subject. These were themselves less differentiated than now, and some scarcely distinguishable unless as parts of a compact whole. Segregation followed quickly on the revival of the 'seventies and 'eighties. I well remember Sir Joseph Hooker saying ruefully to me in the early 'eighties, "You young men do not know your plants". That was at the time when systematic botany was beginning to lose its hold as the main staple in Britain. His judgment was true: we did not know them in the Hookerian sense.

A counterpart to Hooker's plaint may be found in the ironic hyperbole of a distinguished physiologist, who is reported to have said at a later date, "I suppose I do know half a dozen species of the British flora". These illustrations suggest the inevitable effect of that fission of a science which is apt to follow upon its detailed study. Hence as the years went on the position of the head of a botanical department, so often single-handed, became increasingly difficult. If he attempted to keep abreast of all branches he would become, like a medieval knight, overweighted by his armour of facts and theories, and ever less able to keep his place in the front line of research. Extinction as an effective unit would loom large.

From 1885 onwards there has been an increasing desire among young investigators to publish their results early. This offers promotion as its reward: for a published output of detailed research commonly weighs more with a selection committee than general knowledge, or the ability to administer and to teach. A premium is thus placed upon early specialisation, and the young aspirant is in danger of developing "like an ill-roasted egg, all on one side". Some great departments already have special sub-departments of pomology, of citrus fruits, or of bananas, to which specialists severally devote their lives. Among these various cults we may well ask, where do the major departments of morphology, physiology and classification come in? Doubtless each of the minor branches is in touch more or less directly with one or more of these foundations of the organised whole. But each may be pursued without any realisation of what that whole actually is.

A necessary corrective will be an avoidance of too early specialisation, and the cultivation of the type of mind that strikes a fair balance between the fundamental branches. This is indispensable above all for the administrative head, who is responsible for maintaining a balance between the various branches in the organisation of his department. There is no difficulty in finding among young graduates those able to carry out special inquiries of detail. What will be required more and more urgently as time goes on is the synthetic mind, that ranges over a wide field with adequate command of detail, and is able to compare, evaluate and deduce. This is essential for the all-round botanist, that less common type from which comes the successful head of a department. Risks of development await both types. The former may continue his analysis and never advance beyond providing recorded details for others to use. He may, however, develop powers of synthesis as he proceeds, and through successive steps of increasing constructive power attain some more responsible position. The risks of the naturally synthetic mind are different. If the young investigator is dexterous in presentment of his results, he may soon find himself advanced to a position of command. Then comes for him a testing time, when a decision must be taken whether administration or research shall dominate. The nature of his office will probably give

opportunity for both, and the precedence of one or other will be largely a matter of his own choice. At first the question rarely presents itself in an acute form. The cumulative effect of years often decides whether their victim shall quite unconsciously become part of an organising machine: or whether he shall continue to be a direct influence in creative science. Happy is the man who can do both.

It is not difficult to cite examples that illustrate these divergent results. In the lives of some of our greatest men the strangle-hold of administration has tended to choke the active spirit of personal observation. Among those who have passed away we may contrast the lives of Huxley and his friend Darwin. I well remember at South Kensington the glass jars holding material of the pearly nautilus which awaited the dissection that never found its place among Huxley's crowded hours of departmental committees and meetings of the Royal Society Council. On the other hand, Darwin, cloistered at Down, was free at a like age to continue his work on orchids and earthworms. Michael Foster and Thiselton-Dyer, who shared with Huxley the burden of the reorganisation of practical biology in the 'seventies, left little behind them as their published record beyond textbooks and official documents. Administration atrophied personal research in both of them. Even Bayley Balfour, who had shown his mettle as an investigator before he was thirty years old, spent his best period in ministering to the scientific wants of others: and only returned in his last years to the detailed systematic work in which he was a master. It is not for us to judge in such instances whether or not the results of administration have justified the sacrifice of personal opportunity for creative work. We are all debtors to these great men. But they are here cited as examples of a prevalent danger that grows more insistent as years advance. Administrative activity and continued personal research are conflicting factors in the individual life. The former has often become dominant even where the instinct of inquiry is strong.

Returning, in conclusion, to the intra-departmental aspect of this question, the most vital relation is between the professor and his students. How will his decision as to the balance between administration and research affect them? It may be urged, in support of giving priority to the former, that the smooth working of a well-organised department amply justifies the time and thought that it demands. The larger the department, the more pressing the demand will be: the students feel the result of good organisation, though few of them would analyse it back to the source. On the other hand, the effect of a prevailing atmosphere of research in a department is tonic and stimulating. It was the very essence of the Huxleyan revival that it converted every student into a potential investigator. The stimulus should emanate from the head of the department, passing either direct from him, or through lecturers and demonstrators to the individual student. But the method loses its point if the professor himself is in practice a mere administrator. Such chains of influence are felt rather than visualised; often the stimulus is almost unconsciously conveyed. An allusion in a lecture to experiences in the field, or an observation on material collected abroad, gathers up the attention of a class and makes it think more effectively than floods of fact at second hand.

A still more direct influence follows if a student penetrates with a question to the private room, and the professor rises from his microscope to reply; perhaps he may even allude to some observation that is interesting him at the moment. The student at once feels that he is in touch with the margins of knowledge. The opportunity for such touches is lost if the private room is a mere 'office'. I have found it sometimes known by that paralysing name. The undifferentiated private room, part laboratory part administrative centre, has qualities worth retaining not only for economy of space and time, but also in affording occasional completion of contact between the potential researcher and the professor actually at work.

Thus dangers lurk within the growing elaboration of a scientific department. Not the least of these will be to secure a due balance between administration and research in the person of its official head. Again I say, happy is the man who can hold the balance until strength itself fails. Among the distinguished graduates of Glasgow we possess two notable examples. Sir Joseph Hooker's youth was spent in acquiring experience and material; his middle age in working it up, in the intervals of administration as director of the Royal Gardens at Kew; in his old age he brought to completion systematic works of the greatest magnitude and value; but in the very last years of his long life we saw him still engaged in describing species new to science. On the other hand, Lord Kelvin continued the administration of his Department of Natural Philosophy for more than half a century; concurrently he carried on his own researches, and applied their results practically to the requirements of modern life. Until the day of his death he remained Chancellor of the University of Glasgow, and held the honourable title of a Research Student under Ordinance. Neither of these great men ever relaxed his hold upon personal observation. There is no stronger link than this between a professor and the real student.

Obituary

Prof. J. D. Cormack, C.B.E., C.M.G.

JOHN DEWAR CORMACK was born in 1870, a son of Alexander Cormack, rector of Dumbarton Academy. His career as an undergraduate at the University of Glasgow was a distinguished one, and those of his fellow students who are left still remember the successes and the prizes he gained at his class examinations.

In 1892, Cormack proceeded to Yorkshire College, Leeds, where he was appointed as lecturer in engineering subjects, specialising chiefly in electrical work. In 1896 he returned to Glasgow as assistant to the late Prof. Barr, and for some years acted as lecturer in electrical engineering. In 1901 he was appointed to the chair of mechanical engineering at University College, London, where he remained for twelve years. He took a prominent part in the affairs of the University of London and did conspicuous service on the engineering examining boards for both internal and external students.

In 1903, Cormack succeeded the late Prof. Barr as regius professor of civil engineering and mechanics at the University of Glasgow. He was welcomed back to his old college with enthusiasm, for his reputation as an exceptionally fine lecturer and teacher, as well as his prowess as a Rugby player and a golfer were well remembered. His appointment coincided with the affiliation to the University of the Royal Technical College, when much anxiety was felt over the possible troubles that might arise in the changes that would inevitably take place in the teaching and examination systems of both institutions. That the affiliation has been a great success was in a great measure due to the enthusiasm with which Prof. Cormack entered into the closer association of the two great engineering schools.

With the outbreak of war in 1914, Prof. Cormack gave up for the time his university work and placed his engineering knowledge at the disposal of the nation. His labours were largely in the aeronautical branch of war service. He occupied in succession the positions of chief contracts officer of military aeronautics, director of aircraft supply and equipment, and assistant controller of the aeronautical departments. From 1917 until 1919, he was in the United States as a member of the British Mission. In addition to the honours indicated by C.B.E., and C.M.G., he had the decoration of Chevalier of the Legion of Honour conferred upon him by the French Government; he was also an honorary brigadier general and honorary group captain R.A.F.

In 1932, Prof. Cormack was elected as president of the Institution of Engineers and Shipbuilders in Scotland, thus following in the footsteps of his famous predecessors in the engineering chair—Rankine, James Thomson, and Barr. His election indicated the esteem in which he was held by the Clydeside engineers and shipbuilders, and his term of office, which had only expired a few months before his death, will be long remembered for the quiet and efficient manner in which the business of both council and general meetings was conducted.

Prof. Cormack's death was sudden and unexpected. During the summer months he had been receiving medical attention, but he had taken up his university duties at the beginning of the session and was lecturing until a day or two before his death. A chill rapidly developed into pneumonia, and he died on Saturday, November 30.

As a professor of engineering Prof. Cormack was more attracted by teaching and administrative work than by experimental research. His students will long remember him for his lucid, well-delivered lectures as well as for the kindly interest he took in both their studies and college activities, and the efforts he made to start them in their engineering careers.

Dr. William MacDonald

THE death of Dr. W. MacDonald at the age of sixty years removes an enthusiast for South Africa and a firm believer in her future as the seat of a white civilisation. A Scotsman by birth and education, he spent some time studying in the United States and in France before settling in South Africa. There he realised that the prosperity produced by the recently discovered gold mines could only be stabilised by a concomitant development of agriculture, and he became the leading protagonist of his time for the dry-farming system. His two books—"Dry Farming" and "The Conquest of the Desert"—focused attention on what was, and probably always will be, one of the greatest obstacles to intensive agriculture in South Africa, and although modern policy is directed, perhaps wisely, towards encouraging extensive animal husbandry rather than the more intensive dry farming advocated by Dr. MacDonald, the influence of his work can be traced in the way that policy has developed. The growth of the citrus industry owes not a little to his encouragement in its early days. He had some of the enthusiasm of Cecil Rhodes for colonisation, and became director of the South African Land Settlement Bureau which did much to promote immigration before the Great War. He was proprietor, editor and a frequent contributor to the *Agricultural Journal of South Africa*, and was the prime mover in the institution of a faculty of agriculture at the University of Pretoria.

While MacDonald's life's work was in agriculture, he also took a deep interest in the mining industry, realising that this must be the real foundation on which a South African civilisation would be built. He is best known in England for his book "The Romance of the Rand" (1933), in which he gives a vivid account of the discovery of gold by his friend, Mr. F. Struben, and the early struggles of the pioneers.

News and Views

President Masaryk

It was announced in Prague on December 14 that Prof. T. G. Masaryk, who has been president of the Czechoslovakian Republic since its foundation in 1918, has tendered his resignation. Prof. Masaryk was sixty-eight years of age when he returned to Prague at the end of the Great War and now, at the advanced age of eighty-five years, after guiding the destinies of the nation for seventeen years, he has expressed a wish to retire. Some time back he was taken ill with eye trouble and rheumatism, but he made a remarkable recovery and resumed duties and especially his reading of current scientific literature. During the Great War, Masaryk held a professorship at King's College, London, but his educational work receded as his powers as a statesman came to be recognised and utilised. His own efforts to secure the independence of Czechoslovakia were realised on October 28, 1918. Masaryk's long career has been a continual series of struggles in the interest of truth, both in science and in affairs. He began life as an apprentice to a locksmith but, through the efforts of his schoolmaster, continued his education at Brno Grammar School and the University of Vienna where, in 1878, he was awarded the Ph.D. degree.

Masaryk's first philosophical work was "Suicide as a Social Phenomenon of the Present Day" (1881) and it secured for him a Vienna lectureship. In the following year he obtained a professorship at Prague, where at first the 'lonely Slovak' did not make many friends, and his scepticism (justified as investigation proved) of the genuineness of some old Czech manuscripts brought him much abuse. From his philosophical studies he was led to the formation of a 'Realist' movement. "Realism," he declared, "is an attempt to popularise the whole realm of science and philosophy. Without distorting scientific exactitude, realism strives to render science accessible to every class of the people. It is a protest against the monopoly of learning, its endeavour is to socialise scientific and philosophical culture." He married a distinguished American, Miss Charlotte Garrigue, in 1878, incorporating her name with his own. She entered ardently into all Masaryk's work until her death in 1923. They paid several visits together to England, America and Russia, and his wife undoubtedly helped him in the compilation of his philosophical works, especially when he was editor of the scientific section of the Prague daily, *Národní Listy*. Just before the Great War he wrote "Russia and Europe", one of the most important books on the subject, showing as it did the true state of the great Slav country and the directions in which affairs were drifting. His post-War books include "The Making of a State" (1927) and "Les Problèmes de la Democratie" (1924). He was also instrumental in the establishment of the Masaryk Academy of Work, which is concerned with the fostering of research, especially in such branches of applied science as chemical technology. Many valuable original memoirs have been published through the help of this Academy.

Tercentenary of Champlain

On December 25 the tercentenary occurs of the death of Samuel de Champlain, the French explorer who founded Quebec, and was the first governor of Canada. Born in 1567 at the village of Brouage in the ancient province of Saintonge, now the Department of Charente-Inférieure, he served in the wars of the League under Henry IV, but after a voyage to the West Indies, he was placed in charge of an expedition to continue the work of Jacques Cartier, the discoverer of the St. Lawrence. On May 24, 1603, Champlain anchored in that river, and for the next four years was engaged on exploring the Bay of Fundy and other parts. A visit to France was followed by another expedition, and in July 1608 he founded the settlement which he named Quebec. Thence he made a journey up the Richelieu, and discovered and explored the lake which bears his name. Other explorations took him to the western shores of Lake Huron and to Ottawa. Again in France in 1620, he returned with his family and with a commission as governor of the new settlement. About seven years later, owing to the outbreak of war between France and England, his supplies were cut off, and Quebec had to be surrendered. After the declaration of peace, however, in 1633, he was again able to return, and it was in Quebec that he died. He wrote accounts of his voyages, and these were republished in Quebec in 1870.

British Association: Officers for 1936

The annual meeting of the British Association will be held next year in Blackpool on September 9–16 under the presidency of Sir Josiah Stamp. The following sectional presidents have been appointed: Section A (Mathematical and Physical Sciences), Prof. A. Ferguson; B (Chemistry), Prof. J. C. Philip; C (Geology), Prof. H. L. Hawkins; D (Zoology), Dr. Julian Huxley; E (Geography), Brig. H. S. L. Winterbotham; F (Economic Science and Statistics), Dr. C. R. Fay; G (Engineering), Prof. W. Cramp; H (Anthropology), Miss D. A. E. Garrod; I (Physiology), Prof. R. J. S. McDowall; J (Psychology), Mr. A. W. Wolters; K (Botany), Mr. J. Ramsbottom; L (Educational Science), Sir Richard Livingstone; M (Agriculture), Prof. J. Hendrick. The president of the Conference of Delegates of Corresponding Societies will be Dr. A. B. Rendle.

Prehistoric Research in South Africa

IN another column of this issue of NATURE (see p. 998) we publish an announcement of action taken by the Government of the Union of South Africa which will play a part of great importance not only in the advancement of the study of the prehistory of the sub-continent, but also ultimately, it may be asserted with confidence, in the elucidation of the whole problem of the distribution and development in culture of early man. The joint geological and archæological survey of certain sections of the Vaal and Riet River valleys, for which arrangements are being made by the Directors of the Geological Survey and the Bureau of Archæology of the Union, will cover an area which in the view of local archæologists, and indeed, as has been shown notably and convincingly by the exploratory work of Prof. C. van Riet Lowe, is of cardinal importance in the correlation of geological and archæological data in South Africa and the determination of their relation to evidence of climatic variation. As the survey will occupy fully the services of two geologists and an archæologist for at least eight months, the undertaking will be costly; but the expenditure is justified, even in present financial conditions, by the fact that this key area will be inundated when the dams now in course of erection across these rivers have been completed.

THE study of the prehistory of South Africa has made great strides in an incredibly short time, thanks to the enthusiasm of local archæologists and the insight with which they have applied and adapted to local conditions the lessons of European archæology. When, however, the survey now initiated has been completed and its results, whatever they may be, have been made available for correlation with those of analogous studies in other parts of the world, where the records of pluviation and glaciation are being interpreted and brought into relation, the study of prehistory at large will be deeply indebted to the Government of the Union of South Africa for its public-spirited promotion of this investigation while opportunity still served, and to the South African Association for the Advancement of Science for its services to research in urging upon the Government the desirability of an undertaking which not only will promote understanding of the conditions of a problem of the first importance in human history, but also holds out every promise of being of crucial influence in the future of prehistoric studies.

Sign Language as a Form of Speech

IN his Friday evening discourse at the Royal Institution on December 13, Sir Richard Paget discussed "Sign Language as a Form of Speech". The clue to the relationship between bodily gestures and the gestures of the mouth which produce speech was given by Darwin in 1872—namely, in the sympathy of movement between man's hands and his mouth. Charles Dickens, thirty years earlier, in "Pickwick Papers", had noticed the same effect. The deaf mute sign language is natural and universal among deaf mutes of all countries. The Red Indians of North America had a similar language of signs by which they could all communicate. In 1929, William Tomkins published his "Universal Indian Sign Language", which described 700–800 signs. The sign language of the aborigines of North-West-Central Queensland was described by Walter E. Roth in 1897. Garrick Mallery, writing in 1881 on the Indian sign language, described also the sign language of the Neapolitans. He concludes that all these languages are only dialects of a single language—the gesture speech of mankind. Recently, the Russian Academy of Sciences has discovered a sign language, used by women only, in Russian Armenia—also a pictographic script, twelfth to seventeenth centuries, which in many instances illustrates the sign language. Mr. Ivan Sanderson has recently discovered a sign language in the Cameroons; but hitherto gesture languages have been largely ignored. Many people think any alteration of spoken language is sacrilege; actually, all spoken languages are still primitive and unsystematic. Sign language is capable of great development as a universal language. Abstract ideas can be expressed in signs exactly as in spoken language—namely, by metaphorical reference to concrete ideas. Signs—unlike words—can be quantitative as well as qualitative, and shapes can be signed by direct imitation. In experimenting with the development of a new sign language, the vocabulary has been based on C. K. Ogden's 'Basic English' (850 words), but a much shorter sign vocabulary will suffice.

Archæological Museums

THE problem of the preservation and proper display of archæological collections and the associated 'finds' from the excavation of archæological sites is discussed by the Editor of *Antiquity* in the December issue of that journal. Briefly stated, the points to which he directs attention are two: the restrictions of space which preclude display according to modern methods, and differentiation to meet the respective needs of the 'ordinary' man and the student; and secondly, the necessity of a better organisation and distribution of the archæological material available for exhibition. In connexion with the second point, he is clearly preoccupied with the position of the British Museum (Bloomsbury), and here, as he points out, the question of reorganisation and distribution involves legislation. Further comment on the allocation of space to archæological exhibits may perhaps be postponed, pending the publication of a promised article in *Antiquity* which will deal with museum buildings.

THESE questions, however, serve to remind us that there are other aspects of the museum problem, which inevitably must be discussed, if, and when, the organisation of collections and their exhibition come under consideration. How far will it be advantageous, for example, to attempt to define the function of the local (that is, locally owned or municipally owned) museums, or to draft some scheme of co-operation between them and the

national collections, which would serve as the basis for a national system, in which museums of general cultural and archæological interest dovetailed with a grouping of auxiliary museums of localised or specialised function. That there is already a certain amount of co-operation, localisation and specialisation in action is, of course, well known. The university museums, having special functions, would have a special place in such a scheme. There is at present, in fact, a certain amount of specialisation as between the museums of the various universities, the Pitt-Rivers at Oxford being the most conspicuous example. In one direction the way has been pointed out by Dr. R. E. Mortimer Wheeler, in his address when declaring open the Bishop Hooper's Lodging as a folk museum at Gloucester on October 10 last. A report of his address and of the opening ceremony will be found in the *Museums Journal* of December. Dr. Wheeler's most suggestive remark was that pending, or the pessimist might say failing, the institution of a national folk museum, the local museum should set about the collection of the material of local folk culture before it is too late.

English Instrument Making

At a meeting of the Newcomen Society held at the Science Museum on December 11, a paper by Dr. R. S. Clay and Mr. T. H. Court on "English Instrument Making in the 18th Century" was read. As is well known, Mr. Court has contributed largely to the collection of scientific instruments in the Museum. Some of these had been arranged on the lecture table, and during the reading of the paper Dr. Clay used them to illustrate his remarks. In the eighteenth century, he said, England was fortunate in having a number of men who were not merely instrument makers but also men of scientific knowledge. Moxon, Senex, Short, Dollond and Nairne were all fellows of the Royal Society, and they and others such as Benjamin Martin, George Adams and James Ferguson made advances in the construction of scientific instruments which placed English microscopes, telescopes, etc., in the forefront and caused them to be copied abroad. One important invention was that of Marshall, who introduced the method of grinding a large number of lenses together on a block with a spherical tool, another that of the method of drawing brass tubes on a steel mandrel by which tubes capable of sliding smoothly in one another for telescopes could be made. Cuff, it appears, first introduced an all-brass telescope as a commercial instrument. The invention of the achromatic lens by Dollond, the invention of the quadrant by Hadley, the improvement in dividing scales by Bird and Ramsden and the construction of reflecting telescopes by Short all contributed to the supremacy of the English instruments. The biographies of a few of the most famous instrument makers only are known. Short was one of the few who made money by his business ; a good many others were at various times made bankrupt. The outstanding men at the end of the century were Jesse Ramsden (1735–1800) and Edward Nairne (1726–1806).

Dr. R. A. Millikan and the Earth's Magnetic Field

Ever since the time of Gauss, it has been assumed that the intensity of the earth's magnetic field is practically symmetrical. When attempting to find out the nature and distribution of the cosmic rays, Dr. Millikan has discovered that we must seriously modify our ideas about the earth's field. According to a report by Science Service, Washington, D.C., Dr. Millikan in a paper read at a meeting of the National Academy of Sciences at Charlottesville, Va., stated that the magnetic field extends into space for at least 10,000 miles and that the magnetic intensity is stronger on the side of the earth opposite to America. There is a greater effect on the cosmic ray intensity from the north magnetic pole to the equator in the region of India than there is in comparable latitudes in America. The Department of Terrestrial Magnetism of the Carnegie Institution of Washington has compared the magnetic variations on the surface of the earth with Millikan's results determined by cosmic ray intensities. It concludes that the variations of magnetism extend many thousands of miles into space. The earth's field appears to be lopsided.

A Standardisation of Inefficiency

In the *World Economic Survey* just issued by the League of Nations instructive statistics are given of the world production of electrical energy. Taking the average annual issue from 1925 until 1929 as 100, the issue in 1932 was 119, in 1933 it was 125 and in 1934 it was 138. Perusal of the *Survey* shows that in no other branch of industrial activity has such rapid progress been made during this period of great depression. *World Power* of October, in commenting on this, points out that the manufacture of plant does not increase *pari passu* with the demand for electrical energy. Part of the lag may be due to the great advances made in generating efficiency as a result of industrial research. This may have inspired a policy of caution among buyers of plant, and so they may be chary of placing new orders. It may be advisable to correlate technical research and new orders for electrical development, if overseas countries continue to protect inefficient installations by obsolete standardisation regulations. *World Power* states that scientific investigation is likely to receive a severe setback because research work will lack a world market for the products it improves. A secondary boom tends to develop in the sheltered manufacturing industries abroad, which receive added protection from the depreciation of the exchange. A number of foreign countries with depreciated exchanges are adopting plant and equipment regulations which give results much inferior to those obtained by research and the best technical practice. There is in fact a tendency towards standardising inefficiency, and this discourages scientific research.

Modern Physics

Of the series of pamphlets recently issued in Paris by Messrs. Hermann et Cie under the title "Actualités

Scientifiques et Industrielles", six deal with physical questions. M. Jean Perrin, under whose direction the pamphlets dealing with atomistics are issued, is himself responsible for four entitled "Grains de Matière et de Lumière". The first is on the existence of the 'grains', that is, of atoms, electrons and photons, the second on the structure of the atoms, the third on the complexity of their nuclei and on their radio-activity, and the fourth on the changes which can be produced in them by bombardment. Prof. Joffé of Leningrad, who is dealing with the physics of solids, contributes a somewhat longer pamphlet, on semi-conductors, the conductivity of which is due to a small fraction only of the valence electrons attached to their atoms. M. Y. Rocard presents the first pamphlet of the series on hydrodynamics and acoustics, on the statistical theory of fluids and the equation of state, by M. J. Yvon. Each pamphlet gives a concise and readable account of the present state of the subject with which it deals, and is written by one who has himself made distinct and valuable contributions to our knowledge of it.

Radio Data

A SECOND edition of "Radio Data Charts" by Dr. R. T. Beatty (Iliffe and Sons, Ltd. 4*s*. 6*d*. net) is to be welcomed, since the opportunity has been taken to extend its scope to cover the most recent advances in radio technique. The various abacs provided now cover wave-lengths down to five metres, while provision is made for audio-frequencies over the range 20–10,000 cycles a second. This publication contains a series of thirty abacs with explanatory notes and examples, by means of which many of the quantities required in radio-frequency work can be obtained directly without the necessity for laborious calculation. In addition to the means for obtaining the inductance, capacitance and reactance of coils and condensers at both audio- and radio-frequencies, charts are given for obtaining the efficiency and time constant of a grid leak and condenser combination, for designing coils to have a minimum radio-frequency resistance and for the design of attenuation circuits, to select only a few typical examples. The whole series of charts is printed in a clear and easily accessible form and will be found to be most valuable to engineers, experimenters and students dealing with radio-frequency work.

Clough Memorial Research Fund for Geology

THROUGH the generosity of Mrs. Clough, a fund was established in 1935 in memory of her late husband Dr. C. T. Clough, for the purpose of encouraging geological research in Scotland and the north of England. The north of England is defined as comprising the counties of Northumberland, Cumberland, Westmorland, Durham and Yorkshire. Under the terms of administration of the fund a sum of approximately £30 will be available annually. Applications for grants for the period April 1, 1936–March 31, 1937 should state the nature of research to be undertaken, amount of grant desired, specific purpose for which the grant will be used and whether any other grant-in-aid has been obtained or applied for; they should be in the hands of the Secretary, Clough Memorial Research Fund Committee, Edinburgh Geological Society, Synod Hall, Castle Terrace, Edinburgh, not later than February 1, 1936.

Statistics of the British Cinema Industry

AT the meeting of the Royal Statistical Society on December 17, Mr. S. Rowson read a paper entitled "A Statistical Survey of the Cinema Industry". When the figures disclose that in 1934 there were 957 million admission tickets sold for the sum of £40,950,000 (the average price of a ticket thus being 10·3*d*.), and when one further considers the character and splendour of the modern cinema together with the fact that four out of every five people visiting the cinema pay not more than one shilling for a ticket, the cinema is shown to be as one of the sociological wonders of the century, meriting attention and investigation. Of the year's revenue from admissions, the Government claimed £6,800,000 in entertainment duty. The average weekly cinema attendance throughout the year is about 18½ millions. At the end of 1934 there were 4,305 cinemas in Great Britain, with an average of 900 seats in each. In the London postal area alone, there were 401 cinemas. Of the various districts Lancashire had the greatest number with 699, Midlands next with 585, and Yorkshire and district next with 534. North Wales had the smallest number with 62—as opposed to 259 in South Wales. In the London area there was one seat for every 14 of the total population; in the Lancashire area one to nine; in the eastern counties one to nineteen; in South Wales one to ten. Eliminating the population under 15 as infrequent cinema-goers—the number of persons per seat were: in London, 10·9; in the Eastern Counties, 14; in the Midlands, 9·6; in Yorkshire, 8·0; in Lancashire, 7·0; and in South Wales, 7·6. It will be seen from the foregoing that the problem of redundancy or overbuilding is now becoming serious.

Food of the Bullfrog

MR. S. W. FROST had a bullfrog of 200 gm. under observation in a cage provided with a small pond ("The Food of *Rana catesbeiana*, Shaw", *Copeia*, No. 1; 1935). Its feeding capacity is amazing. During the summer it ate more than four hundred and twenty-seven grams of food—more than twice its own weight—in less than five months. The artificial conditions may, however, have caused it to eat more than it would have done in natural surroundings. The food eaten included 56 amphibians (frogs, toads and salamanders), 63 insects (beetles, moths, caterpillars, grasshoppers and cicadas), slugs (*Limax maximus*) and birds. As an example, on June 23 it ate 2 Promethia moths and 8 other insects; June 24, 1 Promethia moth, 3 other insects and 1 nestling sparrow (18 gm.); June 25, 1 frog (6 gm.); June 16, 2 frogs (13·5 gm.). It has a curious method of accepting its food, preferring to take it under water; "sometimes it snatches a morsel of food on the bank of a stream or pond, but invariably jumps into the water and submerges it to swallow".

Swimming Baths and Pools

THE Minister of Health has directed the attention of local authorities for the necessity of cleanliness in swimming pools (Circular 1503. London: H.M. Stationery Office, price 1*d*.). The circular emphasises the opportunity which the winter months offer for ensuring a proper standard in swimming baths and pools. The requisite degree of purity can best be maintained by efficient continuous filtration and continuous controlled chlorination. The recommendations apply to all baths and pools open to the public, whether publicly or privately owned, for local authorities, under the Public Health Act, 1875, have power of control over privately owned pools used by the public.

Pathology and Bacteriology at Leeds

THE annual report for 1934 of the Department of Pathology and Bacteriology in the University of Leeds has been issued, and gives a brief account of the routine and research work prosecuted under the direction of Profs. Stewart and McLeod. The research work includes studies on industrial pulmonary diseases, diphtheria, immunity, and catarrhs of the respiratory tract. Prof. Passey contributes an abstract of work done in cancer research.

Harrison Memorial Prize, 1935: Dr. L. E. Sutton

AT the meeting of the Harrison Memorial Prize Selection Committee, consisting of the presidents of the Chemical Society, the Institute of Chemistry, the Society of Chemical Industry, and the Pharmaceutical Society, held on December 12, it was unanimously decided that the Harrison Memorial Prize for 1935 should be awarded to Dr. Leslie Ernest Sutton. The presentation of the Prize will be made at the annual general meeting of the Chemical Society to be held at the University of Bristol on Thursday, April 16, 1936. Dr. Leslie E. Sutton was educated at Watford Grammar School, and proceeded to Lincoln College, Oxford, in 1925, obtaining his B.A. and B.Sc. with first-class honours in 1929. He was elected senior research scholar of the Department of Scientific and Industrial Research in 1929, and obtained his D.Phil. and fellowship of Magdalen College in 1932. He worked with Prof. P. Debye at Leipzig and with Prof. L. Pauling at the California Institute of Technology, Pasadena, and during the past five years he has been carrying out research at Oxford. His original investigations on dipole moments, including the relation between moments and orientation in benzene substitution, on valency angles, and on electron diffraction are of outstanding merit, and form a notable contribution to our knowledge of physical chemistry.

"Everyday Science" and the Civil Service Commissioners

OUR leading article this week deplores the removal from examinations for higher administrative posts of the Civil Service of the compulsory subject "Everyday Science". In this connexion, Sir Arnold Wilson put a question in the House of Commons asking the Secretary to the Treasury "whether he is aware that the Civil Service Commissioners have eliminated the subject of everyday science, which has been one of the obligatory subjects for competitive examinations for the administrative group of Government service, from next year's examinations; and whether, before taking this decision, the Civil Service Commissioners consulted any society or body representing educational and scientific interests". The reply given on December 16 by the Financial Secretary to the Treasury was as follows: "The answer to both parts of the question is in the negative." The curtness of the reply borders almost on discourtesy to the scientific and educational bodies concerned; and we trust that the matter will not be left in the present unsatisfactory position.

Scales of Ordnance Survey Maps

IN reply to a question by Colonel A. W. Goodman in the House of Commons on December 12, the Right Hon. Walter E. Elliot, Minister of Agriculture, stated that "no decision has been taken to introduce the metre as a unit of measurement in Ordnance Survey maps. The question is among those to be examined by the Departmental Committee, which is at present considering the future programme of the Ordnance Survey Department."

Committee against Malnutrition

IN the anniversary address to the Royal Society (NATURE, Dec. 7, p. 895), Sir F. Gowland Hopkins mentioned a "self-constituted committee" issuing "propaganda against malnutrition". This Committee—a body of research workers and members of the medical profession—is the Committee against Malnutrition, 19c Eagle Street, Holborn, W.C.1. The Committee issues a two-monthly bulletin dealing with all aspects of modern nutritional research and of malnutrition as a social question. The annual subscription is 3*s*., and in the case of associates 5*s*., a sum which entitles them to the full use of the files and library of the Committee.

Fifth Mount Everest Expedition

IT is announced that the party which will make the fifth attempt to climb Mount Everest in the 1935–36 expedition under the leadership of Mr. Hugh Ruttledge has been chosen by the Mount Everest Committee, of which Major-General Sir Percy Cox is chairman. The members of the party will be Mr. E. E. Shipton, leader of the Mount Everest reconnaissance party in Tibet; Mr. F. S. Smythe, who has taken part in three previous expeditions; Mr. P. Wyn Harris (Kenya Civil Service); Dr. C. B. Warren, formerly of St. Bartholomew's Hospital; Mr. E. G. H. Kempson, a master at Marlborough College; Major C. J. Morris, late 2nd/3rd Gurkha Rifles; Dr. Noel Humphreys, who led the Oxford University Expedition to Ellesmere Land last year; Lieut. W. R. Smijth-Windham, Royal Corps of Signals; Lieut. J. M. L. Gavin, Royal Engineers; Mr. F. H. L. Wigram, a medical student at St. Thomas's Hospital; and Lieut. P. R. Oliver, South Waziristan Scouts.

Physical Society's Exhibition

THE twenty-sixth annual exhibition of scientific instruments and apparatus, arranged by the Physical Society, will be held on January 7, at the Imperial College of Science and Technology, Imperial Institute Road, South Kensington, S.W.7. Manufacturers of scientific instruments will be exhibiting their products in the Trade Section. The Research and Experimental Section will contain contributions from research laboratories, and there will be a special sub-section devoted to experiments of educational interest. In addition, the work submitted for the Craftsmanship and Draughtsmanship Competition by apprentices and learners will be on view. Discourses will be delivered on two days at 7.45 p.m. as follows: January 7, R. A. Bull, "Some Instruments used in recording Sound on Film"; January 8, R. W. Paul, "Electrical Measurements before 1886". Admission to the exhibition is by ticket only. Members of institutions and scientific societies may obtain tickets from their secretaries; tickets may also be obtained direct from the Exhibition Secretary, 1, Lowther Gardens, Exhibition Road, S.W.7.

American Association for the Advancement of Science

THE American Association for the Advancement of Science will hold its ninety-seventh meeting at St. Louis, commencing on December 30. On the first evening, the retiring president, Dr. Edward L. Thorndike, will deliver an address entitled: "Science and Values". Among the special lectures are J. B. Taylor, "The Electric Eye and the Human Eye" (Sigma xi Address); Prof. J. E. Woodridge, "The Claims of Science" (first of series of annual lectures to be arranged by the United Chapters of Phi Beta Kappa); Dr. H. G. Moulton, "The Scientific Method in the Investigation of Economic Problems"; Dr. B. A. Houssay, "Hypophysis and Metabolism"; Dr. Karl F. Meyer, "Plague, Past and Present"; Dr. E. H. Barbour, "The Proboscidea of the Plains"; Prof. F. Slocum, "The Changing Picture of the Universe"; Dr. V. O. Knudsen, "The Absorption of Sound in Gases"; Dr. V. Bush, "Mechanical Analysis" (Josiah Willard Gibbs Lecture). A meeting will also be arranged between the secretaries of sections and affiliated societies and representatives of the Press to discuss the broader principles or the technique of the popular presentation of science. Further information can be obtained from the Permanent Secretary, Dr. Henry B. Ward, Smithsonian Institution Building, Washington, D.C.

Announcements

WE much regret to announce the death, which occurred on December 16 at the age of eighty-one years, of Sir Richard Glazebrook, K.C.B., K.C.V.O., F.R.S., from 1889 until 1919 director of the National Physical Laboratory, and from 1908 until 1933 chairman of the Aeronautical Research Committee; also of Mr. P. C. Gilchrist, F.R.S., who was associated with the late Mr. S. G. Thomas in the introduction of the basic Bessemer process for the production of iron, on December 15, aged eighty-three years.

IT is announced that the King has been pleased to appoint Mr. Edgar John Forsdyke, keeper of the Department of Greek and Roman Antiquities at the British Museum, to be director and principal librarian of the Museum, in succession to Sir George Hill, who will retire in Midsummer, 1936.

DR. G. A. YOUNG, chief geologist of the Canadian Geological Survey, has been elected president of the Royal Society of Canada in succession to the late Dr. Reginald W. Brock.

PROF. OTTO LEHMANN, director of the Museum at Altona, has been awarded the Goethe Medal for Science and Art.

A MEDALLION has recently been affixed to the house at Confolens in the Department of Charente, in which the late Dr. Emile Roux, the director of the Pasteur Institute of Paris, was born.

IT has been arranged for a number of the official lectures which are being given in connexion with the Exhibition of Chinese Art at Burlington House, to be published in the *Journal of the Royal Society of Arts*. The first of these, "The Chinese Exhibition", by Sir Percival David, has already appeared, and Miss Helen Fernald's lecture on "The T'ang T'ai Tsung Horses" is being published on December 20. Copies may be obtained from the Secretary, Royal Society of Arts, John Street, Adelphi, W.C.2, price 1*s*. each.

A SPECIAL section of the Illuminating Engineering Society to be devoted to photometry and allied subjects is now being formed. The honorary secretary is Mr. K. F. Sawyer, of the Gas Light and Coke Company, Watson House, Nine Elms Lane, London, S.W.8. Arrangements have been made for the opening meeting to take place at the Westminster Technical Institute, Vincent Square, London, S.W.1, at 6.30 p.m. on January 28. An introductory address, dealing with certain outstanding problems in photometry, will be delivered by Dr. J. W. T. Walsh.

ERRATUM.—In the communications by G. Wald entitled "Pigments of the Bull Frog Retina" (NATURE, Nov. 23, p. 832) and "The Visual Purple System in Marine Fishes" (NATURE, Dec. 7, p. 913), the ordinates of the graphs should read "Extinction (log I_0/I)" instead of "Extinction (109 I_0/I)" as printed.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A John William Hughes professor of civil engineering in the University of Liverpool—The Registrar (Feb. 10).

A principal of the Leathersellers' Technical College—The Clerk to the Governors, Leathersellers' Hall, St. Helen's Place, London, E.C.3.

An engineer to the Government of Nigeria—The Crown Agents for the Colonies, 4, Millbank, London, S.W.1.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 991.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Biometrical Studies on Herbarium Material

ONE type of information concerning species is almost universally lacking in herbarium material, even in that of the most copiously collected species and varieties of plants. Because the lack seems to be due to a general failure to appreciate the value of such information, it has seemed wise to direct attention to the problem, and to indicate methods of dealing with it.

For species which are well represented in herbaria, one can now obtain from the preserved specimens a substantially accurate record of the general range of variation. Seldom or never, however, is it possible to ascertain the comparative frequency of the different variants. In *Fraxinus Pallisae*[1], for example, it is difficult to decide whether one is dealing with various departures from a common morphological central type, or whether the bulk of the population is grouped around two or more extremes with occasional intermediates between them. If information as to frequencies were at hand, it would very probably be possible to diagnose one variable but still coherent species, or, alternatively, to explain the result as due to hybridisation.

In such variables as *Fraxinus Pallisae* and *F. oxycarpa*, it is possible to supplement the customary herbarium material with another kind of specimen which will supply exactly the information which is ordinarily lacking. These supplementary specimens need be little or no more laborious to collect than ordinary ones, nor, if the work be critically done, need they take up undue space in the herbarium. All that is needed, in addition to the kind of specimens usually collected, is a series giving a random sample of the population. This need not consist of complete specimens; any critical portion of the plant will probably suffice. In *Fraxinus*, for example, one leaf per tree, from every tree in a small copse, or from a random sample of the trees in a forest, can be mounted several to a sheet. While the specimens need not be bulky, they should be carefully chosen to be as comparable as possible; in *Fraxinus* they should all be leaves in the sun, or all in semi-shade; they should all be either from fruiting or non-fruiting branches, and if possible from trees of about the same age. Different genera will require other sorts of material. In *Iris* one seed from every one of the plants in a meadow, in *Prunus* one average 'stone' per tree from all the trees in a single mountain valley or along a certain length of beach, in *Centaurea* one head from every plant growing on an area of down, will produce collections which can be filed in packets on a single sheet. Such collections, however, if carefully gathered, will yield valuable and unique biological information.

It is important, of course, that, where great numbers of individuals make it necessary for the collector to choose relatively few, the choice be made as representative as possible. One of the simplest ways of accomplishing this result is to collect along a line (or if necessary along a series of parallel lines) until the necessary number of individuals has been sampled. With low-growing plants it is usually a simple matter to sight across such a community as a meadow or a bog where the plants are growing and to pick out a route which will be representative, and then to collect comparable fragments (leaves, flowers, seed-pods, etc.) of every plant along this line. Some modification of this method will ordinarily suffice for larger-growing species, though more mathematically refined methods for taking such samples might readily be devised[2]. The number of individuals collected will depend, of course, upon the ease of collection, and to a certain extent upon the needs of the particular problem under investigation. Generally speaking, at least twenty-five will be necessary before one can place much confidence in the result, while samples of more than fifty may not give such improved results as to justify the extra labour.

In our opinion, such collections, if once made, should be filed together, even though they may include two or more species. Once separated into their specific components, they are difficult and sometimes impossible to reunite. Cross-references can be made on the orthodox herbarium material, which, of course, should be collected at the same time. There does not seem to be any inherent difficulty either in assembling such material or in filing it in a regular herbarium. It is to be hoped that such collections may be made more frequently, especially from species or groups of species which are difficult or impossible to diagnose precisely by more orthodox taxonomic methods.

Meaning of Certain Constants in Use in Physics

RECENT discussions as to electrical units have led to a consideration of the meaning of the constants μ, K, A, employed in electrical theory. It appears that each of these is needed, as a link, to allow us to express in dynamical ('absolute') units the forces active between certain electrical and magnetic quantities. Thus we have

$$\text{Force} = mm'/\mu r^2$$

and two similar equations, where m, m' are quantities of magnetism.

It is of course the case that μ, or more accurately μ/A, measures the ratio of magnetic induction to magnetising force, the permeability of the medium, while K, or rather $K/4\pi$, is a measure of its permittivity, the ratio of electrical displacement to electric force, but these facts are consequences of theory rather than fundamental definitions of the coefficients μ and K. The object of this note is to direct attention to the fact that many other coefficients used in physics share this role with μ and K.

Hooke's law, "Ut tensio sic vis", might be made the basis of a definition of force; indeed, it is used in the spring balance as a measure of force. A coefficient, Young's modulus, gives us the link by means of which we can express the stretch (tensio, extension) of a spring or piece of elastic in dynamical measure. This is true of all coefficients of compressibility or rigidity. By means of them we are enabled to express dynamically the pressures or tractions required to change the volume or shape of a body by a given amount.

Nor is this use of a coefficient limited to cases in which force is one of the quantities measured. Heat is properly measured as energy; it can also be measured by the rise of temperature produced in a given mass of water. Joules' equivalent is a coefficient which enables us to express a rise of temperature as the ratio of energy to the mass of water; the result is not completely 'absolute', for it involves certain properties of water.

Or again, to take a case involving, no doubt, the properties of a quantity of electricity, the electron, Planck's constant gives us the ratio of a quantity of energy to the frequency of an electron and thus enables us to express the frequency of an electron in dynamical units.

Production of Neutrons by Annihilation of Protons and Electrons According to Fermi's Theory

IN the theory of β-decay as proposed by Fermi[1], one assumes the existence of elementary processes in which a neutron is transformed into a proton by simultaneous creation of an electron and a neutrino. For the inverse process, which is also naturally contained in Fermi's theory, one needs the previous existence of an electron and a neutrino. It might therefore be thought that a proton cannot be transformed into a neutron without the presence of a neutrino source. Such a source, however, is not necessary if it be admitted that in empty space all negative neutrino states are occupied in the same way as the negative energy states of the electron in Dirac's theory of the positron. In this case, for example, the presence of an electron alone is sufficient since the neutrino can be furnished from a negative state.

The transformation of protons into neutrons by positron emission has already been treated by Uhlenbeck and Wolfe[2]. Of course, it could only occur if for the masses M_P, M_N and m of proton, neutron and electron respectively, the relation

$$D = M_N c^2 - M_P c^2 < -mc^2 \qquad (1)$$

were valid. Recent data for the neutron mass seem to exclude such a relation.

By a process of the kind mentioned above, however, the proton in the hydrogen atom together with the electron can be transformed into a neutron, if

$$D < mc^2 - J, \qquad (2)$$

J being the ionisation energy.

Since, at present, relation (2) cannot be excluded with certainty, we have calculated the rate of transition of a hydrogen atom into a neutron. The result depends somewhat on the form of the interaction between the heavy particle and the electron-neutrino field. We have used two such forms, that proposed originally by Fermi (l.c.), the other by Konopinski and Uhlenbeck[3], and we find in the former case:

$$R' = \frac{\Delta^2}{T}; \qquad (3a)$$

and in the latter,

$$R'' = \frac{\Delta^4}{T}; \qquad (3b)$$

$$\text{where } T = \frac{2\pi^2\hbar^4}{g^2\alpha^3 m^2 c} = 8{\cdot}8 \times 10^{10} \text{ sec.} \qquad (4)$$

$$\text{and} \quad \Delta = \frac{mc^2 - J - D}{mc^2} \qquad (5)$$

g is the universal constant as determined by the β-decay with the value $g = 4 \times 10^{-50}$ cm.^{3} erg; $2\pi\hbar$ is Planck's quantum of action; α is the reciprocal of the Bohr radius; c is the velocity of light; and J is the ionisation energy of the hydrogen atom.

If by a very cautious estimation we assume that the lifetime of hydrogen is certainly longer than 10^{13} sec., we find as a lower limit of D from (3a):

$$D > 0{\cdot}9\ mc^2 = 4{\cdot}5 \times 10^5 \text{ e.v.}; \qquad (5a)$$

from (3b):

$$D > 0{\cdot}6\ mc^2 = 3 \times 10^5 \text{ e.v.} \qquad (5b)$$

Since it is very likely that not only are the relations (5) satisfied but also that D is considerably larger than mc^2, a transformation of protons into neutrons could only occur by bombardment with electrons of high energy. We have also treated this case neglecting the Coulomb interaction between the proton and the electron. For the cross-section we obtain with

$$\Gamma = \frac{E - D}{mc^2},$$

in the Fermi case

$$\Phi' = A\,\frac{c}{v}\,\Gamma^2; \qquad (6a)$$

in the Uhlenbeck case

$$\Phi'' = A\,\frac{c}{v}\,\Gamma^4. \qquad (6b)$$

E and v are energy and velocity of the incident electron; A is the universal area

$$A = \frac{g^2 m^2}{2\pi\hbar^4} = 1{\cdot}7 \times 10^{-44} \text{ cm.}^2 \qquad (7)$$

The smallness of the value (7) will scarcely permit detection of our effect, although it increases rapidly with the electron energy. Our calculations have been carried out on the assumption that the mass of the neutrino is small compared with the mass of the electron. In addition, for simplicity, terms of the order m/M have been neglected.

Conditions Determining the Intensity of X-Ray Reflections from Microcrystalline Layers

THE letter of Messrs. Stephen and Barnes on a "New Technique for Obtaining X-Ray Powder Patterns" in NATURE of November 16, p. 793, raises some points of interest with regard to the geometrical-optical conditions governing the device they describe.

As is done in the flat layer method we have developed[1], they observe X-ray reflections from a flat microcrystalline layer by making use of wide beams. The X-ray source is at some distance from the camera and the layer is set so as to make only small glancing angles with the reflected rays. Such conditions correspond to our focusing relation $\sin\alpha/\sin\beta = a/b$ for the case $a > b$. In Fig. 1, this relation is illustrated by reference to the 'toroidal' surface, discussed in previous papers[2], which determines the locus of the points so situated as to reflect from a source A to C through an angle $2\pi - (\alpha + \beta)$. Since the magnification between A and C depends on the zone of the toroid, by making $a > b$ a reduced image of the source with a corresponding increase of intensity can

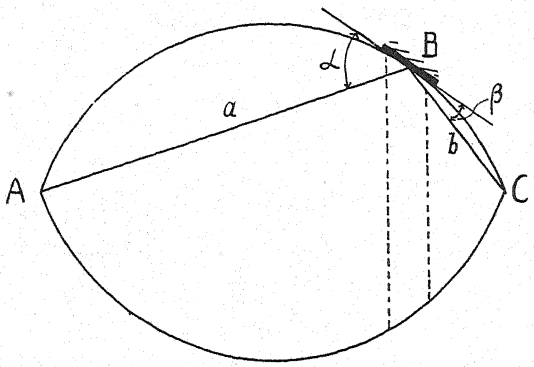

FIG. 1.

be obtained. Apart from this factor of magnification, the intensity is determined by the angular width of the incident beam. To obtain the maximum intensity we have met these combined requirements by placing the source A, which generally is a slit, back in the anticathode itself. The multiple diaphragm used by Messrs. Stephen and Barnes approximates to these conditions, as for a parallel beam $a = \infty$, when the focusing relations always requires the angle β to be small. It would thus appear that their method is in its principles the same as our method of the flat layer. Although they do not use the term focusing, the sharpening of lines and the increased intensity with shortening of exposure are two aspects of focusing and scarcely involve a new principle, claimed in the letter.

This view seems to be supported by Dr. W. H. George's elegant method[3] referred to in Messrs. Stephen and Barnes' letter, of obtaining a strong monochromatic reflection from a copper crystal cut so that its surface is oblique to the reflecting lattice planes. This corresponds to the reflection from an element of the toroid with $a \neq b$, and is entirely accounted for by the focusing relations; we described this in our earlier discussion by saying "that the lattice planes from which reflection takes place are inclined to the surface of the toroid like the tiles of a roof". They are indicated in Fig. 1 by the shaded lines at B.

We look forward to finding in the more extended publication foreshadowed by Messrs. Stephen and Barnes a fuller exposition of the distinctive features of their method and of the underlying principles. In some measurements with a source A at finite distance and a flat microcrystalline layer, we found that with decrease of β below the angle of focusing the intensities did not increase but decreased in accordance with an absorption effect[4] which could not be discussed within the limits of this letter.

Variation in the Lattice Constant of Zinc Oxide

IN the course of electron diffraction investigations, it is often necessary to have a more accurate method of measuring voltage than the spark gap affords. Reference films have been used by several workers, the electron voltage being calculated from the lattice constant as known from X-ray work. Gold films were originally used, but more recently metallic oxide films have been preferred, as they yield very good diffraction patterns. The use of such films obviously demands that the crystal structure shall be stable and the lattice dimensions constant.

During the past three years, I have been using both gold and zinc oxide films in this way. Whilst the former have behaved uniformly well, the latter have showed small but consistent variation in lattice constant, as tested against a high-resistance voltmeter. It is conceivable, but scarcely possible, that both the voltmeter and gold film varied, and that the zinc oxide films were actually stable.

The oxide films were prepared by withdrawing a brass washer of 5 mm. diameter from a skimmed melt of granulated zinc contained in a crucible. The lattice constants of such a newly prepared film were found to be: $a = 3{\cdot}234 \pm 0{\cdot}005$ A.; $c = 1{\cdot}615 \pm 0{\cdot}005$ A. After an interval of one year, during which the film was protected from dust but was exposed to the air, the constants were found to be: $a = 3{\cdot}262 \pm 0{\cdot}005$ A.; $c = 1{\cdot}628 \pm 0{\cdot}005$ A. Six months later the values were found to be slightly higher still: $a = 3{\cdot}279$ A. and $c = 1{\cdot}637$ A., with the same probable error as before. No changes in these latter values were observed after the lapse of a further two months. To check this drift in the lattice constants, a fresh zinc oxide film was then prepared. This gave values very near to those first obtained with the previous film: $a = 3{\cdot}242$ A., $c = 1{\cdot}620$ A. These values compare with those given by Bragg[1]: $a = 3{\cdot}220$ A., $c = 1{\cdot}608$ A.; the difference is not significant, as there is a constant error of $\pm 0{\cdot}5$ per cent in the present work, owing to uncertainty as to the camera length. This error will affect all the values equally, and therefore can have no part in causing the observed drift.

The fact that the lattice constants of zinc oxide films vary in this regular way with time, whilst those of gold films remain constant, must be the result of stresses set up in the films during the rapid cooling

which accompanies their formation, possibly aided by gas absorption. No work has been done on films obtained by collecting zinc oxide smoke[2]. The present results show, therefore, that it is inadvisable to use films of zinc oxide, prepared in the manner described, for high-voltage calibration or measurement.

Ascorbic Acid (Vitamin C) and Phytocarcinomata

IN a previous communication[1], I have given an account of a phytocarcinogenic effect of œstrus hormone on tomato plants. In a similar preliminary experiment using the same technique[2] with tomato plants, about 55 cm. high, the effect of ascorbic acid upon plant-tumour production has been investigated.

Immediately after the inoculation of fifteen plants with *B. tumefaciens*, a 1/10,000 aqueous solution of ascorbic acid (kindly supplied by Prof. A. Szent-Györgyi) was introduced through a petiolar stump. The average total dose thus absorbed was about 27 ml. per plant during the period June 8–22, 1935. Five of the fifteen were tentatively given, on the first day of the experiment, 5 ml. of a concentrated (5/1,000) solution of ascorbic acid. Although the petiolar stump, through which this dose was absorbed, plasmolysed and completely collapsed within 38 hours, no other toxic effects were observed. Afterwards, the dilute solution was given to these plants through another petiolar stump. Twenty-one plants were set up as controls, and treated with an equal amount of water.

At the first signs of necrosis of the experimental tumours, they were cut off and weighed. The average weight of the tumours per plant was: with ascorbic acid, 1·116 gm.; with water only, 0·857 gm. The mean weight of the tumours of the plants treated with ascorbic acid was about 27 per cent greater than that of the control plants, although the total amount of crystalline ascorbic acid administered throughout the treatment amounted only to about 2·7 mgm. per plant; owing to its rapid oxidation in solution, the amount actually absorbed is estimated to have been 40–50 per cent less.

The hydrogen ion concentration of the sap of the treated plants and controls, and of the tumours severed from these plants, was as follows (mean values):

	Concentration of solution	*p*H 24 hours after absorption of first solution	*p*H at end of experiment
Leaves	1/10,000	5·6	5·6
	5/1,000	5·4	5·6
Leaves and stem	1/10,000	—	5·5
	5/1,000	—	5·5
Tumours	1/10,000	—	5·8
Leaves	0 (controls)	5·6	5·6
Leaves and stem	0 „	—	5·5
Tumours	0 „	—	5·8

With the exception of the slight lowering of the *p*H of leaf-sap extracted twenty-four hours after the administration of the stronger solution of ascorbic acid, the acid does not appear to have affected the hydrogen ion concentration of the sap extracted from the treated plants. The greater alkalinity of tumour sap is a characteristic of most tumour tissues.

Histo-cytological examination of tumours from the treated and control plants gave no indication that the increased size of the tumours severed from treated plants was simply due to the stretching of the cells caused by a general stimulation of somatic growth under the influence of ascorbic acid[3]. As the size and arrangement of the cells and that of the phloem-xylem elements were identical in the two, it is deduced that the treatment led to an increase of cell proliferation of the pathological tissues.

It is hoped to extend the range of the experiment outlined above, in order to test whether a parallelism exists, for plants, with the findings of Fodor and Kunos[4], Schroeder[5], and Frisch and Willheim[6], concerning the carcinogenic influence of ascorbic acid on animals.

A New Type of Plant Lipochrome

IN continuation of our investigations upon the Algæ[1], we have observed the presence of a peculiar carotenoid in the unsaponifiable fraction of one of the *Cyanophyceæ* (*Myxophyceæ*), namely, *Rivularia nitida*. The pigment, for which we propose the name *myxoxanthin*, crystallises from ether-methyl alcohol in deep copper-coloured needles, m.p. 117°–118° (uncorr.), and unlike any other phytocarotenoid hitherto isolated, exhibits only one absorption band, having its head at 488–490 mμ in carbon disulphide. In this respect myxoxanthin resembles the Crustacean pigment astacene[2]; but unlike the latter, it has no acidic properties and is completely epiphasic when subjected to the Kraus partition between methyl alcohol and light petroleum. Its failure to yield a sodium salt precludes the possibility of its being hæmatochrome, which pigment is reputed to exist in certain Algæ and is likewise stated to possess only a single absorption band[3].

We have failed to detect the presence of any hypophasic xanthophylls in *Rivularia nitida*, and the absence of these is, so far as we are aware, unique in plant life, although we have found that *Trentepohlia aurea*, a member of the *Chlorophyceæ*, contains only a minute amount of hypophasic xanthophylls, the yellow colour of the plant being due almost wholly to its high β-carotene content. We are at present engaged in collecting a larger amount of *Rivularia nitida* with a view to a closer characterisation of the new pigment.

Structure of the Proboscis in Blood-sucking Diptera

In his letter in NATURE[1], Dr. S. K. Sen still upholds the view, which I have criticised[2], that the salivary duct of *Stomoxys calcitrans* terminates at the base of the hypopharynx, the lumen of the latter being a groove running centrally to near its tip.

The hypopharynx (*h.*) of Diptera is formed by an external and an internal tube. The external tube or the external wall of the hypopharynx of *S. calcitrans* (*e.t.*) is formed by the evagination of the floor of the mouth-cavity and is crescent-shaped in transverse sections (Fig. 1). The internal tube (*s.d.*) represents the elongated anterior portion of the common salivary duct and is rounded. Even in *Culicoides*, where the hypopharynx is partly guttered, the part of the salivary duct forming this gutter extends to near the tip of the hypopharynx.

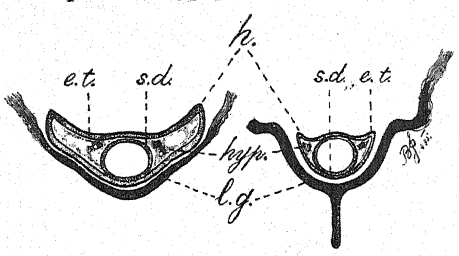

FIG. 1.

What Dr. S. K. Sen has named hypopharynx in his drawing (No. 2) of the transverse section of the proboscis of *S. calcitrans*[3], is actually the most anterior part of the hyoid. His section was evidently cut posteriorly to the base of the hypopharynx.

Fig. 1 shows transverse sections of the hypopharynx of *S. calcitrans* cut through the basal and the distal part of this organ respectively. The drawings also show the position of the hypopharynx in the labial gutter (*l.g.*) and the hypodermis (*hyp.*) occupying the space between the salivary duct (*s.d.*) and the external wall (*e.t.*). In these drawings I have intentionally not shown the theca of the labium, which lies ventrally to the labial gutter, nor the labrum-epipharynx, which lies dorsally to the hypopharynx.

Surface Structure beneath the Pacific

In a letter in NATURE of November 2, p.723, it is stated by Mr. H. F. Baird, acting director of Apia Observatory, that I have found from the velocities of seismic surface waves evidence of the existence of a layer of granite some 10 km. thick below the Pacific Ocean. This statement, based on an abstract only of my paper, is liable to be quite misleading. One extract from the actual paper will make the position clear: "Our ignorance of the structure of the Pacific floor gives no ground for applying the theory of a double surface-layer; it might be worth applying a single layer theory if we had any idea of the properties of that layer. The order of magnitude of the thickness of an equivalent single layer of granite can be found. . . ." If that layer happens to be granite, then the theory gives 10 km. with fair accuracy; if diorite, the thickness is about 16 km.

Independent evidence of the nature of the Pacific floor is badly needed, and it is important that Mr. Baird should have found some evidence of upper and "intermediate" layers from the records of earthquakes that occurred near Samoa. Some years back I endeavoured to trace pulses analogous to P_g, S_g, P^* or S^* in the Suva and Apia readings recorded in the "International Seismological Summary", but without success. A network of seismological stations on some of the Pacific islands, even if established for a limited period of a few years, would give valuable information concerning the structure of the earth's crust beneath the Pacific Ocean.

Electrical Moments of *p*-Quinone and Related Compounds

A DETERMINATION of the electric dipole moment of *p*-benzoquinone in benzene solution by Hassel and Naeshagen[1] gave the value of 0·67 D (D = 10^{-18} E.S.U.). Since *p*-quinone is usually assigned a symmetrical planar structure which should have zero moment, a further investigation of this anomaly was undertaken. The re-measurement confirmed Hassel and Naeshagen's value, and the work was extended to similar compounds with the following results:

Compound	Solvent	Temp.	P_{A+O}	μ
p-Benzoquinone	Benzene	25·0° C.	8·9 c.c.	0·65
„	Carbon tetrachloride	„	9·6 „	0·68
„	*n*-Hexane	40·0° C.	8·6 „	0·66
2 : 5 Dimethyl-1 : 4 quinone	Benzene	25·0° C.	9·4 „	0·68
2 : 5 Dichloro-1 : 4 quinone	„	„	8·8 „	0·64
Tetramethyl-*cyclo*butane-1 : 3-dione	„	„	11·0 „	0·73

The possibility of polar impurities being present can definitely be ruled out, since different specimens prepared or purified by different methods gave identical results. As regards a solvent effect, the values for *p*-quinone in benzene, carbon tetrachloride and *n*-hexane are identical within experimental error, and so if the moment is to be attributed to a solvent effect, it cannot be a specific effect of one solvent.

The construction of a model for *p*-quinone indicated that the molecule was not nearly as rigid as the graphic formula would lead one to expect, only a small force being required to distort the molecule into a multiplanar configuration by simultaneous rotation about the four single bonds.

If a strain of 10° in the carbon angle is produced by an increase in energy of 750 cal. per gram molecule[2], it follows that thermal energy at ordinary temperatures would be far more than sufficient to cause the observed moment for *p*-quinone. Pauling and Sherman[3] have calculated the resonance energy of *p*-quinone, and find the large value of 13,000 calories, and it is probably this high resonance energy which tends to prevent the above type of oscillation in the quinone molecule.

The moments observed for 2 : 5 dimethyl- and 2 : 5 dichloro-*p*-quinone, being the same as that of *p*-quinone itself, offer a serious objection to the flexibility theory. The theory was further tested by measuring the moment of tetramethyl-*cyclo*butane-1 : 3-dione, where, owing to the large strain already present in the four-membered ring, a further

distortion of the molecule should not occur. A small moment, however, of the same order of magnitude, is also found in this case. The tetramethyl derivative was used rather than *cyclo*butane-dione itself, since with the latter compound there is the possibility of enolisation.

From these results it would appear that the values observed for the moments are due either to a general effect of the solvent or to an abnormally large atom polarisation. The question can best be settled by measuring the moments of the substances in the vapour state, and this work is being undertaken.

Occurrence of the Dipterocarpaceæ-Dipterocarpoideæ in Africa

IN a paper read before the Imperial Botanical Conference last August, which is being published in the forthcoming number of the *Empire Forestry Journal*, I referred to the Monotoideæ as "the only known living African representatives of the family Dipterocarpaceæ".

The Imperial Forestry Institute has now received herbarium material of a true Dipterocarpoid tree, from Nigeria, where it was found by Mr. J. H. Mackay, assistant conservator of forests, growing in primitive forest. Two further records of a similar species, and from other areas, have now been reported by Dr. Helen Bancroft, who has recently described the structure of true dipterocarp wood found in a fossil condition at Mount Elgon (Kenya-Uganda). Records of similar wood from Italian Somaliland, by Prof. A. Chiarugi, of Pisa, have indicated that the sub-family Dipterocarpoideæ was well represented in Africa in Tertiary times.

The discovery of living members of the Dipterocarpoideæ, a sub-family noted for its very valuable timbers, opens up further possibilities, from the practical point of view, with regard to the utilisation and development of tropical African forest areas. Academically, it adds further evidence of an inter-relationship of African-Asiatic types which indicates that in some earlier period there has been a closer connexion between Africa and the Indo-Malayan region, to which I referred in my paper.

J. BURTT DAVY.

Imperial Forestry Institute,
University, Oxford.
Dec. 3.

Points from Foregoing Letters

IN order to increase the usefulness of herbarium material, and to enable investigators to ascertain not only the range of variation of certain species but also the comparative frequency of different variants, Dr. E. Anderson and Dr. W. B. Turrill recommend that, in addition to the ordinary herbarium material, a carefully selected random sample consisting of 25–50 specimens of some critical part of the plant (such as leaf or seed) should be collected.

The late Sir Richard Glazebrook directs attention to the fact that not only the electrical and magnetic constants μ, K and A, but also many other coefficients used in physics, such as those of compressibility or rigidity, Young's modulus and Joule's equivalent, are in fact ratios between two different methods of measuring force, or energy, in terms of dynamical ('absolute') units.

Drs. F. Bloch and C. Møller have estimated the rate of transition of a hydrogen atom into a neutron, from the theory of Fermi, which allows the formation of a neutron by the combination of a proton with an electron plus a neutrino. They conclude that the transformation of protons into neutrons could only occur by bombardment with electrons of high energy.

Dr. J. Brentano discusses the conditions determining the intensity of X-ray reflections from crystal lattices. He suggests that the technique for obtaining X-ray powder patterns described in a recent letter by Messrs. Stephen and Barnes can be fully accounted for by the general conditions of focusing, which form the basis of his flat layer method previously published.

The lattice constants of zinc oxide films are found by Mr. V. E. Cosslett, using electron diffraction methods, to vary from 3·234 A., immediately after formation from a zinc melt, to 3·279 A. eighteen months later. The latter appeared to be a limiting value. The lattice constant of gold films remained the same over this time, showing that experimental conditions were unchanged. It is, therefore, inadvisable to use such oxide films as standards in electron diffraction work.

Injections of ascorbic acid (vitamin C) into tomato plants are found by László Havas to increase the size of the tumours produced in those plants by *Bacillus tumefaciens*. Mr. Havas recently described similar effects obtained with sex hormones.

A new pigment, myxoxanthin, has been extracted by Prof. I. M. Heilbron, B. Lythgoe and R. F. Phipers from *Rivularia nitida*, one of the blue-green algæ. The new pigment belongs to the carotene series, but unlike other plant pigments of that nature it has a single absorption band in carbon disulphide solution (maximum at 4880–4900 A.), and resembles in this respect the pigment astacene obtained from crustacea.

If we had independent knowledge of the composition of the sub-Pacific crust, observations of the surface waves of earthquakes would enable the thickness to be calculated. Dr. R. Stoneley, in commenting on a letter by Mr. H. F. Baird (NATURE, Nov. 2, p. 723), points out that valuable information about the Pacific floor could be obtained if a number of seismological stations were established on Pacific islands.

D. Ll. Hammick, G. C. Hampson and G. I. Jenkins have found that *p*-benzoquinone, its symmetrically substituted derivatives and tetramethyl-*cyclo*butane – 1 : 3-dione all have small but finite electrical moments when measured by the solution method. This is anomalous in view of the symmetrical structure usually assigned to these compounds and may be due to a general effect of the solvent or to an abnormally large atom polarisation.

Research Items

Norwich 'Woodhenge'

SOME further results of the excavation of the recently discovered 'Woodhenge' (see NATURE of September 7, p. 365) are described by Mr. J. G. D. Clark in *Antiquity* of December. When excavation began in August last, two rings were observable, of which the inner was interrupted by what was evidently a causeway; but the central area showed no signs of post-holes or other features. An eleven foot section was cut from outside the circle, this running for a distance of 100 ft. in all. Both the inner and the outer ditch proved to be shallow relatively to their width, and between them were the remains of a bank, much ploughed down. The outer ditch produced some third century Romano-British sherds from above a sterile layer overlying the primary silting. The inner ditch produced stratigraphical evidence of importance. Below three feet of infilling, ploughed in when chalk was used to marl the ground, down to the bottom of a black zone, were quantities of early iron age pottery, yet to be examined, and a strong admixture of Romano-British material, which appears to date from the third century of the Christian era. Evidently the iron age levels had been disturbed in Romano-British times. Below the iron age level was a sterile zone of primary infilling on a thin charcoal stratum on the floor of the ditch. This produced sixteen sherds of pottery and three or four 'crumbs' of the same ware, resembling 'beaker' on the inside and decorated in rusticated finger-nail style on the outer surface. The central area was stripped to the gravel and sand. There proved to be eight, not nine, post-holes, the timber part of the monument being on the horse-shoe plan, resembling the arrangement of the inner horse-shoe of blue-stones and of the trilithons at Stonehenge. The set of the ramps of the post-holes points to the erection of the timber uprights before the construction of the inner ditch.

Wild Cat and Domestic Cat

As the result of the measurement of a large number of Scottish wild cats (*Felis sylvestris*), including 42 specimens received complete in the flesh and 70 skulls, John C. Kirk publishes a useful comparison between the wild and domestic cats (*Scottish Naturalist*, 161; 1935). Domestic cats which have run wild soon assume the characters of the wild race, developing longer and coarser fur, longer limb-bones and larger teeth, and after two or three generations in a wild state would be scarcely distinguishable from the true wild cats, and the author thinks that probably there is a certain amount of domestic blood in the wild cat of the present day. In spite of these difficulties and of the fact that no single feature in the skull of the wild cat may not occasionally be duplicated in the domestic cat, the author gives a series of distinguishing marks which can generally be relied upon. On the whole, while the lower jaw is more strongly developed and the muscular ridges of the skull are strongest in the wild cat, the bones of the cranium are generally lighter and thinner than in domestic cats. The wild cat has longer limbs, longer and coarser fur, larger teeth, but shorter small intestine (43–51 in. against 58–66 in.).

Light as a Factor in the Growth of Barnacles

A STUDY of the distribution of the common barnacle (*Balanus balanoides*) upon the different sides of the wharf of the Atlantic Biological Station has led Prof. A. Brooker Klugh and Curtis L. Newcombe to correlate the differences with amount of sunlight (*Canadian J. Res.*, 13, 39, Sept. 1935). A significant correspondence was found between the rate of growth of the barnacles and the amount of illumination. Moreover, the difference between the amount of growth at widely separated vertical levels was similar to the difference in areas on the same level where there was wide variation in the amount of illumination.

Zoology of the Voyage of the *Belgica*

Two recent monographs (Expedition Antarctique belge, Resultats du Voyage de la Belgica en 1897–99 sous le Commandement de A. de Gerlache de Gomery. Rapports Scientifiques. Zoologie. Anvers, 1935) deal with the Pycnogonida (by Louis Giltray) and the Oligochæta by (Leon Cĕrnosvitov). There are few pycnogonids, but these are interesting and include a new species of *Nymphon*, *N. gerlachei*, an abyssal form from 460 m. depth, associated with *N. longicoxa*, Hoek, from Banquisi, lat. 71° 5′ S., long. 89° 3′ W. *N. gerlachei* has a very thin body and long thin legs, probably walking on fine mud. Only one specimen was found—a male. The Oligochætes collected by the expedition consist of eight species, all known forms. A new variety of *Chilota corralensis* is described, living under mosses covering rocks and dead leaves from Lapataia, Terra del Fuego. The type is only known from Corral in Chile, and the present variety, var. *belgicæ*, differs from it in several particulars, especially in colour, form of the body and the situation of the genital papillæ. Immature individuals were also found among roots of plants growing on the rocks near a waterfall in the Island of Londonderry.

A New Family of Sawflies and the Genera of the Cephidæ

MR. ROBERT B. BENSON (*Ann. Mag. Nat. Hist.*, (10), 16, Nov. 1935) has erected a new family, Syntexidæ, for a very interesting species of sawfly, *Syntexis libocedrii*, Rohwer. The species is at present only represented by two adult specimens in the United States National Museum and a few larvæ found boring in the wood of the incense cedar (*Libocedrus decurrens*, Wrr.) in California. The family is placed between the Xiphydriidæ and Cephidæ; but it is really very distinct from either, though heretofore included in the Cephidæ. In dealing with the Cephidæ of the world, five new genera are described; one of these, *Athetocephus*, is erected to contain two peculiar species from Madagascar, only the third and fourth known sawflies from that island. Many new characters used in the keys are illustrated in the twenty line drawings by the author. Attention is directed to the fact that the Cephidæ are not an unspecialised family as is generally supposed, but on the contrary, very highly specialised. In some respects, such as in the presence of a marked constriction at the apex of the basal segment of the abdomen, they show an approach to the formation of a propodeum characteristic of the other great sub-order of the Hymenoptera, the Apocrita.

Histology of Sponges

D. A. WEBB (*Quart. J. Micr. Sci.*, 78, Part 1, Oct. 1935) gives in an article of eighteen pages a useful résumé of the literature published since the beginning of 1914 on the histology, cytology and embryology of sponges. The different kinds of cells and the cytoplasmic inclusions are considered, and the second half of the article is devoted to gametogenesis, fertilisation and embryology. It is remarkable that stages in spermatogenesis are so rare, so that this "process still remains rather a mystery". Authors are, however, agreed that the spermatozoa of sponges are of an ordinary filiform type similar to those of most other animals. The transport of the spermatozoon to the oocyte in *Grantia* by means of an intermediary carrier-cell, as first described by Gatenby, has been confirmed by later workers for *Grantia* and *Sycon*, and for *Cliona* and *Reniera*.

Transpiration and Stomata in Desert Plants

THE first paper to be published by the Faculty of Science of the Egyptian University (*Bull. Fac. Science*, 1, Egyptian University, Cairo, 1934) deals with the vexed question of stomatal control of transpiration in desert plants. Earlier work of this nature is reviewed, and comment and criticism made of the lines of attack, methods of investigation and conclusions of the observers. In these present experiments, the investigators, A. H. Nontasir and A. M. Nigaleid, seem to have taken steps to eliminate some of the errors, often included unwittingly in this type of work, and their experiments have been repeated under varying conditions. An interesting modification is made in the relation of relative humidity to water loss—in this case it is the relative humidity *deficit* of the air which is considered in *direct* proportion to evaporation, which seems a much more rational correlation than that of actual humidity to water loss. The general results indicate once again that stomatal control is almost negligible unless the stomatal aperture is almost closed, that under conditions encouraging maximum evaporation the stomata are wide open, and that when such conditions are removed there is still a time lag in stomatal closure. Actually, in most cases, the water content itself is the most effective limiting factor, resistance to water loss increasing rapidly with falling water content, whilst at the same time spine formation and foliage reduction have a protective effect. Very detailed results of the experiments are given, and the paper is accompanied by a good representative list of references.

Hybrids of Tropical Orchids

A VERY interesting review by M. J. Costantin ("Les Hybrides des Orchidées tropicales", *La Nature*, Paris, November 15, 1935) describes the history of orchid culture since Neumann first succeeded in germinating the seed in 1844. Dominy, an assistant to James Veitch, was the first to hybridise two orchids (1856), and from that time, new hybrid plants have appeared in steady succession, until, at the present time, more than four hundred new kinds are described in most years. These hybrids are all fertile, and in some cases, seed can be produced parthenogenetically, following the mere stimulus of pollen upon the stigma. The account centres round the work of Noël Bernard, who introduced the symbiotic method of culture. Seeds were sown upon a sterilised medium which was then inoculated with a pure culture of a fungus, usually a species of *Rhizoctonia*. M. Costantin discountenances the asymbiotic method of culture, where seeds are grown on sterilised medium, containing glucose, with no added fungus. This is, perhaps, a little anomalous, for modern asymbiotic culture gives 100 per cent germination, and is used by all large orchid growers.

Horizontal Distortion of the Earth's Crust near Tokyo

IN the enclosure of the Tokyo Astronomical Observatory at Mitaka, five geodetic base-lines, each about 100 metres in length, are arranged so as to form a rhombus and its north-south diagonal. Once a year, on an average, since 1916, the lines have been measured, and the results show a relative increase or decrease in the area of the rhombus of the order 10^{-5}. The yearly variations have been discussed by Mr. C. Tsuboi (*Bull. Earthq. Res. Inst.*, **13**, 558–561; 1935), and they are compared with those of the mean annual height of the sea-level at Aburatubo, a mareograph station about thirty-seven miles south of Mitaka. Though the latter variations are partly due to meteorological conditions over the adjoining sea, it is remarkable how similar are the curves representing the two variations, an increase in the area of the rhombus corresponding with an upheaval of the sea-coast. It thus seems probable, as Mr. Tsuboi concludes, that the changes in the area of the Mitaka rhombus are not of local origin, but correspond with larger crust-deformations prevailing over at least the southern half of the Kwanto district.

Flood Regimen of the River Garonne

IN a studiously analytical monograph on the regimen of the Garonne, reprinted from *La Revue Géographique des Pyrénées et du Sud-Ouest* (April–July 1935), M. Maurice Pardé, professor in the School of Hydraulic Engineering of the University of Grenoble, has made an important contribution to the literature on river characteristics and discharges. The Garonne floods, says Prof. Pardé, illustrate most vividly the complex character of the river. In no other fluvial basin in France, otherwise than exceptionally, do floods rise to so great heights. There exist, with several variations, three distinct types of inundation: Oceanic-Pyreneean, Oceanic-Classic and Mediterranean, as compared with a single type for the Seine and the Po, two types for the Loire, three for the Rhine and four for the Rhone. In reality, the flood system is more complex on the Garonne than on the Rhine, since the characteristics of the three types persist in intensity as far as the lower course of the river, while the 'Mediterranean' floods of the Rhine are absorbed in Lake Constance and the summer Alpine floods lose their violence below the Neckar. Alone in Europe, the Rhone and the Danube exhibit a variety of inundations comparable with those of the Garonne basin. The Oceanic-Pyreneean floods rank first in intensity, and occur at all seasons, though rarely in advanced summer or at the commencement of autumn (September, 1772). It is in May and June that they attain their greatest frequency and gravity. The main cause is heavy rainfall on the northern slopes of the Pyrenees and of the Montagne Noir, produced by winds from a north-west or northerly direction. The Oceanic-Classic type of flood, mostly deleterious

in the lower Garonne, occurs chiefly in winter; simultaneously with the Garonne, this type frequently afflicts several other important watercourses in western Europe, primarily the Dordogne, the Vienne and the lower Loire, then the Seine, the upper Rhone, the Meuse, the Rhine, etc. Such floods originate regularly in the passage of an atmospheric perturbation over France, while an anticyclone, essentially convex towards the north-east, is stationed on the south-west of the Iberian peninsula. The 'Mediterranean' type of flood is produced by torrential precipitation induced by the south-east wind in the eastern part of the basin. The severity of the Garonne inundations is remarkable.

Infra-Red Absorption of Crystals

R. B. BARNES, R. R. Brattain and F. Seitz (*Phys. Rev.*, Oct. 1) have elaborated a theory of the infra-red absorption of cubic crystals, and have tried to correlate it with new experimental work on MgO. On the classical theory, a cubic crystal has only one characteristic absorption frequency, corresponding to a vibration in which like ions move together and unlike ions 180° out of phase. The new theory handles the crystal as a system of interacting particles arranged on a lattice, and a general potential function of interaction is set up. The existence of anharmonic terms in the potential function is supposed to modify the selection rules in such a way that a complicated secondary structure is superposed on the single absorption frequency. The experiments were made on crystals of MgO prepared in the electric furnace on evaporated films and on powder. They show the existence of a secondary structure, but the low resolving power and the fact that the crystals were at room temperature, this causing broadening of the lines, make a detailed comparison with theory impossible. Further experiments are being carried out.

Quantum Theory, Geometry and Relativity

THE quantum theory, with its principle of uncertainty, seems to show that ordinary geometry is not applicable to microscopic space. In a series of interesting papers by T. Hosokawa, K. Morinaga, T. Sibata, Y. Mimura and T. Iwatsuki (*J. Sci. Hiroshima Univ., A*, 5, 141, 151, 189 and 205; 1935), a new 'wave geometry' is discussed, which is chosen so as to conform with quantum theory. Its definitions are rather startling at first sight, as they are expressed in terms of matrices and a wave function which is a solution of a generalised Dirac wave equation. From these definitions an extensive theory is developed, more or less on the lines of the ordinary tensor calculus, giving results which are taken as the starting point of a new theory of relativity. It is claimed that this gives Einstein's law of gravitation in a natural manner. Another consequence of the new theory is the existence of gravitational waves, and equations are obtained which, it is hoped, will prove as useful in gravitational theory as are Maxwell's in ordinary electromagnetic theory. In short, the authors are attempting to go beyond the ordinary unified field theories, which leave out quantum theory, and to set up a universal scheme to embrace all physical theories. There are several points that have not yet been fully worked out, and it is too soon to say whether the attempt has been successful; but it certainly opens up what appears to be a very promising line of inquiry.

Diesel Fuel Research

RESEARCHES on Diesel fuels are being carried out by Prof. P. H. Schweitzer and T. B. Hetzel in the Pennsylvanian State College laboratories on oils for Diesel engines (Science Service, Washington, D.C.). The sources of petrol are continually diminishing, and unless it becomes possible to produce petrol cheaply from coal, we must anticipate to look forward to the day when motor-cars will be run with cheap Diesel fuels. Petrol 'knock' is due to the petrol starting to burn evenly in the cylinder, and then suddenly exploding, causing a 'knock'. For smooth running, it is necessary to retard the burning of the petrol, and this can be done by lead tetraethyl. In Diesel engines combustion is not started by sparking plugs but by spontaneous ignition due to the compression of the fuel, its temperature rising above that needed for explosion. If too much fuel explodes at once, there is a knock, and the way to stop it is to make the fuel burn as soon as possible after entering the cylinder, the remedy being to speed up combustion. Schweitzer and Hetzel have developed an ignition lag indicator which will be useful for testing the relative values of Diesel fuels. They employ the principle of a phonograph pick-up device in conjunction with a radio loud-speaker. The fuels are compared for performance over a wide range of compression values and the results found can be usefully applied in practice in special cases.

Preservation of Mine Timber

THE third of the series of Forest Products Research Records is entitled "Experiments on the Preservation of Mine Timber" by Messrs. J. Bryan and N. A. Richardson (H.M. Stationery Office, 1935). The timber used annually in the mines of Great Britain is valued at £6,000,000; it is estimated, however, that less than two per cent receives any preservative treatment. Losses are due to wood-destroying fungi. To some extent the reason why the non-expert is not so readily converted to the idea of preservative treatment is due to the fact that the incidence of attack is variable, some mines being quite free from infestation of this type. When conditions are favourable, such as in humid shallow pits, decay is very rapid, and the timber is short-lived if not treated with a preservative. The cost of timber is consequently high in such situations, and here preservative treatment would probably reduce running expenses of the pit. As is pointed out, the failure of mine timbers may often be due to incipient decay due to fungal attack, rather than to lack of individual strength. Thus preservative treatment may lead to greater safety in the mine. The note explains that experiments were inaugurated at two pits, the Langton Pit, Pinxton, near Nottingham, and the Woolmet Pit at Portobello near Edinburgh. The experiments were carried out with imported and home-grown Scots pine pit props which were treated at the pit-heads with solutions of sodium chloride (common salt), zinc chloride, sodium fluoride, Wolman salts, and placed in workings at about 800 ft. below the surface. In the Pinxton Collieries creosoted props were also used. The results attained so far after 4½–5 years inspection are considered satisfactory—the more expensive preservatives, namely, creosote, Wolman's salts and sodium fluoride, being the best.

Chemistry of the Vitamins

VITAMIN A

SINCE vitamin A has not yet been isolated, methods for the production of highly active concentrates are of interest. A method of comparing the richness in vitamin A of various products is the so-called 'blue value'. This is the number of blue units read with a Lovibond tintometer for 0·04 gm. of solid dissolved in anhydrous chloroform immediately after reaction with a solution of antimony trichloride in chloroform. Previous workers have prepared vitamin A concentrates by vacuum distillation, and very active materials had blue values of about 100,000—usually lower.

An adsorption method of concentration has now been investigated by H. N. Holmes, H. Cassidy, R. S. Manly and E. R. Hartzler[1]. The non-saponifiable portion of halibut liver oil was obtained in solution in pentane, the cholesterol and other impurities were frozen out by cooling for 7–10 days in a bath of solid carbon dioxide and alcohol, and filtered off under pressure, or by suction, through carbon dioxide snow. Solutions of 45,000–50,000, in one case 60,000, blue values were thus obtained. Filtration through an absorption column of Norit oxygen-freed charcoal, with special precautions to prevent oxidation, followed by a column of a new type of magnesia prepared from the precipitated hydroxide, gave blue values of 100,000–140,000, so that a concentrate of vitamin A at least 40 per cent more potent than any previously recorded was obtained.

VITAMIN B_1

By cleavage of vitamin B_1 with sulphite, a basic substance, C_6H_9NSO, is obtained as a colourless oil giving crystalline hydrochloride, chloroplatinate, picrate and picrolonate. E. R. Buchman, R. R. Williams and J. C. Keresztesy[2] now find that this substance gives on oxidation an acid with the formula $C_4H_4NS.COOH$, which is identical with one obtained by Windaus directly from the vitamin. The basic substance is regarded as a tertiary heterocyclic base with a β-hydroxyethyl side chain, $C_4H_4NS.CH_2CH_2OH$, and the vitamin itself as a quaternary salt of the base.

The presence of a quaternary nitrogen in the vitamin B_1 has been confirmed by electrometric titration with alkali by R. R. Williams and A. E. Ruehle[3], when the presence of a moderately strong basic nitrogen was revealed, too strong for a tertiary base, but not strong enough for a true quaternary base. The basic cleavage product, C_6H_9NSO, behaved as a typical tertiary base, but its methiodide closely resembled the vitamin not only in basic strength but also in exhibiting an unusual pseudo-basic behaviour, both substances requiring an additional equivalent of alkali for complete liberation of the base.

It had been suggested that the vitamin contains a thiazole nucleus, and titrations of some thiazole derivatives gave similar results. The conclusion is reached that vitamin B_1 contains two basic groups, one of which is of the same order of strength as the nitrogen in the quaternary salt of its basic cleavage product and in 4-methylthiazole ethiodide. This feature of the structural formula for vitamin B proposed by Williams[4] is thus confirmed.

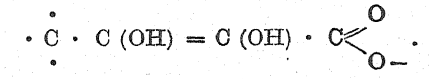
In view of the presence of sulphur in the vitamin B_1 molecule, and the suggestion that it contains a thiazole nucleus, it was obviously of interest to examine the mode of combination of the sulphur by methods recently developed for the study of sulphur in proteins, especially the behaviour towards alkali plumbite and bromine water. The vitamin B_1 and its basic cleavage product behaved very differently with both reagents, according to H. T. Clarke and S. Gurin[5], the vitamin giving lead sulphide relatively rapidly with plumbite reagent and the cleavage product scarcely reacting, and the latter is largely oxidised to sulphuric acid by bromine water under conditions in which the vitamin remains almost unchanged.

These results indicate that the sulphur atom in the base is linked to two carbon atoms in a structure in which the carbon groupings are more susceptible to oxidative attack than is sulphur. The acid obtained by Windaus, $C_5H_5O_2NS$ (see above), yields lead sulphide with plumbite, yet is resistant to oxidation with nitric acid. This is characteristic of the thiazole nucleus, and it is now shown, by synthesis, that the acid is 4-methylthiazole 5-carboxylic acid. The basic cleavage product is shown to be 4-methyl 5-β-hydroxyethylthiazole, which has been synthesised. Titrations of vitamin hydrochloride and of 4-methyl thiazole ethiodide indicate that the last of the three equivalents of alkali used, reacting about *p*H9, opens the thiazole ring with formation of a sulphydryl compound.

Examination of absorption spectra by A. E. Ruehle[6] shows that the ultra-violet absorption of the basic cleavage product of vitamin B_1 is not only similar to that of the thiazoles, but its derivatives also exhibit absorption similar to that of corresponding thiazole derivatives.

VITAMIN C

The titration curves and dissociation constants of *l*-ascorbic acid (vitamin C) were determined by Birch and Harris[7], who found at 16°–18° the values $pK_{a_1} = 4{\cdot}17$ and $pK_{a_2} = 11{\cdot}57$. A determination at 22°–23° by W. D. Kumler and T. C. Daniels[8] is now shown to give the values $pK_{a_1} = 4{\cdot}12$ and $pK_{a_2} = 11{\cdot}51$, in very good agreement. The hydrogen electrode was used. Titration curves for *l*-ascorbic acid and diethyl dihydroxymaleate in alcohol water solution were also determined, in view of the suggested formula for *l*-ascorbic acid in which this compound has no carboxyl group, but contains a grouping



Evidence that a structure of this type may give rise to relatively strong acid properties has been cited.

The β-ketonic ester, diethyldihydroxymaleate, contains this structure, and a consideration of its groups shows that it should be a stronger acid than *l*-ascorbic acid. Actually *l*-ascorbic acid is much

stronger, its first dissociation constant being a thousand times as great as that of the other compound. The apparent inability of the enolised α-hydroxy-β-ketonic ester type of compound to account for the acid properties of *l*-ascorbic acid suggests that some other grouping is responsible for its large first dissociation constant. It may, however, be suggested that the use of the ordinary hydrogen electrode with a compound containing a double bond requires further investigation.

Fire Resistance of Buildings

A LABORATORY of an unusual kind was opened by H.R.H. the Duke of Kent at the end of last month. This is the Fire Testing Station erected at Elstree by the Fire Offices Committee, an organisation representing the tariff insurance companies, for the purpose of investigating the resistance to fire of building materials and elements of structure.

The need of such an institution has been apparent for some years, and has been steadily growing. Little enough is known of the protection against fire afforded by the traditional types of building material, and still less of the many new types which have appeared in recent years. This uncertainty is reflected in the building codes issued by local authorities, which, so far as provisions against fire are concerned, are often contradictory.

A good deal of research has been carried out abroad, notably at the Underwriters Laboratory at Chicago; and in Great Britain, before and during the Great War, the now defunct British Fire Prevention Committee investigated certain aspects of the problem. But the first attempt in Great Britain to put the whole subject on a sound basis was taken by the British Standards Institution in 1932. In this year, it published "Definitions for the Fire Resistance, Incombustibility and Non-Inflammability of Building Materials and Structures" (B.S.S. No. 476), which laid down a test procedure for assessing the fire resistance of structural elements by means of a standard test upon full-sized specimens.

From the evidence of actual fires and from demonstration tests, it has been established that the temperature within a fiercely burning building rises rapidly to about 1,500° F. and thereafter more slowly up to a maximum of about 2,000° F. The standard test provides that specimens shall be heated in accordance with a time-temperature curve which approximates to that of recorded conflagrations; furnace temperatures of 1,000° F., 1,700° F. and 2,300° F. are required at the expiration of 5 minutes, 1 hour and 8 hours respectively from the beginning of the test. It is also necessary to take account of the effect of water from fire hoses impinging on a heated structure. The specification therefore requires that immediately following the period of heating the specimen shall be subjected to a jet from a fire hose applied under standardised conditions for a period equal to one minute for each hour of fire exposure. In the case of load-bearing structures, it is further provided that a load equal to 1½ times the working load shall be maintained on the specimen throughout the whole period of the test. In certain cases, the load must be re-applied forty-eight hours after the completion of firing.

According to the period which elapses between the beginning of the test and the failure of the specimen, the specimen is classified into one of five grades, the highest being represented by a fire-resistance period of six hours and the lowest by one of half an hour.

In the case of walls, floors and other elements which function as separating structures, the specimen is heated on one side only, and failure is indicated either by a temperature rise on the unexposed face of more than 250° F., or by the development of cracks through which flame can pass, or by collapse under load. Columns and other elements which serve only as load bearers are heated on all sides and are said to have failed when collapse under load occurs.

By issuing this specification, the British Standards Institution not only provided a clear basis for the study of the subject, but also directed attention to the absence of adequate testing facilities. As a result of a conference between interested bodies, the Fire Offices Committee undertook to provide these facilities and the Department of Scientific and Industrial Research to assist in the solution of technical problems.

The Testing Station at Elstree consists of two buildings: one contains equipment for testing the fire-resistance of structural elements; in the other, provision is made for continuing the work on sprinklers, fire-extinguishers and other appliances which has hitherto been carried out by the Committee at Manchester. For testing structural elements, three units have been provided—for walls, columns and floors respectively. In each case, heat is provided by a gas-burning furnace operated electrically from a control room adjoining and overlooking the main building. The gas-air mixture is fed to the burners through 'inspirators' which automatically maintain a constant proportion of the two ingredients at all pressures; the air is supplied at a maximum pressure of approximately 15 in. of water and the gas at the normal pressure of the mains. The fuel supplied to different parts of the furnace is controlled separately, with the view of maintaining a uniform temperature over the whole area of the specimen.

Both furnace and specimen temperatures are recorded by thermocouples connected to instruments located in the control room. Platinum rhodium–platinum couples are used for furnace temperatures, and chromel–alumel or copper–constantan couples for specimen temperatures. The leads from each separate equipment pass through a bus-board mounted on the instrument panel, by means of which a quick change-over may be effected from one furnace to another.

In the wall and column units, the load is applied to the specimen by mounting it in a heavy, built-up steel frame designed so that an upward thrust can be given to the bottom beam of the frame by means of hydraulic rams. The rams are operated on a maximum oil pressure of two tons per square inch, the oil being supplied by an electric pump and the load being recorded by a pendulum dynamometer in the control room. These loading frames have a maximum capacity of 500 tons. They stand in pits in the floor of the building, and the furnaces used in conjunction with them are built on wheels so that they can be moved away for the water test. In the floor testing unit, the furnace is fixed and the specimen is lifted away for the water test by a 30-ton travelling electric crane.

The essential aim of the Station is to provide the means of carrying out tests, as rapidly and economically as possible, on the basis of the standard specification. A considerable amount of work upon traditional materials is required, but tests of new types will be run concurrently.

Arrangements have been made whereby the facilities of the Station will be available to the Department of Scientific and Industrial Research, through its Building Research Station, both for carrying out a general programme of research into the fire resistance of traditional materials, and for conducting tests on behalf of manufacturers in accordance with a fixed schedule of charges, when a certificate of performance is required. It is hoped that the industry will take full advantage of the opportunity which now occurs to have the fire-resisting properties of its products assessed on a proper basis.

Scientific Research in Transport

NEW LABORATORY OF THE LONDON, MIDLAND AND SCOTTISH RAILWAY

LORD RUTHERFORD opened the new research laboratory at Derby of the L.M.S. Railway on December 10 (see NATURE, December 14, p. 949).

A distinguished party of guests travelled from St. Pancras by special train, the engine of which was named "Lord Rutherford of Nelson" by Lord Rutherford's small grandson, Pat Fowler, and at Derby luncheon was served on the train. Speeches made during luncheon by Sir Josiah Stamp and Lord Rutherford were relayed to the various cars, and everyone heard excellently. In his speech, the former specially welcomed Sir William Bragg and Sir James Jeans. He recalled that when he was president of the Institute of Transport, he devoted his presidential address to the subject of scientific research in transport and expressed his gratification that some of his dreams have now come true. The days of haphazard and rule of thumb tests are over; the days of controlled and directed experiment under arranged conditions have fully arrived. At the same time, he said, "I would like to stress the fact that we are not trying in this new laboratory to supersede or to rival scientific effort in all directions". The company is still extending its use of outside facilities in connexion with the Department of Scientific and Industrial Research.

Lord Rutherford, in declaring the new laboratory open, said that the L.M.S. is described as a public utility company; but it is more like a State within a State, as it has a gross revenue of nearly seventy millions and its own sea, land and air forces all organised for the most efficient service to the community. On the map, the railway appears to be not merely the backbone but rather the whole vertebrate system of Great Britain. Lord Rutherford said he is convinced that there is scarcely a single unit, whether of machinery or lay-out or even of organisation, that cannot be improved for its purpose by the application of scientific research. But even when valuable results are obtained, there still remains the serious difficulty of introducing them into this great organisation, which has developed over long years a successful routine. To obtain the best results from a laboratory such as the one at Derby, it is essential to develop mutual respect and understanding between the scientific man and the practical man. He expressed the hope that the officers and staff of the Railway will take the greatest interest in the new laboratory and utilise its services to help solve their problems.

Lord Rutherford then declared the laboratory open, and the staff and visitors were divided into groups and shown over it, some of them also inspecting the wagon and locomotive works.

The L.M.S. Railway is probably the largest commercial undertaking in the world. It has an authorised capital of 439 million pounds and gives employment to 223,000 persons. In addition to 7,000 miles of line open to traffic, it possesses 8,000 locomotives, hundreds of thousands of vehicles, 45 steamers and 31 hotels. In addition, it conducts several extensive manufacturing undertakings in connexion with its transport business. In 1930, Sir Harold Hartley was appointed vice-president and director of scientific research. In 1932, the chemical, paint, metallurgical and textile laboratories were formed into a research department. The effect of the completion of the new laboratory is to concentrate in one building the various research sections. In addition to possessing a large staff of specialists to deal with the various problems which are continually arising, the department utilises to the fullest extent the research organisation of the Department of Scientific and Industrial Research. It is also a member of six research associations, and allocates certain problems to research laboratories at the universities.

The Metallurgical Section is concerned with investigations relating to the selection of metals and their manipulation by casting, forging, heat treatment and welding. It also examines materials which have failed to give a satisfactory performance in service. The Engineering Section deals with research on the design and performance of engineering details of machines and structures. It studies aerodynamical problems connected with the air resistance of trains, with wind pressures, ventilation systems and so on. The Textile Section is responsible for the inspection and testing of the various textile materials purchased by the Company, and for drawing up specifications

controlling their quality. This laboratory makes about eight thousand tests every year. The Paint Section specifies and tests all kind of paint materials. It is also concerned with the routine control of the manufacture of paint- and varnish-cleaning agents. In the constant-temperature and humidity room the nature of all textiles is closely examined. A humidity control apparatus maintains constant conditions of 75° F. and 66 per cent relative humidity. This is essential, as the properties of textiles vary largely with temperature and humidity.

In the workshop, special precautions have been taken to prevent the transmission of vibration. In some of the rooms accelerated tests are carried out. For example, in the paint exposure laboratory, by the use of the 'weatherometer', results can be obtained in five weeks which with outdoor exposure alone would have taken twelve months. At the moment, more than a thousand outdoor exposures are in progress. Visitors were impressed by the practical nature of the tests, and the great economic value of the results to the Company.

Energy-Output of the Coal-Miner

IN a paper read before the Institution of Civil Engineers on December 13, Prof. Kenneth N. Moss discussed the energy-output of the coal miner.

The object of the first part of the paper was to show that the performance of manual work necessitates a food-input in excess of the energy-output. Thus if it is required to maintain a high work-output from men engaged in manual work, the engineer in charge must satisfy himself that the calorie-value of their food-input is adequate for the purpose.

Some years ago, Prof. Moss determined the calorie-value of the daily food-input of sixty colliers, and found that the average was a little more than 4,700 Cal. The average oxygen consumption per minute throughout the working shift on the coal-face for twelve colliers was found to be 1,333 c.c., which, after deducting the average oxygen basal resting-rate of 235 c.c. of oxygen a minute, was found to be equivalent to 16,950 ft.-lb. of energy.

The total energy expended below ground during a 7½-hour shift is about 2,800 Cal., and the energy expended during 24 hours is estimated to be about 4,500 Cal. Thus the calorie-value of the daily food-input of a miner should be 4,750–5,000 Cal., to enable him to do his work without loss of body weight or coal-output. The actual average work-output, assuming the mechanical efficiency of the body to be 25 per cent, was 4,237 ft.-lb. per min. during the time spent on the coal-face.

If a miner has to work or walk in places where he has to stoop a good deal, his energy-output is greatly increased, or in other words, the mechanical efficiency of his body is seriously diminished. Thus if a miner has to work in a stooping position so that his body height is reduced by 40 per cent, his energy-output is increased by 65 per cent. If men have to walk a good distance along low roadways the energy expended may be so great as seriously to affect their work-output in the working place. Alternatively, if men are called upon to walk to their work under such conditions, their food-intake must be increased to enable the extra energy to be expended.

Referring to the physiological aspect of the problem, Prof. Moss said that a miner at work in air at a dry-bulb temperature of 98°–100° F., and a wet-bulb temperature of 85° F., can lose as much as 18·56 lb. of moisture through the sweat-glands and respiratory tract during 5½ hours work. If the work-output below ground is equal to 2,800 Cal., it is necessary, assuming that no heat is lost by radiation and conduction, to evaporate 10·6 lb. of water from the skin to neutralise the heat generated in the body during work. The significance of a high wet-bulb temperature is thus clear.

The drinking of water when at work is essential in order to keep the body-temperature normal, though excessive drinking of water is harmful. The significance of the chloride content of the blood points to an effective remedy for heat-cramp and fatigue; the addition of 5–10 gm. of sodium chloride to 1 gallon of drinking water will prevent the cramp, and to a great extent the fatigue, which is caused by hard work under trying air-temperature conditions.

Archæological Research in South Africa

ONE of the biggest drawbacks to the proper study of prehistoric archæology in South Africa has been, and still is, the complete absence of a properly worked out and correlated geological background. The advances and recessions of ice sheets during the Quaternary provide this background in Europe, and broadly speaking, the existence of the geological canvas has not only created a great stimulus to research in prehistory generally, but has actually become an essential feature of the proper study of the subject. In South Africa there is unfortunately no such background. Prehistorians will therefore be interested to know that the Directors of the Geological Survey and the Bureau of Archæology of the Union of South Africa have arranged a joint and detailed geological and archæological survey of certain vital sections of the Vaal and Riet River Valleys and their tributaries, with special reference to climatic and other conditions during the Quaternary. These valleys hold the secrets of climatic fluctuations and earth movements that were experienced in post-Pliocene times in South Africa, secrets that may be found to be intimately interrelated with climatic fluctuations and movements in other parts of the world—in East Africa and Europe particularly. If correlation is possible and earth

movements and 'pluvial' and interpluvial conditions here can be satisfactorily correlated with similar conditions in East and Central Africa and with glacial and interglacial conditions in palæarctic regions, we must ultimately be led to a better, if not a proper appreciation of the relative time horizons when men practising similar material cultures appeared on the scene in these continental extremes. The issue is of the greatest moment in that men who made Chelles-like tools are believed to have appeared in Southern Africa during early Pleistocene times, and this new undertaking, sponsored entirely by the State and under strict control, therefore represents the greatest step forward prehistory has known for some time.

The sequence of prehistoric material cultures in South Africa is too well known to need recapitulation here. From the Stellenbosch Culture (Chelles + Clacton types to Acheul + Old Levallois types) through the Fauresmith Culture (La Micoque + Combe Capelle + Levallois types) upwards, the story is complete. All we need is the geological and particularly the climatological background.

Ancient river terraces, stratification and its causes, associated fauna, alluvial deposits, etc., will be examined by geologists and archæologists working in the closest harmony over several hundred square miles, and it is confidently anticipated that this work will lay the foundation for a better, if not a full appreciation of the geological and climatological canvas on which all our pictures of prehistoric man in South Africa must be drawn. This work should undoubtedly lead us to a better appreciation of possible and more far-reaching correlations with climatic fluctuations and earth movements in other parts of the world, and so to the relative dating of the appearance of particular lithicultural horizons in widely separated areas.

The value of the Vaal River was recently brought out by Prof. Van Riet Lowe, director of the Bureau of Archæology, in the article "Implementiferous Gravels of the Vaal River at Riverview Estates" in NATURE of July 13, 1935 (pp. 53–56). Similar conditions, Prof. Van Riet Lowe assures us, exist over many hundreds of miles along this amazingly rich valley.

The areas to be attacked immediately are those that will be inundated after the completion of the huge dams at present in course of erection at various sections across these rivers.

Fieldwork is being started immediately, and it is anticipated that it will continue for at least eight months. Two geologists and an archæologist are taking the field at once. The major issue is undoubtedly geological and this side of the problem is therefore being stressed.

Study of Nutrition

INQUIRY BY LEAGUE OF NATIONS EXPERTS

THE Expert Commission on Nutrition appointed by the Health Committee of the League of Nations met on November 25 at the London School of Hygiene and Tropical Medicine. Those present were:

France: Prof. L. Alquier, director of the Institut d'Hygiene Alimentaire, Paris; Prof. L. Lapicque, professor of physiology at the Laboratory of Physiology, Sorbonne, Paris.
Scandinavia: Dr. Axel Höjer, Generaldirektor, Medicinalstyrelsen, Vallingatan 2, Stockholm.
United Kingdom: Prof. E. P. Cathcart, professor of physiology, University of Glasgow; Prof. E. Mellanby, secretary of the Medical Research Council, London; Sir John Boyd Orr, director of the Imperial Bureau of Animal Nutrition, Reid Library, Rowett Institute, Aberdeen.
United States: Prof. E. V. McCollum, professor of biochemistry, Johns Hopkins University, Baltimore; Dr. Mary Schwartz Rose, Columbia University, New York; Dr. W. Sebrell, chief of the Department of Nutrition, National Institute of Hygiene, Washington, D.C.
U.S.S.R.: Prof. Sbarsky, director of the Central Nutrition Institute, Moscow.

Two other members of the Commission, namely, Prof. Durig of Vienna, and Prof. Schiotz of Oslo, were unable to attend the meeting.

The Commission elected Prof. Mellanby as chairman and Dr. McCollum as vice-chairman.

A statement was presented on the origin of the studies of the question made under the auspices of the League of Nations. After a general exchange of views, the Commission decided to draft a statement on scientific principles governing dietaries of certain population groups—namely, women during pregnancy and lactation, infants, school-children, and adolescents up to the age of twenty-one years.

Two sub-committees—one on energy-producing substances, under the chairmanship of Prof. Cathcart (members: Profs. Alquier, Lapicque, Sbarsky and Sebrell); and the other on non-energy-producing substances (such as mineral salts, vitamins, etc.), under the chairmanship of Prof. McCollum (members: Profs. Höjer and Mellanby, Sir John Boyd Orr and Dr. Schwartz Rose, with Dr. Harriette Chick of the Lister Institute as secretary)—were entrusted with the task of drawing up detailed recommendations to be submitted to the plenary commission at a later meeting.

In the course of the week, each of these committees drew up its own report, and from them a combined report covering the whole subject was drafted and, after due consideration, adopted unanimously. This report is now being printed at Geneva in English and French, and will be published in the near future. It will undoubtedly arouse great interest among those concerned, both from the scientific and social aspects of nutrition. The report of this Commission of Experts on Nutrition will then be sent on to a mixed committee which includes economists and experts in agriculture as well as representatives of the present Commission. Prof. Mellanby and Prof.

McCollum were appointed representatives on this mixed committee, with Sir John Orr and Dr. Mary Schwartz Rose as substitutes. This mixed committee will meet in February 1936 at Geneva.

The modern knowledge of nutrition being still in the stage of development, the Commission had to consider future progress. It drew up a list, in order of priority, of the problems for future study at various scientific institutes already engaged on similar lines of research, with a view to practical progress.

Educational Topics and Events

CAMBRIDGE.—The Lowndean professorship of astronomy and geometry will become vacant by the retirement of Dr. H. F. Baker on September 30, 1936. A meeting of the electors will be held on January 31, 1936. The General Board has recommended and the Council of the Senate has determined, that at this election preference shall be given to candidates whose work is connected with geometry in the widest modern sense. Candidates for the professorship are requested to communicate with the Vice-Chancellor and to send him, on or before January 14, 1936, ten copies of any statement or testimonial which they desire to submit to the electors.

It is recommended by the Faculty Board of Engineering that J. A. G. Haslam, of Corpus Christi College, be appointed assistant in research in the Sub-Department of Aeronautics with a stipend of £500 a year, made up of £300 from the University grant and £200 from Sir John Siddeley's gift for aeronautical research.

SHEFFIELD.—The title of honorary lecturer in physics has been conferred on Dr. W. H. George, Sorby research fellow.

Mr. H. T. Protheroe has been appointed assistant lecturer in metallurgy (founding).

The Rockefeller Foundation, New York, has made a grant of £200 in aid of research in the Department of Pharmacology.

THE annual report of the Yorkshire West Riding County Council on the county minor scholarships examinations, recently issued, records an important advance in the employment of intelligence tests. For the last three years, while an intelligence test has been *taken* by all candidates, it has been *used* only as a means of differentiating the border-line cases. This year it has been taken into account in all cases except those where low marks in English and arithmetic precluded the possibility of awarding a scholarship. One effect has been to give the chance of a scholarship to candidates obtaining a high 'intelligence quotient' whose marks in arithmetic and English would not last year have been high enough to bring them within the range of the border-line. The examiners believe that, as a result of the employment of the test, awards have been made only to those candidates who have the necessary ability and educational background to enable them to profit by a secondary school education. Special attention was directed last year to the widely prevalent fault of reading the questions carelessly and of introducing irrelevant matter into the answers. This fault was much less conspicuous this year.

Science News a Century Ago

The Elephant House at the Zoological Gardens

IN the issue of *The Times* of Christmas Day, 1835, is a note on the Zoological Gardens from a correspondent who says: "The elephant has taken possession of the new house which has been prepared for his reception, and he now enjoys the society of the young female of his order presented by His Majesty. The house is by far the best building in the gardens, and is every way worthy of so great a personage. There is a mode of heating it adopted which we understand is perfectly original and seems likely to supersede all other methods in use in warming churches, chapels, and all buildings having incombustible floors. The simplicity of the plan is as remarkable as it is apparently effective and unexceptional. . . . The fuel used is inconceivably small, and the cheapness, simplicity and safety of this new method of heating cannot fail to engage the attention of all scientific and practical men."

A Christmas Experiment in Magnetism

FARADAY notes in his Diary an experiment, made on the day after Christmas 1835, on "the possibility that some metals, not magnetic at common temperatures, might become so at low temperatures". He must have been occupied at the time with preparations for the Juvenile Lectures, for he gave the Christmas course of 1835-36 on electricity; but the day was a very cold one, for he records the temperature as 25° F.; and neither Christmas festivities nor lecture preparations could induce him to forgo so favourable an opportunity. The apparatus was carried up to the roof of the lecture theatre and there, where the fullest advantage of the low out-of-doors temperature could be taken, the experiment was made.

He had a magnetometer with a delicate astatic needle: "This kind of needle was used as the most delicate test". Some wires of various metals were tied up in little bundles with platinum wire. "Then cooled these bundles in liquid sulphurous acid, in watch glasses containing a little mercury also, and when below the freezing point of the mercury, brought them close to the ends of the astatic needle to ascertain if they had become sensibly magnetic; but could not observe the least indication of such an effect, though I think the temperature must occasionally have been 60° or 70° below Zero of Fahrenheit".

New Classification of Animals

ON December 26, 1835, the *Athenæum* stated: "M. de Humboldt has presented to the French Academy of Sciences, in the name of M. Ehrenberg, correspondent of the Academy in Berlin, a table dividing the animal kingdom into 29 classes. This division is founded on the organisation and generality of a type, lying in the sensitive, vascular, locomotive, nutritive, and propagative systems. Twenty-two of the groups belong to animals without vertebræ, which are divided according to the presence or absence of a heart, Cordata and Vasculosa. In the latter, the vessels do not present anything like pulsation, and the digestive organ is either simple and solitary, as in the Tubulata, or divided and multiform, as in

the Racemosa. In the course of his travels in Syria, Nubia, Dongola, the Red and Caspian Seas, etc., M. Ehrenberg has had an opportunity of examining a number of organised beings, and has continued his microscopic researches since that period; but he only offers his table as a sketch capable of perfection, and successive developments."

Christian Gottfried Ehrenberg was born in 1795 and died in 1876. His first travels, lasting from 1820 until 1826, were made with Hemprich, and it was in 1829 that he set out with Humboldt to visit the Ural and Altai mountains. His great work "Infusionsthierchen" appeared in 1838.

Goodyear and India Rubber Manufacture

QUOTING from the *New York Journal of Commerce*, the *Mechanics' Magazine* of December 26, 1835, said: "A discovery has recently been made by Mr. C. Goodyear, by which India-rubber, after having been dissolved, can be restored by a cheap process to its original whiteness, and the pure grain formed into a fabric to be used instead of cloth, leather or parchment, and can be moulded into almost any form; and can also be combined in a variety of ways with cloth, cordage or leather. Being first made white, it admits of every shade of colour, worked in, and as durable as the rubber itself. A variety of fine specimens are now being exhibited at the Mechanics' Institute at Castle Garden, which will give an idea of the general utility of the invention."

Charles Goodyear (1800–60) first turned his attention to rubber in 1834. His work of 1835 was only partially successful, but four years later he accidentally discovered the process of vulcanising. He has been called "the Palissy of the rubber industry".

Societies and Academies

LONDON

Royal Society, December 12. F. C. COURTICE and C. G. DOUGLAS: The effects of prolonged exercise on metabolism. In the normal postabsorptive subject, there is a striking fall of the respiratory quotient during rest subsequent to work which may last for hours. This is accompanied by ketosis and a progressive slow fall in the carbon dioxide combining power of the blood. Ketosis can readily be prevented by taking a carbohydrate rich diet on the previous day, but still occurred with great frequency when either an ordinary breakfast or a quantity of sugar was ingested shortly before beginning the experiment, the main effect in the latter case being apparently increased utilisation of carbohydrate during the work. The fall of respiratory quotient is attributed mainly to a reduction of the ratio of carbohydrate to fat oxidised owing to depletion of stores of available carbohydrate during the work, but in addition there may be some conversion of fat into stored glycogen, though only to a small extent. During post-exercise rest there is reduced sugar tolerance, and the possible influence of endocrine secretions on carbohydrate metabolism during muscular work is discussed. W. L. FRANCIS: The surface membranes of muscle fibres. Using Osterhout's methods as a guide, the following results have been obtained. The *p*H of fresh muscle brei is found with a quinhydrone electrode to be 7·1, in agreement with estimates by other workers of the *p*H of resting living muscle. The *p*H after 24 hours is 6·7. The composition of an aqueous solution resembling brei in its inorganic content is discussed. The stumbling block is the phosphate, which can only be made 1/5 as concentrated in aqueous solution as in the muscle fibre. The diffusion potentials between brei and various electrolyte solutions were measured. They point to the mobility of anions being very low in brei compared with their mobilities in aqueous solution. The vapour pressure of brei is found by Barger's method to be equivalent to 1·06 per cent sodium chloride. The effects of cut muscle, brei and various experimental solutions on the resting potential are investigated with the view of finding what the 'asymmetry' potential of the surface membrane would be if the media on both sides were the same. The value would be 10–20 mv. reckoned inwards. The diffusing substance need only saturate the interfibrillary spaces in order to produce its full effect on the potential at the fibre surface.

PARIS

Academy of Sciences, November 18 (*C.R.*, 201, 917–996). ABRAHAM WALD: The curvature of surfaces. P. RACHEVSKY: A dual metric geometry, based on generalised Cartan spaces. A. KHARADZÉ: A functional operator and the generalisation of Legendre polynomials. GEORGES GIRAUD: Problems of the type of Dirichlet and Neumann in certain cases where the data are discontinuous. PIERRE BOOS: The characteristic properties of certain analytical surfaces. PAUL FLAMANT: Two functions attached to a function capable of summation, and their application to the limit of Lebesque integrals. F. LEJA: A harmonic function connected with any closed ensemble of points of space. LÉON BESCHKINE: The equations of equilibrium of thin surfaces. ANTOINE MAGNAN and CLAUDE MAGNAN: Making evident small differences of the refractive index in liquid media. Application to the study of the movements of water such as that produced by the motion of a fish. The apparatus records the motion of the water on a kinematograph: six photographs are reproduced. PIERRE ERNEST MERCIER: The characteristic functions of a cantilever wing (resistance in bending). JACQUES VALENSI: Study of the flow of air round the wing of an aeroplane: marginal phenomena. Results obtained by a photographic method: two photographs are reproduced. DANIEL BARBIER: The colour temperatures of the stars. PAUL SOLEILLET: The coherence of vibrations in optical resonance. JEAN ROULLEAU: The determination of the contact resistance metal – cuprous oxide. JEAN MERCIER: Contribution to the study of the synchronisation of oscillators. CHARLES DEGARD: The diffraction of electrons by chloroform, and the structure of the molecule: the Urbain model and the tetrahedral model. The Urbain formula (the co-ordinative formula $CCl_2.HCl$) and the usual tetrahedral $CHCl_3$ both agree with the experimental results. Experiments on electronic diffraction cannot decide between the two formulæ. PIERRE JACQUET: The practically instantaneous action of certain colloids on the electrolytic deposit of copper. During the electrolysis of copper sulphate solutions, it was found that only the proteins (gelatine, serum albumin) have a marked action during the first moments of electrolysis: the gums act much more slowly. HENRI BIZETTE and TSAÏ BELLING: The magnetic double

refraction of nitric oxide. Experimental results obtained with the large electromagnet of the Academy of Sciences, the nitric oxide being under pressures of 80 and 100 atmospheres. MLLE. ARLETTE TOURNAIRE and ETIENNE VASSY: The continuous spectrum of deuterium. Comparisons of the spectra of deuterium and hydrogen show slight differences. The curves of the two gases coincide at about 4000 A., and then deviate very slightly as the wave-length diminishes. The continuous spectrum of deuterium is a little more intense than that of hydrogen. PAUL GOLDFINGER, WLADIMIR LASAREFF and BORIS ROSEN: The energy of dissociation of carbon monoxide. Among the different possibilities deduced from the CO spectrum, only the value for the dissociation energy 9·1 v.e., giving 123·6 kcal. for the heat of sublimation of carbon at 0° K., is not in contradiction with the thermo-chemical and spectroscopic data. LÉON GUILLET, JR.: The modulus of elasticity of the copper–beryllium alloys. Beryllium increases the modulus of elasticity of copper: the alloy with 15 per cent of beryllium has a modulus equal to that of steel. MARCEL PRETTRE: The influence of the gases adsorbed by the wall of the vessel on the chain reaction of mixtures of hydrogen and oxygen. JEAN AMIEL: Some organic cupritetrachlorides and cupritetrabromides. JEAN LOISELEUR: The formation of protein thioderivatives with the aid of carbon disulphide. Carbon disulphide transforms casein, gelatine and egg albumin into thio derivatives, probably by forming thiosulphocarbamic groups with certain amine groups. These substances are soluble in organic solvents. YVES VOLMAR and BJÖRGE HANSEN: The alcoholysis of olive oil. By fractional distillation under pressures below 1 mm., methyl palmitate, oleate and methyl arachidate were isolated. ALFRED SILBERSTEIN: The crystalline parameters of the double bromide of copper and ammonium. This double salt, like the corresponding chloride, is quadratic. The parameters resulting from an X-ray study are given. JACQUES BOURCART: The quaternary in the Meknès (Morocco) district. SIVASUNDEN DEB: The discovery of nummulites in the nummulitic grits of the Alpes-Maritimes, and on the origin of this series of strata. G. DENIZOT: The distribution of the lower alluvia in the Loire valley. FRANCK BOURDIER: The stratigraphy of the quaternary ante-Wurmian alluvia of the Grésivaudan and of the Chambéry valley. RAYMOND DECARY: The Mahajamba River of Madagascar and its temporary captures by the Kamoro. Details of the five changes of course of this river since 1864, conditioned by changes in the rainfall in this region. DENIS BACH and JEAN FOURNIER: The assimilation of oxalic acid by *Aspergillus niger*. ANDRÉ BOIVIN, MAX MARBE, MME. LYDIA MESROBEANU and PETRE JUSTER: The existence in *Bacillus tumefaciens* of an endotoxin capable of causing the formation of tumours in plants. JOSEPH MAGROU: The immunity and hypersensibility of the *Pelargonium* towards reinfections by *Bacterium tumefaciens*. J. ANDRÉ THOMAS: A new mode of direct cellular multiplication. Meroamitosis. PIERRE LESNE: Certain faunistic relations between Madagascar and south-eastern Africa. LÉON BINET and G. WELLER: The liver and glutathione. JACQUES PARROD: The formation of hydrocyanic acid, starting with some organic compounds, in the presence of ammoniacal copper sulphate. This appears to be a general property of reducing sugars. Carbon monoxide and formaldehyde give no hydrocyanic acid under the same conditions.

LENINGRAD

Academy of Sciences (*C.R.*, 3, No. 4; 1935). P. K. RASHEVSKIJ: Metric duality in Finsler's two-dimensional geometry, particularly on an arbitrary surface. J. SEKERZH-ZENKOVICH: On the theory of currents. V. M. CHULANOVSKIJ: The rotation structure of the nitrogen molecule in the Schumann region. S. A. ARZYBYSHEV: Note on the paper "On the electrolysis of copper in rock salt" (*C.R. Acad. Sci.*, 4, 25; 1934). A. ZHUCHOVICKIJ: A new method of solution of variation problems of quantum mechanics. N. A. PREOBRAZHENSKIJ, A. M. POLIAKOVA and V. A. PREOBRAZHENSKIJ: Alkaloids of the leaves of jaborandi (6). Synthesis of racemic homopilopic acid. M. M. KATZNELSON and M. I. KABACHNIK: Amination with sodium and potassium amides. (4) Nitration of α-amino-anabasine. A. E. FERSMAN: The periodic system of energy coefficients. V. A. DEVIATNIN and V. M. DOROSHENKO: A chemical method for determining vitamin C. F. LOEWINSON-LESSING: The chemical composition of tectites. A. M. DJAKONOV: New Ophiurans from the Sea of Japan (1). S. A. CHERNOV: New data on the distribution of the Indian snake *Lycodon striatus*, Shaw, in Soviet Middle Asia.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Saturday, December 28

ROYAL INSTITUTION, at 3.—Dr. C. E. K. Mees: "Photography" (Christmas Juvenile Lectures. Succeeding lectures on December 31 and January 2, 4, 7 and 9).

'Justice' in Africa

AS the year draws to its close, the passing of time reminds us of the useful convention whereby we are encouraged to enter upon some sort of a stocktaking preparatory to the closing of the annual account. In such a survey of the past year, the chain of events which has threatened, and still endangers, the peace of the world must be a salient item. Here, however, the very magnitude of the issues involved hampers critical judgment, and while the event is weighed in the scale according as it has made for or against the working of the machine which we call the League of Nations, it may not readily be discerned that 'profit and loss' are not to be assessed in terms of the number of nations declaring their formal adherence to Article xvi, but rather in any real progress towards the universal application of the fundamental principle of justice as between man and man, towards which the League was a gesture of aspiration, as well as an admittedly imperfect piece of machinery for its attainment.

However posterity may apportion blame as between Italy and Abyssinia for breach of the peace—no attempt will be made here to estimate the merits of the dispute—there can be no question that the principle of the League, as well as the letter of its Covenant, has been violated. Should the League fail to vindicate that principle, through it the prestige of white civilisation will be affected throughout Africa.

The admission of Abyssinia to the League is a matter of past history. It is profitless now to discuss whether that admission was justifiable or not. But it would be idle to pretend that she stood upon an equal footing with other members of the League. Admission was an earnest of security in the upward struggle from barbarism to which her rulers were then committed; and this attack on her by a nation of advanced civilisation with all the resources of a modern armament at its command is a breach of an implied pledge of her right to integrity, which no political, diplomatic or economic argument can justify. It is a cynical reversion to the acquisitive methods of the nineteenth century, which led to the partition of Africa among the interested Powers of Europe.

The attack of Italy on Abyssinia, however strong the argument from economic necessity or pressure of population now that other outlets are restricted, is out of harmony with the spirit of the twentieth century. Native races—using the term in a loose conventional sense—can no longer be regarded as 'inferior' and mere raw material for exploitation, whose lands may be developed, regardless of their rights and interests, solely for the benefit of a superior white race. An attitude of mind more nearly in accord with the present trend of scientific study of racial problems demands that the relations between white and black, which are a consequence of the inevitable expansion of European civilisation, should be regulated by an adjustment of the conflicting claims which arise from the clash of two cultures in some respects incompatible but, it is hoped and indeed as experience is showing, not ultimately and entirely irreconcilable. Where white civilisation successfully vindicates its claim to the superior position, it is not as an overriding, but as a tutelary force. The final ruling, for all but areas of overwhelmingly white settlement, was given in the dictum of Lord Passfield's famous White Paper, in which it was declared that "the interests of the native must be paramount". This to the native is his Magna Charta, the warrant on which the

white administration must justify its control and occasional modification of native custom and belief. This was the spirit which framed the African mandates of the League of Nations; it is not the spirit or the practice of Italian colonisation, either in Cyrenaica or in north-east Africa. Settlement here is frankly and avowedly Italy overseas, with all that that implies in regard to native interests.

The moral obligation to guard and guide the native in changing conditions is naturally not confined to mandated territory, but rests on all administrations alike. To some critics this obligation seemed in danger recently, when the development of the Kakamega gold mines was under consideration; but in fairness to the Administration of Kenya it has to be admitted that the point at issue did not really arise out of a disregard of the interests of the native, but from a difference of opinion over the question of immediate benefits, especially financial and economic, as opposed to ultimate well-being, which anthropologists and others felt would be jeopardised by the displacement of native holdings, and the cultural disintegration which is inseparable from the opening up of any area in Africa to mining enterprise.

On difficult questions such as those raised by the Kakamega gold mines—questions of frequent occurrence, though not often arousing such widespread interest—much light is thrown by two recent publications dealing with the relation of governors and governed in East Africa. Of these Dr. Thurnwald's "Black and White in East Africa"* is especially valuable for his survey of the whole course of contact between an African tribe and European civilisation from its very beginning. He also examines in great detail the various measures by which the administration deals with every aspect of its native contacts, including its organisation for the improvement of native conditions in both a material and a spiritual sense, while at the same time he gives due heed to all interests, both black and white, involved in the problem.

It is to be noted that Dr. Thurnwald, in concluding, quotes in reference to 'the outlook' the evidence of certain prominent chiefs before a commission in 1932, in which they elaborated an argument that present conditions of education and labour tend to destroy among members of the younger generation the feeling that they have a stake in the country. This is attributed to the breaking up of the old closely-knit and strongly localised family and tribal ties through these agencies. This view is of importance as a native criticism of such current tendencies as aim at 'civilising' the native. Against it, on the other hand, must be set the view, which appears to be gaining ground in West Africa—naturally among the more advanced members of the native community—that 'indirect rule' and the anthropological approach to administrative problems have been formulated as a principle with the express purpose of retarding the development of the people. Extreme as this view may be, it is unnecessary to stress the importance of its recognition as an element in the problem of which account must be taken, lest the most progressive and intelligent among the natives should be alienated. Those who hold such opinions are not necessarily all discontented or disgruntled agitators.

Even more interesting than Dr. Thurnwald's book in certain respects is an account of an experiment in anthropological and administrative research combined, which was carried out in Tanganyika*. Dr. Gordon Brown, anthropologist, and Mr. Bruce Hutt, District Officer of Iringa, joined forces, and for a year worked in close and continuous co-operation, the administrator posing questions to the anthropologist as they arose in the course of his work, and the anthropologist supplying the answer from material obtained by an investigation made *ad hoc* among the people on the special point.

The result was illuminating in more directions than one. Most important perhaps for the future of 'indirect rule'—the Hehe, the tribe under investigation, came under indirect rule in 1926—is the clear demarcation of the limits within which the application of anthropological research to administrative problems is practicable; but no less useful was the experience of the manner in which the posing of a question by the administration may open up new lines of thought and research for the anthropologist.

In so far as it is possible to summarise the result of a co-operative effort, of which every detail is worthy of careful consideration by those interested in scientific research and native administration, the work of these authors would go to show that

* Black and White in East Africa: the Fabric of a New Civilization; a Study in Social Contact and Adaptation of Life in East Africa. By Richard C. Thurnwald. With a Chapter on Women, by Hilde Thurnwald. Pp. xxii+419+16 plates. (London: George Routledge and Sons, Ltd., 1935.) 21*s.* net.

* Anthropology in Action: an Experiment in the Iringa District of the Iringa Province, Tanganyika Territory. By Dr. G. Gordon Brown and A. McD. Bruce Hutt. (Published for the International Institute of African Languages and Cultures.) Pp. xviii+272. (London: Oxford University Press, 1935.) 7*s.* 6*d.* net.

in imposing indirect rule upon the tribes of Tanganyika, the administration builded better than it knew. For investigation of the *status quo*, which was accepted by the system of indirect rule as guiding principle, as for example in continuing in office the 'headman' of the old regime, has revealed that underlying the outward form were unsuspected ramifications going deeply into social and religious belief and practice, which would have been destroyed and their benefits lost by any change that, to superficial observation, might have seemed to be little more than one in form alone.

The extension of the form, or at least the spirit, of indirect rule in the British areas of administration—the position of the Union of South Africa and the French Colonial system demand separate consideration—is in itself an adequate rejoinder to inquiry as to how stand the backward peoples of Africa there in relation to the principles of which the League of Nations is at present the nearest approach to living expression.

The aim of indirect rule clearly is by means of care for the existing order to make haste slowly. Hitherto, the efforts of those who have the interests of Africa at heart have been directed to protection of the native through the preservation of his institutions; but this at the best is no more than a means to an end, an attempt to control the pace of development, and to avoid too rapid and disastrous breaking up of custom. But lest the native critic be justified, has the time not now come to ask ourselves: What comes next? What is the policy of development that lies behind and gives meaning to 'indirect rule', if it is not to be regarded as entirely static?

If any trust is to be placed in signs of the times, the day is rapidly approaching when some such question will have to be faced; and by the practical wisdom and foresight shown in the event will the answer given by white rule in Africa be judged. We now stand at a point far removed from Kipling's concept of "the 'eathen in 'is blindness", and, to revert to the issue from which we started, the proposals for a compromise in the Abyssinian conflict cannot be allowed to evade responsibility by treating whole territories and peoples, whose future is at stake, as pawns in a game. *Fiat justitia, rual cœlum*, it may be, is no motto for statesmen, who are 'realists'; but, unless the whole stream of history is destined to change its course, it is the acid test which will be applied by posterity. In the interests of world peace, it may be necessary to cede disputed territory, but under conditions which place the interests and well-being of the inhabitants before colonial ambition.

A Himalayan Expedition

Nanga Parbat Adventure: a Himalayan Expedition. Translated from the German of Fritz Bechtold by H. E. G. Tyndale. Pp. xx+93+80 plates. (London: John Murray, 1935.) 10*s*. 6*d*. net.

THIS is an account of the German-Austrian expedition of 1934, under the leadership of Willy Merkl, which attempted to climb the Western Himalayan mountain Nanga Parbat. This mountain culminates in a peak 26,620 ft. above sea-level—it is the tenth highest in the Himalaya. It rises directly from the Indus valley. Here it is possible to see in a single view from the river bed to the mountain top no less than 23,000 ft. of tremendous precipices. We believe this is the greatest amount of slope exposed in the world.

Nanga Parbat has unfortunately acquired an evil reputation. On its slopes in 1895, A. F. Mummery and his two Gurkha companions were lost. In 1932 a German-American expedition, also under the leadership of Willy Merkl, including two members of the expedition under review, failed to reach a greater height than 23,000 ft. owing to porter troubles and bad weather. On that occasion, porters were recruited from Nanga Parbat district "and there lay one of the main causes of its failure. Consequently it was decided at home to spare neither trouble nor expense in order to fetch Himalayan 'tigers' from Darjeeling to Kashmir", that is, men who had taken part in the Everest and Kamet expeditions. The original party comprised eight climbers, a group of three scientific workers, a doctor and a camp commandant, with a full complement of porters.

The expedition appears to have been well equipped when it reached the base camp, and both climbers and porters were experienced. Notwithstanding this, it met with the worst disaster that has befallen any Himalayan adventure. Of the advance party of sixteen, no less than nine lost their lives on the mountain—three Europeans,

including the leader, and six porters. In all, eight camps were formed above the base camp (13,012 ft.), the highest being 24,446 ft. From this point, so far as could be judged, there was no great mountaineering obstacle to be surmounted between it and the summit, which was about two miles (measured on the map) distant, while the actual nearest point reached, at a height of 25,300 ft., was only about one mile from the top, and some 1,300 ft. below it.

Here the whole advance party of five Europeans and eleven porters was caught in one of those sudden and violent storms which are a feature of the Himalayas. They had to retreat, when their goal seemed to be within easy reach, with the consequences already mentioned. Many gallant attempts were made at rescue, but all were driven back by the deep snow and blizzard.

When a disaster of this magnitude occurs, it is only natural and right to inquire so far as possible into the causes which may have led to it. It must be remembered every precaution may be nullified by the occurrence of a sudden and violent storm, accompanied by heavy snowfall. Having said this does not mean that the arrangements were free from criticism. One is forced, after reading this story, to ask the questions: Were the advance party sufficiently acclimatised? Were the high camps sufficiently equipped, before the final attempt was made, to provide for the contingency which actually occurred? Was the supporting party sufficient for the occasion?

Had camps VI and VII been provisioned and equipped with sleeping-bags, the storm might have been provided for, and the disaster at least mitigated, if not avoided. The narrative does not discuss these points. The advance party, which made the attempt on the summit, was so large as to leave very little support. It consisted of five European climbers out of the original total of eight. Drexel had died of pneumonia and Herr Bechtold, who was for a time a member of the advance party, was absent at the end, having escorted two exhausted porters to a lower camp, while another climber had returned sick to camp IV (20,300 ft.). It will be seen then how weak the supporting party was, and how very much lower down it was than the advance climbers, and with very difficult ground in between. With this distribution it would, in fact, have been difficult to keep up communication with those above even in fine weather, and in the actual circumstances quite impossible. When the danger in which the advance party found itself was recognised, every endeavour was made to help, but all failed in the face of the storm.

There were with the expedition a surveyor, a geographer and a geologist. While the rest were climbing they made a tour of the mountain. Their report, which is not included, should be interesting. The oxygen equipment which was with the expedition does not appear to have been used by the climbers. It was requisitioned from the base camp, but arrived too late for the gas to be administered to Drexel.

The book is illustrated by 110 magnificent photographs. There are three maps showing the routes taken and position of the camps. H. L. C.

The Molecules of Life

Die Röntgenspektrographie als Untersuchungsmethode bei hochmolekularen Substanzen, bei Kolloiden und bei tierischen und pflanzenlichen Geweben

Von J. R. Katz. (Handbuch der biologischen Arbeitsmethoden. Herausgegeben von Prof. Dr. Emil Abderhalden. Lief. 436. Abt. 2: Physikalische Methoden, Teil 3, Heft 6.) Pp. 3401–3716. (Berlin und Wien: Urban und Schwarzenberg, 1934.) 20 gold marks.

THIS book, which may be said to embody the long experience and considered views of one of the leading exponents of the X-ray method of structure analysis, is not concerned exclusively with the giant molecules of biological tissues, since it deals also with 'laboratory' colloids; but it is a direct and valuable contribution to a theme which must, deep down, be the theme of all scientific research. It seems to be clear now that we are living in an epoch marking, among other things, the decisive entry of physics and chemistry into biology, and the passage of time can only emphasise the great part played by X-ray analysis. The sooner, therefore, that its aims and principles become more familiar, the better.

Dr. Katz has tried here most conscientiously to minimise the difficulties and lay bare the pitfalls, and has strongly indicated what he considers the best method of approach; but as in all branches of science nowadays, there is always the trouble of limited time, and one has to live and work among crystallographers to appreciate to the full their point of view. Nevertheless, structure analysis is

essentially a habit of thought, the habit of thinking three-dimensionally: and this much at least can and should be acquired by all who are interested in the properties of molecules, especially those molecules, such as the proteins, polysaccharides and other high polymers and condensation products, in which is enshrined our very existence. It is the *shape* of molecules that counts in the end.

To one who is used to the research outlook of the English-speaking peoples, there is perhaps something lacking from this book: one misses rather the thrill and romance of advancing with the new physical weapons ever deeper and deeper into the biological unknown. Let us be cautious, by all means, but let us also be brave.

W. T. A.

The Cinematograph and the School

(1) The Cinema in Education:
a Handbook for Teachers. By D. Charles Ottley. Pp. xi+130+4 plates. (London: George Routledge and Sons, Ltd., 1935.) 3*s*. 6*d*. net.

(2) The Film in the School
Edited by J. A Lauwerys. Pp. 140+4 plates. (London: Christophers, 1935.) 3*s*. 6*d*.

(3) A National Encyclopaedia of Educational Films and 16mm. Apparatus
Pp. 288. (London: Central Information Bureau for Educational Films, Ltd., 1935.) 21*s*.

(1) THE reviewer is biased against this volume by the statement on the jacket that "here for the first time the film's place in education is defined, its function analysed, and its possibilities as a teacher described in words that all may understand". This claims too much; but perhaps the book is better than it might appear. There is first an apologia for films in school, then the larger part of the book is taken up with accounts of films and projectors available, and finally there is a summary of a few lessons aided by films and a series of short statements about the use of films culled from various sources.

Too much has been attempted, and while it is true that many different subjects are mentioned, it is doubtful whether in fact enough is said on any one matter except 9·5 mm. films; indeed, if the cinema in education is the subject of the book, a quite disproportionate amount of space is devoted to these films, with which the author is evidently most familiar and on which he speaks with most authority. For the teacher who has a 9·5 mm. projector the book may be useful. The author points out, for example, that one advantage of these small films is that they can be bought outright and not hired, as are the 16 mm. films, and that consequently they can be edited and cut to suit the user; he gives examples of what he has done in the way of re-editing and combining films which he has bought, and shows how much can be done with them.

(2) "The Film in the School" is a contrast to "The Cinema in Education". Its purpose is clearly stated; it is "to give advice, as practical and detailed as possible, to those who would like to use films in their work", and it is fulfilled not unsatisfactorily. The book comprises seven chapters written by authorities on their subjects. The editor in the first chapter deals with "The Place of the Film in Education", with an emphasis on "place", and makes many interesting and valuable suggestions. Chapter ii, "Choosing a Projector", gives a clear and balanced account of the advantages and disadvantages of different kinds—not makes—of projectors. It may be noted in passing that a loose leaf supplies information on the picture-size and cost of most 16 mm. projectors, sound and silent. The third chapter deals with "The Film in the Classroom", and describes a few lessons which have been given with films. "The Mass Demonstration" is mostly devoted to giving the details of organisation of, and conclusions to be drawn from, the St. Pancras experiment by Capt. Griffiths, who took a prominent part in that experiment.

In the fifth chapter, on "Film Making in School", Mr. Ronald Gow points out that "as school textbooks are, naturally, written by teachers it is not unnatural to suppose that the educational film of the future will also be written by teachers" and gives accounts of films which he produced. Miss Mary Field describes the method and difficulties of the commercial producer of educational films, and in the last chapter the technique of "Using a Projector" is clearly described by Mr. Waley. There is an appendix which states the contents of the principal film libraries and a short bibliography.

It will be seen that the volume deals with facts, not theories, a welcome development in the literature of educational films.

(3) This "Encyclopaedia", though it has a different name, is in fact a new and much improved edition of the Catalogue of Educational Films published in 1933. Additions consist of articles, a

useful list of addresses of those from whom films may be obtained, lists of 16 mm. projectors, lists of film cameras and materials, and a library list.

The chief change is in the arrangement of the catalogue of films; these are now first listed under the headings 35 mm. and 16 mm.; each of these is divided into sound and silent films and these again into agriculture, art, biology and the rest. This is a very great improvement. Another change, which is not altogether an improvement, consists in giving the length of all films in reels, instead of using reels, feet and minutes; as the vast majority of films listed are of "1 reel" the information is not extremely useful.

The volume will save searching commercial catalogues, but it is not easy even yet to find what films are available on any particular topic on, say, 16 mm. silent stock—and that is the main use of a catalogue. Indeed, it still takes time to trace all the films in a particular subject such as geography; some of the best hide themselves under agriculture, science (anthropology) or engineering and industry.

Civilisation and its 'Crises'

The Source of Civilization
By Gerald Heard. Pp. 431. (London and Toronto: Jonathan Cape, Ltd., 1935.) 12*s.* 6*d.* net.

MR. GERALD HEARD, in his new book, has given us plenty to think about. The substantial merits of his work are, that it is a bold attempt at a comprehensive survey of human evolution, and that it is inspired throughout by a passionate belief that only by peace with his fellows, and a sense of harmony in the universe, can his full powers be developed, or rather, as Mr. Heard would say, can he escape his imminent destruction. In the first aspect—that of comprehensiveness—it is a brilliant expression of the current spirit which refuses more and more to limit the historical vision to politics and is eager more and more to trace backward by prehistoric discoveries the origin of the fundamental directions of human thought and action. It demands an evolutionary solidarity with all life.

In the second aspect, as a passionate pacifist manifesto, it is one of the most notable post-War publications. No one else has attempted—at least in English to our knowledge—so wide and detailed a denunciation of 'violence' in all its forms. When we criticise, therefore, it will be understood that it is with the deepest sympathy with the two main objects which Mr. Heard has in view. That it provokes, in that spirit, both scientific and historical criticism, is clearly a testimony to its force. Such widespread syntheses are one of the greatest needs of the time, but to be useful they must be met by friendly and searching examination.

The book, however, covers such an amazing wealth of facts and suggestions drawn from psychology, prehistory, Eastern philosophy and religious lore, that it is only possible here to make a few general remarks.

Mr. Gerald Heard's thesis, broadly speaking, is that man is naturally not a fighting but a pacific and friendly creature. He springs from a stage in the animal genealogy much further back than the brutal gorilla or any of the so-called 'primates', nearest in fact to the harmless tree-shrew. At an early stage he enjoyed a consciousness of his community with other animals, and the outside world generally, which he has since lost; and it is by the recovery of this at a higher stage of development that his salvation, if it is at all possible, will be secured. This early stage has now retreated into the depths of the subconscious, and the main purpose of psychology is to bring it again into the light. This was once apparently secured in the civilisation of what is frequently referred to as the "Eastern arc of the proto-civilisation" (represented by the recent discoveries in the Sind region). It was continued in the early culture of India, and on this account the practice of Yoga is so important. Except in this region, the early pacific civilisation was everywhere destroyed by 'violence' and individualism. This individualistic violence is promoted by the exercise of the mind in the one-sided exploration of external Nature, which tends to make man aggressive and acquisitive and is at the root of all the imperialisms from Assyria to the Great War. We must return and strive to regain a united consciousness, if civilisation in the true sense is to be saved.

Our criticism must be that such a scheme of human evolution, in spite of its many valuable sidelights and suggestions for further inquiry, is a simplification invalidated by its obvious *parti pris* and by the elevation of small and isolated facts into decisive arguments. The human stock, with its, say, half a million of years for distinctive growth, cannot be thus confined into one type of conscious life which we select as it suits our theory. That man's greater awareness was, as Mr. Heard says, his best qualification for a later rise, is abundantly clear, and that he rose and developed his powers because he was more adaptable. The

stress on these points contain some of the most valuable thoughts in the book.

But it is impossible to maintain that the earlier man had not also combative elements in his nature. His constant normal character is sufficient evidence of this, and the weapons and remains of slaughtered foes which are a part of so many prehistoric cites and excavations. We know little enough yet about our early ancestors in those vast æons of life, but we certainly know that fighting for their lives and their food was at least one element in their age-long task. When we come down to later times, in which historical records are available, it is no less clear that sword or 'violence' cannot be dismissed as an entirely decadent and harmful thing. Alexander's empire was not the mere "Macedonian raid" which is here described, nor was the Roman Empire the last word in stupid violence.

The whole story is much more complex than that; but one or two capital facts emerge which are not allowed for in such a condemnatory survey. One, that Rome gave us, in spite of her crimes, the framework of modern civilisation in which we live, and which, it may be added, shows more hope of surviving than Mr. Heard would allow. In fact, if we survive at all, which one may postulate without over-confidence, it will be owing, among other things, to the work of Rome, including her sword. Perhaps still more important is the fact that the Greeks, to whom we owe the first definite formulations of knowledge—both objective and subjective—did this work in a constant atmosphere of war. With them at least the fighting did not inhibit keen and disinterested thought.

A last word of criticism must be that the unifying work of science is scarcely allowed for at all. This is perhaps the most serious omission. It is omitted, because to admit it would be to admit that our present scientifically organised society is actually the most stable, whereas the argument requires us to believe that civilisation is in its most acute 'crisis' and can only survive if we retrace our steps. Retrace we cannot; advance, enlarge and correct we may. The correction will include much of what Mr. Heard desires, and, above all, the further suppression of the instinct to war, which is a diminishing and not an increasing factor in our make-up. But towards that most desirable of consummations we must include, as a prime and growing factor, the disinterested pursuit of truth both as to the world around us and our own nature; and it will consist rather in developing and making more articulate the conscious than in attempting to read and make a guide of the deep-down and often misleading promptings of the subconscious. F. S. MARVIN.

Les fossiles: éléments de paléontologie

Par Prof. Marcellin Boule et Dr. Jean Piveteau. Pp. vii + 899. (Paris: Masson et Cie, 1935.) 170 francs.

HERE is a textbook of palæontology prepared for France, where the subject is considered apart both from biology and from geology. The introduction dealing with these subjects is of the shortest character, and is followed by a history of the science, in which the credit for its foundation is given to Leonardo da Vinci and Bernard Palissy, artists in paint and in clay.

The main part of the work is a systematic account of the organisms of the primary, secondary and tertiary periods, followed by that of quaternary man. Groups of organisms are treated in respect to their popularity rather than their scientific interest. Thus more than 500 pages are devoted to vertebrates, while such important phyla as Protista, Porifera and Cœlenterata together are only assigned 41 pages, while insects have 9 pages in spite of the great evolutionary interest of their fossil forms. From a biological aspect the classification often does not satisfy; thus the Stromatoporids were probably Foraminifera, while the Artiodactyles and Cetacea are usually regarded as derived from the Creodonts.

The author's technique is that of a fine museum guide rather than that of the more discursive and critical teacher. At the same time the latter will appreciate "Les fossiles", since most fossil genera are mentioned, while there are 1,330 figures, of which a very large percentage are original. Unfortunately, there is no bibliography to help the reader to dip deeper into the science.

Old and New: Thoughts on the Modern Study of History

By F. S. Marvin. (University Extension Library.) Pp. 224. (London: Ivor Nicholson and Watson, Ltd., 1935.) 4*s*. 6*d*. net.

THE title of Mr. Marvin's earlier book, "The Living Past", published in 1913, and frequently and deservedly reprinted, was almost a stroke of genius. In a phrase, it seemed to reveal, or at least to suggest, the true nature of the historian's task. The question whether history is a science has often been discussed, and is one which might naturally appeal to many readers of NATURE. Mr. Marvin is too wise to spend his efforts upon the somewhat academic question whether the methods and the materials of history fairly bring it into the category of what is usually called science. He prefers to go straight to the problem what we are really doing, or ought to be doing, in that study of the past which is called history, and how the process has been changed by the general movement of thought, scientific and philosophical, in modern times. He then proceeds to deal with certain selected aspects of history, by no means repeating his earlier work, but again leaving the reader with a high sense of human achievement, notwithstanding the terrible setbacks that have to be recorded. The chapters on the scientific work of the ancient Greeks, and on the marvellous technical advance in modern times, will prove specially interesting to scientific readers.

An Introduction to Comparative Zoology: a Text-Book for Medical and Science Students. By F. G. Sarel Whitfield and A. H. Wood. Pp. x+354. (London: J. and A. Churchill, Ltd., 1935.) 15*s*.

HERE is a textbook for the Kitchener School of Medicine at Khartoum, and presumably the animals with which it deals form the syllabus of that School, together with some consideration of embryology, heredity, evolution, ecology and metabolism. The morphology of the types is done admirably. The size, print and especially the illustrations are exceptionally good. There may be a sufficient reason in the psychology of students for making the work so morphological in Khartoum, but the tendency in Great Britain is for the teacher to lighten morphology with a consideration, most elementary of course, of function in relation to the environment in which the animal dwells. Here much emphasis is laid on parasites, blood flukes, tapeworms, *Ascaris*, ticks and 'medical' insects being included besides all the types usual in Great Britain. This may be wise, for the applied side anyhow will have to be considered later by the student in a tropical country, where he will be seeing the effects of animal parasitism. In any event, parasites are not good forms on which to teach observation, which surely is of the first importance to the commencing student. If all these additional types are to be considered, why not omit the dogfish altogether? It has little to do with the Sudan and the course would be sensibly lightened without much loss.

(1) A Manual of the Common Invertebrate Animals, exclusive of Insects
By Prof. H. S. Pratt. Thoroughly revised edition. Pp. xviii+854. 7.50 dollars.

(2) A Manual of Land and Fresh Water Vertebrate Animals of the United States (exclusive of Birds)
By Prof. H. S. Pratt. Second edition. Pp. xvii+416. 6 dollars.
(Philadelphia: P. Blakiston's Son and Co., Inc.; London: J. and A. Churchill, 1935.)

THESE two books are thoroughly revised and greatly improved second editions, and are really two volumes of the same work. They aim at giving descriptions of the common invertebrates and vertebrates of the United States, by means of which their relationships and names may be determined. The insects are excluded, their half million or so of species obviously requiring separate treatment. The classificatory keys, the analytical tables and descriptions have been tested by us in several groups, and appear to be admirable, while the numerous illustrations (184 and 974 respectively) are well selected. They enable the visitor to the coast, mountain, plain or lake to name quickly any beasts that he may be watching in the open, or perhaps at home under magnification, with reasonable certainty, and this encourages him to observe. They are clearly books valuable in every classroom and library in North America, as similar synopses of the local fauna would be in any country.

West Coast Shells: a Description in Familiar Terms of the Principal Marine, Fresh-water and Land Mollusks of the United States, British Columbia and Alaska, found west of the Sierra. By Josiah Keep. Revised by Joshua L. Baily, Jr. Pp. xi+350. (Stanford University, Calif.: Stanford University Press; London: Oxford University Press, 1935.) 17*s*. net.

FIFTY years ago, conchology was a hobby both in Europe and America, and most large seaside towns had societies for its study. The infinite variety and the beauty of the shells were their attractions, and it was not unusual to pay several pounds for a prime specimen. Now shells are recognised as a part of the complex of every coast, often governing factors in its formation. This rewritten book of Josiah Keep, originally published in 1881, is 'tuned up' to a new conchology that may well some day be as popular as the old. Oysters, razors, limpets, borers, burrowers, clams, etc., as titles of chapters indicate its key, and the technique of their consideration is both simple and scientific. British natural historians may well read it, for on the coasts of Britain dwell each of the above groups, but such would be well advised to take old Keep's advice: "While you admire their lovely shells, think even more of the quiet and pleasant lives they spend in their ocean home".

Wild Life Studies
By Frances Pitt. (Argosy Books, No. 3.) Pp. iv+189+9 plates. (London: Thomas Nelson and Sons, Ltd., 1935.) 3*s*. 6*d*. net.

THIS is a series of studies of the private lives of certain birds and beasts, most of them common dwellers in the English fields and hedgerows—voles, weasels, hedgehogs, peewits, owls, hawks and such. There are also two chapters on puffins and seals. Miss Frances Pitt writes on all these animals with an intimacy and humour which ensure ease and enjoyment for the reader, and the perusal of the book should certainly add interest and pleasure to a Nature lover's rambles. The author directs attention to the useful work done by animals commonly known as pests in a manner refreshingly free from sentimental special pleading. The pen drawings by G. E. Collins are delightful.

The Life and Writings of Giambattista Vico
By H. P. Adams. Pp. 236. (London: George Allen and Unwin, Ltd., 1935.) 8*s*. 6*d*. net.

A BOOK on Vico in the English language has long been overdue. Mr. Adams, in giving us the benefit of detailed studies of living Italian scholars, has revealed to a wider circle of readers the greatness of mind of one recognised by Goethe as a patriarch of modern thought. Indeed, after a detailed analysis of Vico's writings, Mr. Adams shows how he has influenced the trend of modern philosophy, from the eighteenth century down to the contemporary Italian thinkers. Thus the book under review will be found of interest to the historians of philosophy as well as to those of literature and political theory. T. G.

Charles Darwin as a Student in Edinburgh, 1825-27*

By Prof. J. H. Ashworth, F.R.S.

CHARLES DARWIN in his autobiography, written in 1876, gives in half a dozen pages ("Life and Letters", I, pp. 36–42) an account of his two academic sessions as a medical student in Edinburgh. This account includes brief references to his naturalist friends and acquaintances, a statement that he collected specimens in the tidal pools on the shore of the Firth of Forth and by going out with the "trawlers", and that he made new observations on the "so-called ova of Flustra", which "were in fact larvæ", and on the egg-cases of *Pontobdella muricata*.

It is now possible to form a more adequate conception of his early progress as a naturalist with the help of the minute book of the Plinian Society of the University of Edinburgh and of a notebook begun by Darwin in Edinburgh in March 1827, the latter of which I have been permitted to see by the kindness of Prof. C. G. Darwin and Mr. Bernard Darwin.

Charles Robert Darwin came to Edinburgh at the age of sixteen years and eight months, and with his elder brother Erasmus, who had been a medical student at the University in the previous year, signed the matriculation book, "Charles Darwin—Shropshire", on October 22, 1825. His class cards for the academic year 1825–26 were presented to the University of Edinburgh by the late Sir Francis Darwin in 1909, together with the wrapper inscribed by Darwin, in which they were found among his papers. The cards are: For the University Library, materia medica, chemistry, anatomy, clinical lectures, principles and practice of surgery and a 'perpetual ticket' for the Royal Infirmary.

In his autobiography, Darwin writes that the lectures "were intolerably dull, with the exception of those on chemistry by Hope. . . . Dr. Duncan's lectures on Materia Medica at 8 o'clock on a winter's morning are something fearful to remember. Dr. —— made his lectures on human anatomy as dull as he was himself". The "Dr." referred to was Alexander Monro *tertius*, who did not sustain the great reputation made by his grandfather and his father, who had preceded him in the chair of anatomy. Darwin attended the clinical lectures and he records that he also "attended regularly the clinical wards in the hospital". He enrolled in the class of 'Principles and Practice of Surgery', but all that is known about his attendance in this subject is his own note that on two occasions he was present at "very bad operations"—these were before the days of chloroform—and that he "rushed away before they were completed".

In his second year at the University, Darwin enrolled in the classes of midwifery, practice of physic and natural history.

Robert Jameson, then fifty-two years of age, was, and had been for twenty-two years, professor of natural history, which then included zoology and geology. He devoted himself chiefly to mineralogy, but his published work shows his interest also in marine zoology and in birds, and as editor of the *Edinburgh Philosophical Journal* and of the *New Philosophical Journal*, he maintained a wide outlook on science in general. He formed an extensive and important natural history museum in the University of Edinburgh, which was notable for the excellent state of preservation of its specimens and their scientific arrangement and for its large collection of birds. The entire museum collection, said to have been, in Great Britain, "second only to that of the British Museum", was handed over a year after Prof. Jameson's death to the new Government Museum of Science and Art, now the Royal Scottish Museum.

Darwin found Prof. Jameson's lectures "incredibly dull"; "the sole effect they produced on me was the determination never as long as I lived to read a book on Geology, or in any way to study the science". Fortunately, he did not adhere to this decision; within ten years he had made the observations for his three geological memoirs, one of which, on coral reefs, has become a classic.

The detailed syllabus of Prof. Jameson's lectures, as drawn up by him in 1826, shows the range of his teaching, which included not only zoology and geology but also instruction in meteorology and hydrography and some reference to botany in its relation to "the animal and mineral kingdoms". The course of zoology began with a consideration of the natural history of man, was followed by an account of the chief classes of vertebrates and invertebrates, and concluded with lectures on the philosophy of zoology in which the first subject was "Origin of the Species of Animals".

This would be the course as given in Darwin's second academic year, and the lectures, which

* From an address to the Royal Society of Edinburgh on October 28, part of which formed the subject of a paper to Section D (Zoology) of the British Association at Norwich.

began on November 8, 1826, were on five days a week and were stated to extend over five months; hence there would be about one hundred lectures, in addition to which there were 'conversations' with the professor in the Museum, and excursions. While Prof. Jameson's teaching of some parts of geology was unacceptable owing to his adherence to extreme and discredited Wernerian views, the recorded judgments of Robert (later Sir Robert) Christison and of Edward Forbes on his teaching in general and on his enthusiasm for his subject and for the Museum under his charge show that they did not share Darwin's opinion of Prof. Jameson's course.

Although Darwin apparently did not receive from Prof. Jameson's lectures much instruction in zoology, he was able to acquire in other ways while in Edinburgh a considerable acquaintance with this subject.

Soon after coming to Edinburgh, Darwin became aware that his father would leave him "property enough to subsist on with some comfort" and this was, as he states, "sufficient to check any strenuous effort to learn medicine". Much of the time available after his attendance at classes would probably be devoted to his pursuit of natural history, especially during his second year when his brother was no longer with him in Edinburgh. His classes were in the same building as the Natural History Museum, and therefore any spare time could be immediately put to good use in the Museum, where he was likely to find at work two experienced naturalists, Dr. Robert Grant and William Macgillivray, whom he came to know well. Further, his membership of the Plinian Natural History Society brought him into association with other enthusiastic naturalists in Edinburgh at that time.

The Plinian Society was founded in 1823, and the two minute books from February 1826 to the end of the Society's existence in 1841 are preserved in the University Library. The Society, which met every Tuesday evening in the College or University of Edinburgh, had about one hundred and fifty members, but the number recorded as being present at the meetings does not usually exceed twenty-five. The secretary in February 1826 was Dr. Robert Grant, and the record includes the names of those present and of those who took part in the discussions.

Darwin was elected a member of the Society on November 28, 1826, and at the meeting a week later, at which the election of officers and council took place, he was chosen as one of the five members of the council, from which it may be concluded that he was very favourably known for his interest in natural history. There were five presidents—Messrs. Ainsworth, Coldstream, Kay, Browne and Fife—three of whom, Browne, Coldstream and Fife, had proposed Darwin for membership of the Society. He states in his autobiography that he found the meetings of the Society stimulating and that he "used regularly to attend"; the record shows that he was present at all but one of the nineteen meetings held from the date of his election to April 3, 1827.

The minute book is of interest as showing the subjects discussed in the students' natural history society in Edinburgh one hundred years ago, and it indicates the wide range of the communications presented during the period of Darwin's membership. Darwin is noted as having participated in the discussions on four of the evenings; it would have been particularly interesting to know what he said on the principles of natural classification and especially on specific characters when he spoke in the discussion on that subject.

On March 27, 1827, not "at the beginning of the year 1826" as stated in the autobiography, "Mr. Darwin communicated to the Society two discoveries which he had made:

(1) "That the ova of the Flustra* possesses organs of motion".

(2) "That the small black globular body hitherto mistaken for the young of Fucus lorius [loreus] is in reality the ovum [or, as he wrote in the autobiography, the egg-case] of the Pontobdella† muricata".

At the request of the Society, Darwin promised to draw up "an account of the facts and to lay it, together with specimens, before the Society next evening". The minute of the next meeting records that he presented to the Society "a specimen of the Pontobdella muricata with its ova and young ones", but does not mention any account, and if the manuscript was placed before the Society it has not been kept.

In his note-book, Darwin gives under the date April 20 a short account of the yellow embryos and ciliated larvæ of *Flustra carbasea*, records that two other species produced motile "ova" and adds a description of the egg-cases of *Pontobdella* and of the young leech when ready to escape. These observations, which occupy four and a half pages of the note-book, were not published by Darwin.

Three days previous to Darwin's paper at the Plinian Society, that is, on March 24, 1827, Dr. Grant read to the Wernerian Natural History Society of Edinburgh, as the minute under that date records, "A Memoir regarding the Anatomy and Mode of Generation of Flustræ, illustrated by preparations and drawings", and "a notice on the Mode of Generation of the Pontobdella muricata of Lamarck".

* *Flustra*, the 'sea-mat', a genus of Polyzoa, obtained by dredging or found thrown up on the shore—the brown sea-weed now known as *Himanthalia lorea*.

† *Pontobdella*, a leech frequently found on the skate and hence often called by the fishermen the skate-leech.

Grant's paper contains a more detailed account than Darwin's of the ova of *Flustra* and of the ciliated embryos and larvæ which Grant reared in watch-glasses into young colonies.

Grant prepared a description of the cocoons of *Pontobdella*, published in the *Edinburgh Journal of Science* of July 1827, in which he stated that "the merit of having first ascertained them to belong to that animal is due to my zealous young friend Mr. Charles Darwin of Shrewsbury, who kindly presented me with specimens of the ova exhibiting the animal in different stages of maturity".

Another significant factor in Darwin's studies in natural history in Edinburgh was his friendship with some of the Newhaven fishermen, whom he sometimes accompanied when they dredged for oysters "and thus got many specimens". His note-book records *Pennatula mirabilis* (now *Virgularia mirabilis*) and *Pennatula phosphorea* from the Firth of Forth, which were no doubt obtained in that way; the cocoons of *Pontobdella* which he found on oyster and other shells were probably collected on some of these expeditions, and he procured his specimens of *Flustra carbasea* "from the dredge boats at Newhaven".

Darwin's note-book, which is inscribed on the fly-leaf "Charles Robert Darwin, March 1827", provides interesting evidence of his observations on animals collected in the Firth of Forth. He found a lumpsucker stranded on the rocks at Leith and "dissected it with Dr. Grant"; a fairly complete examination was made of its internal organs including the heart and its valves. He records and sketches the "ova" (egg-masses) of several molluscs, adds sketches of the ciliated larvæ of three of them, and gives brief descriptions of the two sea-pens, *Virgularia mirabilis* and *Pennatula phosphorea*, which he had procured no doubt with the help of the Newhaven fishermen. The last zoological entry in the note-book is that he "observed with Mr. Coldstream" a starfish, which he identified as *Asterias rubens*, but which was almost certainly a specimen of the closely similar starfish first differentiated from *rubens* as a new genus and species by Michael Sars in 1846 and now known as *Leptasterias mülleri*. Darwin saw his starfish in the act of discharging its eggs. In this species the eggs are incubated in the space enclosed by the arched disc and the inwardly bent bases of the arms.

With Darwin's Edinburgh notes were two lists of animals, one of "the Vermes found in the Frith of Forth and other parts of Scotland" abstracted from a paper by Prof. Jameson (1811), and the other of "Fishes found in the Frith of Forth" from a paper by Patrick Neill (1811). Each list was written on two double sheets, about 6 in. $\times 3\frac{1}{2}$ in., and the two sheets were fastened together by a strip of gummed paper. These lists could be carried in a pocket-book, and would be convenient for reference in his collecting expeditions.

Darwin left Edinburgh late in April 1827, when little more than eighteen years of age, and early in the following year went to Cambridge.

Reference was made to Darwin's friends in Edinburgh, of whom the most important was undoubtedly Dr. Robert Edmund Grant, then about thirty-three years old. He had graduated M.D. Edinburgh in 1814 and had studied natural history and medicine in 1815–20 in Paris and other Continental universities. He returned to Edinburgh in 1820 and explored the coasts of Scotland and Ireland and made studies, including dissections, of many animals which he collected. Grant was the author of a series of papers on sponges in 1825 and 1826, and many of the observations therein recorded were made on the shores of the Firth of Forth. In addition, he published or wrote, in the years 1825–27, more than a dozen other papers on Cœlenterata, Mollusca, Polyzoa, Crustacea, on the structure of the eye of the sword-fish, and on the anatomy of the *paca* of Brazil; he was at that time a most energetic collector and investigator, especially of marine invertebrates. Darwin states that he often accompanied Grant to collect animals in the tidal pools, and he records in his note-book that he dissected with Grant the lumpsucker he had found at Leith. It was a great advantage to Darwin to have this experienced zoologist as his friend.

In his autobiography Darwin relates that one day when he was walking with Grant the latter "burst forth in high admiration of Lamarck and his views on evolution"; Darwin adds that he listened in silent astonishment, and so far as he could judge without any effect on his mind. That exposition on Lamarck acquires fuller significance when it is remembered that Grant studied in Paris during the period 1815–20, and that he would devote much of his time to work in the Museum of Natural History, where he would very probably come into association with Lamarck only a few years after the latter had published his "Philosophie Zoologique" (1809) and while he was preparing his great work on the natural history of invertebrates (1815–22).

In the summer of 1827 Grant left Edinburgh to become the first professor of zoology in University College, London.

William Macgillivray, thirteen years Darwin's senior, was, during the time Darwin was a student in Edinburgh, assistant and secretary to Prof. Jameson and acted as assistant-keeper of the University Museum of Natural History. He was known for his papers on molluscs and on birds, and

was afterwards (1841) appointed professor of natural history in Aberdeen. With him Darwin "had much interesting natural-history talk", and while birds are not specifically mentioned, it is scarcely possible that Darwin could be in frequent association with Macgillivray—whom the late Prof. Alfred Newton regarded, after Willughby, as "the greatest and most original ornithological genius save one (who did not live long enough to make his powers widely known) that this island has produced"—without utilising such an opportunity of acquiring some of his special knowledge of the classification and structure of birds. Darwin records that in Edinburgh he had lessons on preparing birds from a Negro who had travelled with Waterton, and there is extant evidence of his interest in birds at this time in two 'keys' in manuscript found among his Edinburgh notes. One is a key to the genera of British birds and the other, to about one hundred genera of birds, was "copied from Brisson's *Ornithologie*, 4th Edit. . . . 1826", hence it was written during his second academic session.

Darwin "became well acquainted with several young men fond of natural science". He mentions Ainsworth, Coldstream and Hardie (this should be Arding, a member of the council of the Plinian Society), but he might have added the other presidents of the Plinian Society—Kay, Browne (father of Sir James Crichton-Browne) and Fife, with whom also he would be frequently associated during his last five months in Edinburgh. These men were all senior to Darwin by two to four years; Browne was already L.R.C.S. and the others qualified in medicine in 1827.

Darwin attended, with Grant, meetings of the Wernerian Natural History Society and heard, among others, Audubon, who spoke at the meetings in December 1826 and January and February 1827, and he was present at one meeting of the Royal Society of Edinburgh, where he saw Walter Scott in the chair as president.

I suggest that if, with the information now available, Darwin's experiences in Edinburgh are reviewed, there are good grounds for the conclusion that, while he gained comparatively little from the formal lectures, he had excellent opportunities, of which he appears to have availed himself fully, of developing his early taste for natural history and collecting, and that in Edinburgh he laid the foundation of his knowledge of the science of natural history.

Utilisation of Pine Forests

Cellulose Pulp

A STUDY of the methods of utilising the vast areas of pine forests which occur in various parts of the world is a matter of considerable importance from the scientific and economic points of view, and both aspects have recently received considerable attention in Australia and in the United States. In each case the manufacture of cellulose pulp for the paper and allied industries has been the main objective; but the problem has been approached from somewhat different aspects in the two countries. Thus, the American workers have erected a large-scale experimental plant, and have carried out numerous pulping trials, whilst in Australia a more fundamental study of the chemistry and structure of the woods has first been made, with small-scale pulping trials to provide additional information. The two studies are therefore, in a sense, complementary; and it is interesting to consider them together.

It is well known that the objection to the use of the southern type of pine for pulping has always been the high resin content, which is a source of considerable trouble to the paper-maker. It is true that the soda and sulphate (kraft) processes of digestion remove most of this, but such methods are not always desirable for economic reasons. The mechanical and acid (sulphite) processes, which are generally preferred, provide no solution of the resin problem; it seems, in fact, that the latter induces polymerisation of the resins, which are thereby converted into an objectionable substance resembling pitch.

The key to the problem appears to be the differentiation of the sapwood and the heartwood, and it has been found from investigations on thinnings, which contain very little resinous matter, that the elimination of heartwood also eliminates the resin trouble. As an example, in the case of the longleaf pine, the average figures given for the resin in the sapwood and heartwood are 2 and 7–10 per cent, respectively. With this is also involved the question of the diameter of the tree, because in the past there probably has not been a full appreciation of the great diameter to which a tree can grow before the sapwood begins its transformation into heartwood; this is in spite

of the fact that, so long ago as 1897, F. Roth[1] stated that this transition really begins before the tree is twenty years old, and that twenty to twenty-five years is the usual age. Roth also found that the average diameter of the fibres of the spring-wood is about twice that of the summer-wood, so that, unless this difference is taken into account, measurements of the relative widths of such woods may give a false idea of the total amounts present.

The analytical data compiled by W. G. MacNaughton and F. Allen from various published sources[2] and from their own work confirm the fact that, as indicated by Roth, the difference in apparent density of the spring- and summer-woods depends on the wood structure. They also demonstrated the low resin content of southern pines free from heartwood. Laboratory pulping tests were carried out on these young pines both by the sulphite process and by mechanical methods, and average yields of 45 and 93 per cent being obtained, respectively; these are similar to the average figures obtained with other species of the wood.

The engineering and the economic aspects of the problem have been more fully discussed in several publications by C. H. Herty[3]. A small-scale plant has been erected in Savannah, Georgia, under the auspices of the Department of Forestry and Geological Development, and reels of paper 26 inches wide can be made on a small Fourdrinier machine. In order to overcome the difficulty of 'blue stain', due to sap in the summer season, experiments were made with green wood, and contrary to expectations this was found to give a pulp almost free from resin trouble. On the other hand, after seasoning for three months, the pitch trouble was more pronounced, and as this is contrary to experience with northern spruce, it suggests the desirability of an investigation into the natures of the resin from these two sources and the changes they undergo on seasoning.

Herty's account of this work is marked by an enthusiasm which, in view of the commercial possibilities involved, is probably justified. It is reassuring nevertheless to turn to a paper by L. C. Anderson[4] which is an independent account of the behaviour of the new pulps on a modern Canadian newsprint machine. Incidentally, the paper so made was used by the Georgia newspapers for a special edition to commemorate the event. A mixture of 25 per cent of sulphite and 75 per cent of ground wood (both from Loblolly pine) was used, and the complete absence of pitch trouble was confirmed. The data show quite definitely that from the point of view of the operator the utilisation of these pulps presents no unusual difficulties. On the other hand, the paper produced is considered to be poorer in quality than that made from spruce or balsam. It was limp to the hand, and the tensile and bursting strengths and smoothness and porosity values were all poorer than the corresponding average data for the northern woods. It must be remembered, however, that the pulps were prepared in a plant of experimental scale, and it is a well-known fact that the quality of pulps may usually be corrected as a result of tests on the paper made from it. There is little doubt therefore that a process operated in the normal way would give better results.

A more recent development of the work in the Georgia laboratories is the production of cellulose for viscose rayon, and Herty and Rasch[5] have described the properties of the material obtained by a short high-temperature digestion process; the yields of cellulose were 88–90 per cent.

It is now of interest to turn to the contribution of the workers in Australia, where the numerous afforestation schemes of recent years have resulted in the planting of large areas of pines, mainly *Pinus radiata* (*insignis*). The utilisation of this material is obviously of the same economic importance here as in Georgia, and the problems are very similar.

In the first of a series of chemical investigations on *Pinus radiata*, W. E. Cohen[6] deals with the nature and distribution of the non-volatile ether-extractives and the occurrence of heartwood. Eighty-five samples (6–22 years old) from South Australia, Victoria and New Zealand were extracted with ether, and the acid and ester values of the extract were determined. Experimental sulphite pulping tests were also made on a sample from a 22-year-old tree.

The results suggest that seasonal variations and changes in the nature and amount of the ether-extractive during storage are more important factors than have hitherto been realised, and that the age of the tree and the amount of heartwood present bear no definite relationship to the yield of extractives from a whole log section. The amount of ether-extractive in the inner rings was always more than in the outer rings, especially when the former contained heartwood. The ratio of the acid value to the ester value was taken as an indication of the nature of the resinous matter; the acid content is raised when heartwood is present, and high yields of resins having a high ester value are obtained in the presence of resin ducts such as occur usually in trees 16–18 years old. There is also evidence that the time of collection affects the results, because young samples (6–12 years old) collected in March had a much lower acid/ester ratio than those collected in September.

The pulping tests established definitely the difficulty of dealing with wood containing appreciable amounts of heartwood, and an increased temperature-gradient and penetration-period were required in such cases. The resin-contents actually obtained were the very low figure of 0·35 per cent for pulps from sapwood, and 3·84 per cent from heartwood pulps. No pitch trouble was experienced with the former, but the indications are that the latter would give trouble from this source.

Recent Research on Cancer

THE twelfth annual report of the British Empire Cancer Campaign gives summaries of the past year's progress in most of the cancer research centres of the British Empire. During the year, more than £32,000 has been distributed by the Campaign in encouraging and supporting research along a very broad front, extending from pure physics, such as methods of inducing radio-activity in normally inactive elements, to the study of the origin and development of tumours in the human body. With the hope of improving and extending clinical research, a new clinical research committee has been formed with the co-operation of all the London teaching hospitals. Such an organisation can help considerably in comparing results and preventing overlapping and duplication of research.

The problem of the cause of cancer has been attacked mainly by means of experimental carcinogenesis, in many different institutes. Many years ago, Fibiger found that gastric cancer occurred in rats fed on cockroaches infected with *Gongylonema neoplasticum*, when the rats become hosts for the parasites. Prof. R. D. Passey has now found that infected rats do not develop cancer if they are fed on a full and healthy diet in place of the white bread diet used in Fibiger's experiments. This indicates that diet may influence the occurrence of malignant disease. In the Cancer Hospital Research Institute a new, very active carcinogenic compound, methyl cholanthrene, has been produced from deoxycholic acid (a normal constituent of bile), and has been synthesised. In structure, methyl cholanthrene is allied to sterols and sex hormones and to other carcinogenic agents, and it is conceivable that a similar active carcinogenic compound might arise adventitiously in the body by some 'error' of metabolism. This suggests a possible link between industrial cancer, such as that of gas workers and mule spinners, and natural or spontaneous cancer.

Sarcomata have been induced in fowls by synthetic carcinogenic agents and by tar in many different laboratories, and attempts have been made to obtain a filterable virus from the neoplasms so obtained. Prof. J. McIntosh has described three tar-induced sarcomata capable of propagation by cell-free filtrates. On the other hand, careful work carried out in Sheffield, Glasgow and Edinburgh, with fowl tumours induced by 1 : 2 : 5 : 6-dibenzanthracene, has not given any evidence of a filterable virus in these tumours. Prof. E. Mellanby has found that the virus of the Rous chicken sarcoma, which can be propagated by cell-free filtrates, is present, not only in the normal organs of infected birds, but also in dibenzanthracene tumours of birds bearing the filterable tumour. If a fowl bearing a tumour induced by 1 : 2 : 5 : 6-dibenzanthracene is infected with Rous chicken sarcoma, the virus of the latter passes into the dibenzanthracene induced tumour, so that an extract of the dibenzanthracene tumour injected into other fowls produces tumours resembling the Rous tumour and not the dibenzanthracene tumour.

In the study of tumour viruses, the high-speed centrifuge is being developed into a useful tool. The air-driven and air-floating centrifuge is relatively simple and inexpensive, and as it rotates at 40,000–60,000 r.p.m. it makes it possible to subject liquids to forces up to 70,000 times that of gravity. By means of this centrifuge it is possible to concentrate the active agent of fowl sarcomata. The concentrates contain elementary bodies, possibly virus particles, which can be examined under the microscope.

Work on the nature of the changes occurring in isolated cancer tissue continues to give interesting results, but the problem of the anomalous high rate of lactic acid formation in the presence of oxygen remains unsolved. Dinitro-phenols which cause increases in temperature and metabolism in man and animals also increase the respiration and lactic acid production of isolated tumour tissue—the mechanism of the biological effect of nitrophenols is still obscure. On the other hand,

naturally occurring coloured oxygen carriers such as pyocyanine and lactoflavine increase the oxygen consumption and decrease the lactic acid formation of tissues. Dr. F. Dickens has found that other dyes which are photo-sensitisers, such as phenosafranine, cause increased aerobic lactic acid production. It is remarkable that some irritants such as mustard gas (dichloro diethyl sulphide) and cantharidine prevent or delay the carcinogenic action of tar or similar agents. Dr. I. Berenblum and Dr. L. P. Kendal found that these anti-carcinogenic agents are able to inhibit glycolysis to a greater extent than respiration. It seems to the present writer that this effect may be allied to the effect of iodoacetic acid inhibiting the lactic acid production of muscle.

In the recently formed Cancer Department of St. Bartholomew's Hospital, a million volt X-ray plant is being installed. This should give a more powerful source of short-wave radiation than any radium bomb or X-ray plant at present in use. The results from this plant will be of extreme interest. The present report gives data referring to the radiological treatment of patients in many hospitals, and the pooling of results in this way must be of value in assessing the value of radiological methods in clinical work.

Radiations from radium and X-ray tubes have been used in many experiments on chick embryo and on tadpole tissues. Gamma-rays are found to have most effect on cells that are about to divide; once cell division has commenced, the process completes itself in a normal manner even in the presence of gamma-rays. The first effect of gamma-radiation is therefore apparently to reduce mitotic activity; but this is followed in turn by periods of apparent recovery, degeneration, abnormal mitosis and final recovery. Further examination of the effect of radium on tissue cultures of chick embryo tissue seems to indicate that the lethal effect depends on the actual amount of radiation rather than the time over which the radiation is spread.

Several specimens of human carcinoma removed in operation have been grown *in vitro*. An interesting phenomenon demonstrated by Dr. T. Lumsden with tissue culture methods is the action of antibodies capable of killing cancer cells *in vitro*. The effect of the anti-cancer sera has now been photographed with a cinema camera, and the death of tissue culture cells in the presence of the serum is strikingly shown in the film. It would be of interest to see the effect of the rat anti-cancer serum on tissue cultures of human carcinomata.

It was shown some time ago that snake venom had a toxic effect on malignant growths. The toxic effect of cobra venom on tumours is not prevented by anti-venom serum, and it may be possible to check the toxic effect of the venom on the host without inhibiting the effect on the cancerous growth. This is possibly a hopeful method of attacking the problem of curing cancer. With the active research that is being prosecuted along so many divergent lines in many laboratories, it is possible to say that advances are being continually made, but by which way the goal will be attained it is quite impossible to forecast.

Obituary

Prof. Charles Richet

A STONE'S throw from the tip of the headland of Giens, in the south of France, there is a cluster of rocky islets. One of the most picturesque of them is pointed at with awe by the local country folk, as the home of a famous old man who carried out mysterious experiments and tried to communicate with the world beyond. It was, indeed, the country home of Prof. Charles Richet, well known in physiology and abnormal psychology, who died on December 3 in Paris.

Physiology and medicine owe to Richet the discovery of anaphylaxis, in 1902, which marked a decisive advance in modern medicine, and for which he was awarded the Nobel Prize for Medicine in 1913. This discovery was the result of a series of experiments and researches dating so far back as 1887, a year before the foundation of the Pasteur Institute, when Richet was the first to carry out an injection of serum into a human being. He was thus one of the founders of serotherapy.

In 1902, Richet was studying with Portier the action of the poison of sea-anemones, when they remarked that dogs which had withstood without any inconvenience an intravenous injection of a minimal dose of an aqueous extract of the tentacles of *Actinia*, always died after a second but weaker injection administered to them in the same way a few days later. But as this second injection was not strong enough to kill a fresh animal, they came to the conclusion that the first dose of a serum does not always immunise, but on the contrary, renders the organism more sensitive for a certain period and though the effect of the first dose seems to have disappeared. Thus were cleared up many mysterious cases of intoxication and an explanation was forth-

coming, in particular, of the occurrence of sudden death after repeated and successful administration of serum. The name of 'anaphylaxis' was given by Richet to this type of sensitiveness; and since that time a number of experiments have considerably improved the practice and effectiveness of serotherapy. Richet's "Dictionnaire de physiologie", begun in 1895, is a comprehensive study of the whole subject. He also wrote "Recherches sur la sensibilité" and "La Physiologie des muscles et des nerfs".

In later years, Richet was interested more and more in psychology and especially in the investigation of borderland phenomena. He objected to the use of the words "abnormal" or "occult" in connexion with such phenomena, as he held them to be just as natural as any others, and therefore just as much entitled to investigation by the ordinary methods of science. In 1905, the year in which he was elected president of the Society for Psychical Research, he proposed to give the name *Métapsychique* to the new science of these phenomena, which he classified under three principal types: cryptesthesy (clairvoyance), telekinesy (action at a distance without contact) and ectoplasmy (materialisation). He contended that as these phenomena occur, they must be real and subject to laws which ought to be discovered by unbiased scientific investigation. These views, which follow closely the work of Sir William Crookes (1872), are illustrated in his "Thirty years of Psychical Research", of which an English translation appeared in 1923, and which is an immense collection of cases of varying evidential value. A smaller volume, partly based on the first, appeared in English in 1929 under the title "Our Sixth Sense". Though Richet considered metapsychics to be still in its infancy, he hoped, with many other distinguished philosophers and psychologists, to see it gradually develop into a full science.

In the realm of psychology proper, Richet adopted the mechanistic theories of Descartes, which he endeavoured to extend to man himself, as had already been suggested by Lamettrie's "L'Homme Machine". Mind cannot be independent of matter, but rather subject to its fundamental laws. There is no gap between the psychical and the physiological; and the 'higher' faculties of man can be easily explained by inferior phenomena with such laws as those of reflex movements, of irritation and of association ("Traité de psychologie générale", 1912). Consequently, if introspection is useful for the study of the decisions of the conscience, it cannot help in the investigation of psychological phenomena, which must be entirely experimental. This ruthless determinism, which was well in keeping with the prevalent ideas among French men of science at the beginning of this century, caused Richet to deny the necessity of any metaphysical conceptions and to predict the death of metaphysics.

Charles Richet was born in Paris on August 25, 1850. Following the footsteps of his father and his maternal grandfather, he studied science and medicine and obtained an M.D. at the Paris Faculty of Medicine in 1876. He then worked under Marey at the Collège de France, and in 1887 he was appointed professor of physiology and medicine in the University of Paris. His first discovery was that of the presence of hydrochloric acid in the gastric juice. He investigated the relation between respiration and the area of body surface; and he carried out a good deal of research on animal heat. He also studied the problem of epilepsy and the treatment of tuberculous patients by dieting them on raw meat.

The interests of Charles Richet were not limited to physiology and psychology. He followed from the beginning the development of aeronautics and he made a name for himself as a novelist and a playwright, two of his plays ("Socrate" and "Circé") having been performed at the Odéon, in Paris. He was also a convinced pacifist and president of the Société pour l'Arbitrage entre les Nations. A member of the Academy of Medicine since 1896, Charles Richet was elected in 1914 to the Academy of Sciences. His scientific jubilee was celebrated in 1926, at the Paris Academy of Medicine, with the official participation of savants from many countries. On that occasion, Marshal Foch invested him with the insignia of Grand Cross of the Legion of Honour. T. G.

WE regret to announce the death last September in his seventieth year of the eminent Italian physiologist, Prof. Luigi Mariano Patrizi, who was born at Recanati near Ancona on September 13, 1866. He studied under J. Moleschott in Rome, where he qualified in 1890. After serving as assistant to Angelo Mosso at Turin, he occupied in succession the chair of physiology at Ferrara (1894), Sassari (1896) and Bologna (1924). During the period 1911–24 he was professor of criminal anthropology at Turin. His work was chiefly concerned with the psychometry of attention, the physiology of the intellect and criminal physiology and psychiatry. His publications include a psycho-anthropological study of Leopardi and his family (1896), the physiology of the bandit Giuseppe Musolino (1904), "The Orator" (1912), "After Lombroso" (1916) and a work on the physiological measurement of the emotions and passion (1924).

WE regret to announce the death on November 19, at the age of sixty-six years, of Dr. Dan McKenzie, who besides being a consulting surgeon in diseases of the ear, nose and throat and a former editor of the *Journal of Laryngology and Otology*, was a keen student of medical history and folk-lore. In addition to a textbook on his speciality, of which the second edition appeared in 1927, he was the author of "The City of Din" (1916), "Aromatics and the Soul: a Study of Smells" (1923), and "The Infancy of Medicine: an Enquiry into the Influence of Folk-Lore upon the Evolution of Scientific Medicine" (1927), of which a notice appeared in NATURE of January 28, 1928, p. 133.

News and Views

Sir Archibald Geikie (1835-1924)

THE centenary of the birth of Sir Archibald Geikie falls on December 28 this year; it is a fitting occasion to remind older geologists of what many of them owed to him during their earlier years for his teaching and writings, and to direct the attention of younger geologists to the changes that have come over the science since Geikie began his labours. It was his good fortune to take up geology when major principles still required documentation and exposition; he devoted much attention to the significance of denudation in the shaping of existing forms of land surface and to the results of volcanic activity, and in pursuit of field evidence travelled extensively in Europe and North America. Possessed of a logical mind, great industry and a lucid and dignified prose style—which gave him pleasure to employ—he early assumed and continued during his life to occupy a leading position as an exponent of physical geology. During his tenure of office as director-general of the Geological Survey of the United Kingdom he secured opportunities for a considerable literary output, including the compilation of his great textbook, first published in 1882, which after several revisions is still in use, but how different from its successors with their lavish employment of photographic reproductions. Sir Archibald corresponded freely with his geological contemporaries abroad, worthily maintaining the status of British geology, and he received generous recognition from many foreign societies. He took an active part in the administration of scientific institutions, and held the presidency of the Royal Society in 1904 and of the British Association in 1892; but it was as a writer of readable geological literature that he earned the appreciation both of the serious student and the general reader, and made thereby an indelible mark on his epoch.

Education and Administration among Backward Peoples

IN another column of this issue of NATURE (see p. 1003) it is suggested in discussing 'indirect rule' of native peoples in Africa that the anthropological approach to problems of native administration is open to the danger of taking too conservative a view in the attempt to regulate the effects of cultural contacts. How this is to be avoided, without at the same time impairing the lessons of anthropological study, is the main thesis of an essay by Mr. F. C. Williams, Government anthropologist of the Territory of Papua, which was awarded the Wellcome Medal for Anthropological Research by the Royal Anthropological Institute in 1933 ("The Blending of Cultures: an Essay on the Aims of Native Education": Territory of Papua, Anthropology, Report No. 16. Government Printer, Port Moresby. Pp. 46. 1*s*.). Mr. Williams, whose conclusions, necessarily, are largely coloured by his experience in Papua, points out that, rightly regarded, the problems of native education and native administration are one. Education, thus understood, he maintains is a process of three operations, or "tasks":—maintenance, fostering necessary or desirable elements in native culture; expurgation, eliminating undesirable elements, such as sorcery, cannibalism and head-hunting; and expansions, which, while recognising that change is inevitable, seek to guide it by the incorporation of progressive elements which native culture is ready to assimilate, as, for example, improved methods in horticulture. It will be noted that this throws upon the administration the responsibility of formulating a 'blend' of cultures, which is both conservative and progressive, and will not prove detrimental to native character and morale. This demands an intensive study of native culture, but at the same time one which the successful administration of native affairs in Papua has shown to be not impossible.

The Outlook for Consumers

UNDER this title, P.E.P. (Political and Economic Planning) issues a broadsheet, No. 63, which should interest everyone, because all the world is a consumer and comparatively few are producers or distributors. We all think that we suffer, at times, from the greed or petty dishonesty of those who stand on the other side of the counter, yet for the most part we grin and bear it, taking little thought of the methods that might be used to give us value for our money. Fundamentally, the problem is the one that is penetrating ever more deeply into the social conscience, namely, how the proceeds of useful human labour should be apportioned equitably among producers, distributors and consumers. Some are convinced that the principle now ruling is that of the jungle—sweets to the sweet and the hindmost to the devil—and that pending the time when men are educated morally to the same degree as some are now educated intellectually, the only solution is the total elimination of 'profit' in the Marxian sense, or drastic regulation of profits, as now practised in certain Continental countries.

OTHERS, however—and P.E.P. is apparently among them—assume that, in the main, what was, will be, and that desirable changes can or should be effected only on the basis of the existing order: evolution rather than revolution. It is from the latter point of view that the authors of the broadsheet approach the subject of consumers' interests, and after laying down that, as a rule, the buyer gets what he deserves, and that to effect any useful change he must stir himself and co-operate with his fellows, they proceed to enumerate and discuss five possible ways in which the consumer can assist himself or be assisted. One way of helping the consumer is to improve the shops. For several reasons, the old personal relationship

between shopkeepers and customers has largely disappeared, and the former are no longer the trusted purchasing agents and advisers of the latter; goods are left to sell themselves; the salesman merely wraps them up, sees that they are paid for, and passes them over the counter. The recent foundation of the Retail Trading Standards Association is a move in the right direction, but will not prove effective unless more consumers take an active interest in standards and exert a firm but constructive pressure to secure a fair deal for the consumer.

A SECOND way is for consumers to elect or appoint representatives to protect their interests. Parliament cannot be expected to concern itself with detailed questions, but special consumer councils might succeed if they could arouse public interest. Thirdly, the consumer might be protected by direct Government action. Certain State departments, for example, the Ministry of Health and the Board of Trade, already help in this respect; but they do not go far enough and can only deal with cases that come within the ambit of the law: their services are certain to increase, but no great good can be done unless public opinion is aroused and made effective through a special consumers' organisation. Another method of helping the consumer is suggested by the success of Consumers' Research, Inc., in the United States, a voluntary organisation that investigates goods offered for sale and marketing practices, and makes known the results to its members. Closely allied to the concept of a consumers' research organisation is that of a 'trade union', which would comprise consumers of certain specified products, would stand up for their rights and bring pressure to bear when occasion demanded. An example of such a body is represented by the Automobile Association, which recommends hotels and garages, elaborates route plans and provides free legal defence.

Economics of the U.S.S.R.

IN a recent issue of the *Manchester School*, Vol. 6, No. 2, there is an interesting article on "U.S.S.R. Economics—Fundamental Data, System and Spirit" by Prof. M. Polanyi, who points out that the present moment appears to be a favourable one for taking stock of the achievements of the Russian Revolution. Socialism has been definitely instituted, and communism has been relegated to an uncertain future. Also the recent introduction of a marketing system makes it easier to review the economic situation, as we can now compute values in terms of money. Planned economy is a corollary of communism, but in fact, Prof. Polanyi states, a system of planned economy has never been attempted in the U.S.S.R. since the repeal of communism in 1921. For one thing, as Stalin bluntly admits, there has never been a proper distributive system at all. The First and Second Five Year Plans were not systems of planned economy, but merely systems of planned production, and even this is an overstatement for no great stress was laid on the systematic nature of the plan. The Soviets claim that they have carried out the First Five Year Plan, but in doing so they pass over in silence the biggest item of their plan, namely, the planned increase of agricultural production by fifty-five per cent; instead of this being achieved, a very serious fall took place during the first five year period. During the last four years, the outline of an economic system based on the principles of marketing has been developed. Prof. Polanyi concludes that while he is convinced that no return to private ownership is possible in the U.S.S.R., it seems that public and collective management is developing on lines almost identical with those in the marketing system of capitalism.

Watt Bicentenary Exhibition at the Science Museum

A SPECIAL exhibition was opened at the Science Museum, South Kensington, on December 20 to commemorate the bicentenary of the birth at Greenock on January 19, 1736, of James Watt, the famous engineer and inventor. The exhibition will remain open until April 19. Many objects of particular interest are being shown, including three original beam engines, two of which were erected in Soho Manufactory in 1777 and 1788 respectively and the third in London in 1797, and various original experimental models, including the separate condensers of 1765 which led to his most important contribution to the development of the steam engine. The Garret Workshop, where Watt frequently worked from 1790 until his death in 1819, and which was moved with its contents from Heathfield Hall near Birmingham to the Science Museum in 1924 for permanent preservation, is on view. A large number of drawings, some by Watt himself, have been lent by the Birmingham Public Libraries Committee and form a detailed survey of the progress in steam engine design from 1775 until 1800, the period of Watt's partnership with Boulton. Numerous portraits of Watt, Boulton and their scientific friends have been generously lent for the occasion by the National Portrait Gallery, the Victoria and Albert Museum, the Royal Society, the City of Birmingham Art Gallery and others. About one hundred letters between Watt and Boulton have been selected from the voluminous correspondence preserved at the Assay Office, Birmingham, which gives an intimate picture of Watt's difficulties and achievements. Some of the memorials and books written on the life and work of Watt are exhibited also. Catalogues of the Memorial Exhibition, the Garret Workshop and the Stationary Engines Collection are on sale in the Science Museum. Special Bicentenary Lectures are being given by the guide lecturer in the lecture theatre and the gallery on various days during the period of the exhibition. Particulars can be obtained on application.

Function of the American Chemical Society

IN his address at San Francisco on August 19 in receiving the Priestley Medal of the American Chemical Society, Prof. W. A. Noyes said that the two outstanding problems to be solved by our generation are the abolition of war, and a better

distribution of work and the products of our industries. Chemistry can no longer be thought of as an isolated branch of science, and independent of the rest of our lives. While providing for the development of personality and initiative, it is necessary to restrain those who will not contribute their share in co-operative service. Discussing the growth of the American Chemical Society, Prof. Noyes referred to the proposal to start a journal of organic chemistry as the outcome of a feeling that the Society does not sufficiently provide for the publication of non-industrial research. Emphasising the fact that chemistry is not an isolated science sharply divided from physics, biology, or even economics, sociology and political science, Prof. Noyes suggested instead the publication of the existing journal in two parts. The first part, published early each month, would contain the papers at present classified under the heading, "General, Physical and Inorganic". The second part, published late in each month, would appear under the sub-heading "Organic and Biological". Both parts would appear under the heading *Journal of the American Chemical Society*, and the pagination would be continuous. A single index would be issued, but each part would have its own editor. In concluding, Prof. Noyes discussed the question of training, the importance of giving all students a broad knowledge of our chemical heritage, and of encouraging the chemist to see his work as a unit in a co-operative democratic organisation which serves the community and gives a reasonable return to workers, directors and capital.

"Purging" Scientific Literature in Germany

THE *Chemiker Zeitung* of November 30, p. 978, prints a notice to German chemists requiring them in future to avoid the use of "foreign" words. It is explained that this can easily be accomplished, and among the illustrations given appear the following:

Förderanlage	instead of	Transportanlage
wirtschaftlich	,,	rationell
für, or je	,,	pro
durchlassig	,,	porös
zusammenpressen	,,	komprimieren
Nachahmung	,,	Imitation
Stück	,,	Exemplar
Ausmasse	,,	Dimensionen
umgrenzen	,,	definieren
Hochstwert	,,	Maximum
Tiefstwert or Niedrigstwert	,,	Minimum.

Vorbild, *Form* or *Muster* are suggested as alternatives to *Schema*, but the Editor, having perhaps seen comments on this subject in the notice of Joos' "Lehrbuch der theoretischen Physik" and in subsequent correspondence in NATURE (September 28, p. 495, and October 26, p. 675), points out that such innovations as *Kleinsehwerkzeug* for *Mikroskop* and *Scheidekunst* for *Chemie* should not be adopted, as they might be regarded as ridiculous by others.

New Telephone Developments

IN the *Review* (No. 3, 1935), published in English by the Ericsson Telephone Factory of Stockholm, there are described two interesting developments of telephony. One of them is called the 'laryngophone' which has been specially designed for use in aircraft. Owing to the noise in airships, ordinary carbon microphones with diaphragms cannot be used. The diaphragm of the new telephone is actuated by being lightly pressed against the throat in the neighbourhood of the larynx. For aircraft, it is necessary to have both hands free, and a headphone of normal design can be conveniently fitted in the pilot's helmet, the laryngophone being worn without discomfort inside his collar, extraneous noise not being transmitted by it. This type of instrument can be usefully applied for fire control on warships, in engine rooms, on motor vehicles, tanks, etc. The other instrument is useful in connexion with the buoy-telephones which have for many years been used in the submarines of the Swedish navy. In the latest development, two buoys, with buoy telephones, are used. Each buoy contains a telephone set, and an electric lamp is fitted on the top of it. Flash signals are sent from the submarine to attract attention to the buoy. An instruction plate on the buoy tells how to open the lid of the compartment containing the telephone set, and the submarine is rung up in accordance with the directions printed on a plate on the telephone cover. Buoy telephones are fitted at each end of the submarine. The lamps are supplied from the 110 volt accumulator of the submarine and light up when a watertight telegraph key is closed.

The British Film Institute

THE British Film Institute's second annual report, issued on October 1, records notable advances (long overdue) in its task of "furthering effective co-operation between those who make, distribute, and exhibit films on the one hand, and all who are interested in the artistic, educational, and cultural possibilities of films on the other". The scope of its activities is indicated by the chapter headings: The Cinema for the Schools, Free Trade in Educational Films, National Film Library, Vouchers of Approval, Entertainment Panel, Dominions, India and Colonies Panel, Medical Panel, Scientific Research Panel, Summer Schools, International. Its regular publications comprise *Sight and Sound*, on sale to the general public at 6*d*., quarterly; a monthly film review on sale to associate members at 2*d*.; and news letters circulated to members. In addition, there are occasional leaflets of which the best known, No. 5, on projection apparatus and films for schools, achieved a circulation of nearly 10,000; another, No. 8, gives a full account of the National Film Library established by the Institute last July. A scheme has been worked out for the award by the Institute of vouchers of approval to films voluntarily submitted to it for examination and, as a corollary of this, expert and authoritative advice is given to producers before and during production. The Entertainment Panel has undertaken a systematic inquiry

into the supply of suitable films for children's performances. The Medical Panel has compiled a catalogue of British medical films and will issue supplements from time to time. The Scientific Research Panel is collecting material for a report on the extent to which the cinematograph is, and can be, used in the advance of scientific knowledge. The first Film Summer School for teachers was held at Scarborough last August. Ten local branches, known as Film Institute Societies, have been at work during the year, at Becontree, Bristol, Brighton, Chichester, Leeds, London, Manchester, Liverpool, Belfast and Salford.

Research and the British Academy

PROF. J. W. MACKAIL, in his presidential address to the British Academy delivered in July last (Oxford University Press, pp. 11. 1*s*. net), laid it down as a principle that "the products of the Academy as an organised body . . . are all, in their different ways, and from their different angles and lines of approach, means towards an end", which he went on to define further as including two interlinked motives: to maintain a standard of learning and to preserve the continuity of civilisation. This view of the functions of the Academy would lay a heavy burden of responsibility on any body, however august; but if the further dictum be accepted that it is by the first that the second may be most directly and most effectively attained, it adds an impressive weight to the opinion the president expressed at an earlier stage in his address, that the Academy's grant from the Treasury of £2,000, only recently restored to its full amount, is quite inadequate. In the field of pure scholarship, certain enterprises, it is true, have been able to make progress through the Academy's subsidy. Yet even here, in what might be regarded as the Academy's special province, in number they make a poor showing. In the vast and wider fields of humanistic studies the prospect is even less encouraging. In archæological research, now that the excavations at Samaria have been brought to an end, apart from the contribution to the British School of Archæology in Iraq, which stands in a special category, the only body to which the Academy contributes is the British School of Archæology in Jerusalem. Archæological research unfortunately falls between the two stools of science and letters, belonging to the one by its technique, to the other in the applications of its results. This contention apart, in comparison with Continental academies, the British Academy is second to none in the standing of its fellowship; but its material contribution, as a body, to the advancement of the subjects which have been brought within its purview is negligible.

Mining in Tanganyika Territory

WE have received an interesting pamphlet from Tanganyika Territory entitled "Mining Publicity Pamphlet", and issued by the Department of Land and Mines. It shows at the outset a useful map of the Territory, and after a short introduction there is full information for all prospective immigrants, including such points as the customs duties and the mining and prospecting laws which have been adopted. There is an account of the geology and physiography of the Territory, and economic minerals and mineral production are fully described. We find, for example, that the value of mineral production has increased largely and in many cases has doubled since 1932 when Great Britain went off the gold standard, with a correspondingly rapid rise in the price of the precious metal; in fact, the value of all minerals has increased since 1932 with the exception of mica, which is less than half in 1934 what it was in 1932; whilst the value of the minerals produced is put down as close on £200,000 in 1932, in 1934 they had risen to close upon £364,000. Gold mining is, of course, a great attraction at present, although the pamphlet states that "it is to be anticipated that the internal prosperity it [gold production] is creating will exert its beneficial influence on other forms of mining within the territory". This is one of the few regions where the old-time prospector still finds work, and existing gold fields, containing both reef gold and alluvial gold, are fully described in the pamphlet in question. The pamphlet is of distinct use to immigrants proposing to enter Tanganyika Territory, and its perusal is strongly recommended to any who are proposing to go out, and especially perhaps to those intending to follow gold mining.

The Spahlinger Tuberculosis Vaccine

A JOINT committee on tuberculosis of the Medical Research Council and the Agricultural Research Council has issued in the form of a green paper (London: H.M. Stationery Office, 2*d*. net) observations on the experiment with Spahlinger vaccine in Northern Ireland, the report on which was issued some weeks ago. In this experiment, 11 calves were vaccinated with the Spahlinger anti-tuberculosis vaccine, and 7 calves were kept unvaccinated as controls. Six months after the vaccination, all the calves were given the same dose of virulent tubercle bacilli intravenously. The difference in the effect on the two groups was striking. Of the 7 controls five died of acute tuberculosis within 25–73 days. On the other hand, none of the 11 vaccinated animals died from the acute disease, one died on the 607th day, and the remaining 10 lived until slaughtered on the 783rd–890th day. All, except one, of these were in good condition although found to be tuberculous to greater or less extent. The joint committee concludes that a case has been made out for further investigation, that the number of animals used in the Irish experiment were not enough to give statistically conclusive results, and that the general use of the vaccine should be deferred until a thorough investigation has been made.

The Physique of Man in Industry

IN 1927, the Industrial Fatigue (now Health) Research Board published a report of an inquiry on "The Physique of Women". The results of this inquiry appeared to be of such value that the Board decided to institute an investigation of the same kind

amongst men. Prof. Cathcart directed the work, assisted by Messrs. Hughes and Chalmers, and in the analysis of the data by Miss Blair and Miss Werner, and their report has now been issued ("The Physique of Man in Industry". Med. Res. Council. I.H.R.B. Report No. 71. H.M. Stationery Office, 1935. 1*s.* 3*d.* net). It records the physical examination of 13,656 male volunteers aged fourteen years and upwards in fifteen areas in England and Scotland. The total includes 10,593 employed men, 1,328 unemployed men and 1,735 students. The data recorded were height, weight, grip (both hands), pull when standing, and distance of middle finger tip from the ground. The student group had the highest average height and weight, but were inferior in strength to those in manual occupations. The unemployed group was slightly inferior in weight, and definitely inferior in strength, to the employed group. No certain index of physical fitness, industrial or other, was discovered. From the average elbow height (43 in.) of the employed, it is deduced that the comfortable height of a working bench for the average man standing should be about 38 in.

Biological Control of the Mediterranean Fruit Fly

THE Mediterranean fruit fly (*Ceratitis capitata*) has, for many years, caused ravages among many kinds of edible fruits in the Hawaiian Islands. The introduction of several species of parasites from Africa and Australia has resulted in a very appreciable reduction in the abundance of the pest in question, but a sufficiently efficient degree of control, from the commercial point of view, has not so far been achieved. We learn from Science Service, Washington, D.C., that a scheme has been put in hand which involves further application of biological control methods. In order to carry out the project, the Hawaiian Planters' Association is sending two of its entomologists, along with others from the Department of Agriculture, to Africa with the object of searching for suitable parasites. Other entomologists are proceeding to Brazil with the same aim in view. The whole project is being administered by the U.S. Bureau of Entomology in conjunction with the leading local organisations concerned in Hawaii. The Hawaiian Islands are famous as being the territory where some of the most successful examples of the biological method of pest control have been achieved. The plan of campaign against the fruit fly is expected, if successful, to lead to great benefits to the small farmers of the territory by increasing the supply of fruits that grow so luxuriously in those islands.

New System for Nature Recording

AFTER much discussion, extending over two quarterly meetings, the council of the British Empire Naturalists' Association has agreed to form a special section to deal with field natural history records. A properly spaced system of observers is to be built up all over Great Britain, and eventually a committee of experts will be formed to decide upon the problems to be tackled, and the methods to be adopted. Plans are at present being made for a conference of branch secretaries in London next April. For some ten years, the British Empire Naturalists' Association has worked a system of publishing in its quarterly journal, *Country-Side*, bird, plant and insect records of seasonal and statistical interest, grouped in the various counties. Not only was this incomplete, in that records were more quickly forthcoming from southern areas richest in resident naturalists, and other northern areas were neglected, but also in flora especially no complete review could be made owing to the necessity of finding room for other matters in the journal. The new scheme will be welcomed by historians of field natural history, who often have to go through masses of local and national publications for scattered field records of varying value.

A New Natural History Magazine

A NEW German periodical, edited by A. Benninghoff, K. Beurlen, K. Hildebrandt and K. L. Wolf, offering a variety and standard of contributions which ought to commend it to many readers, has recently appeared. The title, *Zeitschrift für die gesamte Naturwissenschaft*, suggests the breadth of its objective, the scope of which is extended by the inclusion of Nature philosophy and the history of Nature knowledge and medicine. The articles of the first issue (April) are not over-long—about fifteen pages—a short summary precedes each, and the matter, while avoiding too technical treatment, makes a serious contribution to the subjects discussed. K. Hildebrandt writes upon "Positivismus und Natur", and other major articles deal with "Morphologie und Erdgeschichte", "Bedeutung und Aufgabe geologischer Forschung", "Subjektbezogenen Nomenklatur in der Biologie", "Warum studieren wir Biologie ?", to which the final answer is "Wir studieren Biologie, weil wir müssen". A variety of subjects are discussed in short contributions, and there are seven signed reviews of books.

Use of the Astrolabe

ALTHOUGH the astrolabe has found some support among surveyors, it has not been widely used by British astronomers. An extensive account in English of the practical use of the modern astrolabe has recently been published by Mme. Chandon and M. Gougenheim in the *Hydrographic Review* (**12**, No. 1). This account contains full details of the working and practical operation of various modifications of the astrolabe, and should be studied by all who are interested in the accurate determination of position. It may be hoped that this paper will stimulate astronomers to devise a means of eliminating personal equation from the astrolabe, so that the instrument may eventually compete with the transit circle in the accurate determination of longitude.

Pathological Investigations at Edinburgh

IN the annual report for 1934 of the Laboratory of the Royal College of Physicians of Edinburgh, by the curator, Sir Robert Phillips, an account is given of the research and other activities. Much work has

been done, particularly on the pathology of the mamma, by Miss Dawson, and about 1,000 reports on tumour growths were issued; the sections made, together with the material from which they are derived, are preserved and indexed for future reference and research. The death rates of Great Britain and Sweden and the spread of infectious diseases have also been investigated statistically. More than 15,000 examinations of specimens for medical men were carried out.

Society for the Study of Alchemy and Early Chemistry

A SOCIETY for the Study of Alchemy and Early Chemistry has been founded in London. It is intended to place the study of alchemy and early chemistry on a broad basis, and for this reason the Council of the Society is desirous of securing the co-operation of scholars in various countries who will contribute to the interests of the Society. It is proposed to hold regular meetings, beginning early in 1936, at which papers will be read and discussed, and to publish a journal in which accounts of the papers will be given as well as special articles, written contributions by members of the Society and reviews of books. The following council has been elected: Prof. J. R. Partington (*chairman*), Dr. F. Sherwood Taylor (*Editor of the Journal*), Gerard Heym (*Hon. Secretary*), K. de B. Codrington, L. F. Gilbert, Prof. S. R. K. Glanville, Sir Richard Gregory, Dr. E. J. Holmyard, Dr. D. McKie, Dr. L. W. G. Malcolm, Dr. Stephen Miall. Further information can be obtained from the Hon. Secretary, Society for the Study of Alchemy and Early Chemistry, 8 Bream's Buildings, Fetter Lane, London, E.C.4.

International Geological Congress, 1937

THE organisation committee of the seventeenth session of the International Geological Congress, which will meet in Moscow in 1937, has issued a second circular outlining the scope of the various subjects proposed for discussion. In connexion with the problems associated with the geology of petroleum and coal, it is hoped to make an estimate of the oil reserves of the world and to review the coal resources of the U.S.S.R. and other countries. A discussion of the stratigraphy, igneous cycles, tectonics and mineral deposits of the Pre-Cambrian is proposed. The stratigraphical limits of the Permian System, at present a source of widespread controversy, again comes up for consideration. An attempt is to be made to correlate tectonics, magmatic evolution, ore deposits and geochemistry, and as a further theme a review of the data bearing on these problems with special reference to Asia is proposed. Another geochemical problem is that of the occurrences of rare elements. Geophysical subjects to be discussed include measurement of geological time; isostasy and anomalies of gravity; terrestrial magnetism; and seismology. Finally, it is hoped that reports will be presented on the history of the various branches of geology. Further particulars may be obtained from the General Secretary, Dr. A. E. Fersman, Sretenka 8, Moscow 10.

Announcements

DR. H. S. GASSEN, professor of physiology at Cornell University, New York, has been nominated director of the Rockefeller Institute in succession to Dr. Simon Flexner.

PROF. YAS KUNO, until recently of the Japanese Medical College, Mukden, South Manchuria, and now of the Institute of Physiology, Kyoto Imperial University, Japan, has been appointed a member of the Permanent International Committee of the Physiological Congresses. This is the first time that a representative of Far Eastern physiology has been appointed to the Committee. Prof. Kuno was a pupil of the late Prof. E. H. Starling at University College, London, and is a member of the Physiological Society, Great Britain. He has done very important work on perspiration and body temperature, and has written an excellent book on the subject.

MR. M. C. LAMB, principal of the Leathersellers' Technical College, will retire from his present position at the termination of the current session, having then attained the age of sixty years. Mr. Lamb has been associated with the College from the time of its opening in 1909, and has had forty years' experience in the teaching of leather technology, having been appointed a demonstrator in the Leather Department of the University of Leeds so far back as 1895. During the period of his occupation of the principalship, the College has been progressively successful, and is now regarded as the most efficient and best equipped of its kind in the world, attracting students from every centre where leather is produced.

AMONG the awards for 1935 made by the Royal Horticultural Society are the following: *Victoria Medal of Honour*, Sir Daniel Hall, for his scientific work in connexion with horticulture; *Veitch Memorial Medals*, Dr. A. D. Cotton, for his services to horticulture, and Prof. E. J. Salisbury, for his book "The Living Garden"; *Loder Rhododendron Cup*, Mr. A. Rehder, of the Arnold Arboretum, U.S.A., for his work on the genus *Rhododendron*.

A DISCUSSION on "Probability" will be held by the London Mathematical Society on January 16, at 5 p.m., in the rooms of the Royal Astronomical Society, Burlington House, W.1. The following have promised to take part: Prof. H. Levy, Sir Arthur Eddington, Dr. P. Dienes, Prof. R. A. Fisher, Dr. Harold Jeffreys, Prof. J. B. S. Haldane.

IN reference to the article on the annual Congress and Exhibition of the British Institute of Radiology in NATURE of December 14, p. 960, Dr. J. Read informs us that the first continuously evacuated tube constructed by Lauritzen worked intermittently at 750 k.v., not 600 k.v.; also that the Soiland Clinic tube worked at 550 k.v., not 100 k.v., and that the Clinic has now installed three 200 k.v. constant potential Latour circuits in cascade in place of the cascade transformers.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 1030.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Mathematical Psychology of War

THIS is relevant to the Naval Conference. A letter in NATURE of May 18 was intended to show, by reference to historical facts, that a certain pair of equations did represent, at least crudely, the behaviour of nations prior and subsequent to the Great War. In order to proceed to deductions, it is convenient now to change the notation. The hypothesis aforesaid is that

$$\frac{dx}{dt} = ky - \alpha x + g \quad . \quad . \quad . \quad . \quad (1)$$

$$\frac{dy}{dt} = lx - \beta y + h \quad . \quad . \quad . \quad . \quad (2)$$

in which x denotes the variable preparedness for war of one group of nations, y that of the opposing group; t is the time; k and l are 'defence coefficients'; α and β are 'fatigue-and-expense coefficients' and g and h are measures of dissatisfaction with the results of treaties. Each of k, l, α, β, g, h is regarded as temporarily constant. Of these, k, l, α, β are each positive; but g and h may have either sign, and will be positive for the 'have-nots', negative for the 'haves'. The international situation is thus represented by a point (x, y) in a plane. Let us think of this point as a particle moving in accordance with the equations. If the particle be tending towards plus infinity of both x and y, then war looms ahead. But if the particle be going in an opposite direction the prospect is peaceful.

If dx/dt be zero, the equation (1) represents a straight line; similarly for dy/dt and equation (2). The intersection (x_0, y_0) of these two straight lines is the point of balance of power. It is given by

$$x_0 = (kh + \beta g)/(\alpha\beta - kl), \quad y_0 = (lg + \alpha h)/(\alpha\beta - kl) \qquad (3), (4)$$

But, unfortunately for those who live under a policy of balance of power, the point of balance has several awkward possibilities. First, by a rare chance, $\alpha\beta$ might equal kl so that the lines would be parallel and no point of balance would exist. Secondly, it is quite probable that the point of balance may be situated in one of the quadrants where x or y or both are negative; so that balance could be attained only by negative preparedness for war, that is, by positive preparedness for co-operation. Thirdly, although the particle is undoubtedly in equilibrium when it coincides with the point of balance of power, yet that equilibrium may be unstable.

To investigate stability the equations have been solved by a standard method via the auxiliary equation

$$m^2 + (\alpha + \beta)\, m + \alpha\beta - kl = 0; \quad . \quad . \quad . \quad (5)$$

and it is found that the particle, wherever it begins, will ultimately arrive at the point of balance (x_0, y_0) if

$$kl < \alpha\beta, \quad . \quad . \quad . \quad . \quad (6)$$

whereas the particle will ultimately go off towards infinity if

$$kl > \alpha\beta. \quad . \quad . \quad . \quad . \quad (7)$$

That is to say: the international régime is unstable if, and only if, the product of the two defence coefficients exceeds the product of the two fatigue-and-expense coefficients.

In the unstable régime, the particle will tend towards one or other of two opposite infinities according to where it begins. We may classify the starting points by making a transformation to polar co-ordinates (r, θ) centred at the point of balance, so that

$$x - x_0 = r\cos\theta, \quad y - y_0 = r\sin\theta \qquad (8), (9)$$

For then

$$\frac{d\theta}{dt} = l\cos^2\theta + (\alpha - \beta)\cos\theta\sin\theta - k\sin^2\theta, \quad . \quad . \quad (10)$$

whence it follows that there are always two real lines given by

$$2k\tan\theta = \alpha - \beta \pm \sqrt{(\alpha - \beta)^2 + 4lk} \quad . \quad . \quad (11)$$

on which $d\theta/dt = 0$. The particle cannot cross these lines. They form barriers dividing the plane into four angular portions. In particular, if $\alpha = \beta$ and $l = k$ the barriers are at $\theta = \pm\pi/4 \pm \pi$. When the balance of power is unstable ($kl > \alpha\beta$) the barrier at $\theta = -45°, +135°$, or in general at

$$2k\tan\theta = \alpha - \beta - \sqrt{(\alpha - \beta)^2 + 4lk}$$

is of profound significance, for it divides the international plane into two portions, one of a drift towards war, the other of a drift towards co-operation.

The 'constants' are liable to secular change. The progress of engineering and chemistry has notably decreased α and β, so that if l and k were unchanged, the international régime would now be much more unstable than it was a century ago. The defence coefficients k and l are influenced by the suspicion or goodwill distributed by print or broadcast.

Over all, it must be remembered that the equations describe the rivalries of two groups having populations of the same order of magnitude. In the new tentative practice of 'collective security', one population is many times greater than the other, and a quite different course of events may be expected.

Chemical Action caused by Neutrons and Gamma Rays and the Effects of these Agents on Colloids

FOR more than a year we have been engaged in investigating the action of neutrons and γ-rays: (*a*) in affecting the stability of colloids, and (*b*) in promoting chemical reactions. As sources of γ-radiation we have used platinum containers filled with radium sulphate, or radium emanation sealed into glass tubes surrounded by a few millimetres of lead. Neutrons were obtained from sources similar to these to which metallic beryllium had been added. Since all the neutron sources used emitted γ-rays, every titration was carried out in triplicate on (1) a non-irradiated control; (2) a specimen irradiated by γ-rays alone; (3) a specimen irradiated by neutrons and γ-rays from the same or an equal source. The strengths of the sources ranged from 30 mC to 150 mC and the periods of irradiation from a few hours to two weeks.

Irradiations were usually carried out in the following manner. The sources were enclosed in a test tube which contained either water and a metallic lead filter, or a solution of borax and a cadmium filter. This tube was surrounded by a glass vessel containing the liquid under examination. The test tube and vessel were again surrounded by a large mass of water, or placed in a cavity in a block of paraffin wax. In this way, full advantage was taken of the now well-known methods of slowing down and absorbing neutrons.

Amongst the chemical actions investigated have been the oxidations of potassium metabisulphite and sodium bisulphite, and the decomposition of hydrogen peroxide. In each case it was found that the action provoked by a pure γ-ray source was increased by using a source of equal strength which also emitted neutrons.

The following colloids have been investigated: Hydrosols of silver and gold, the sulphides of arsenic and cadmium, and vanadium pentoxide and ferric hydroxide. When prepared in the standard way it was found that a source emitting both neutrons and γ-rays increased the stability of the negatively charged colloids and decreased the stability of the positively charged colloids. A similar but definitely smaller effect was obtained with pure γ-ray sources of the same strength. Anomalous results could, however, be obtained when foreign electrolytes were intentionally added to the colloidal sol before irradiation.

In all the actions outlined above, it was found that the effect which must be attributed to the neutrons alone was of the same order of magnitude as that due to the γ-rays alone. The greater efficiency of slow neutrons in producing these effects is strikingly exhibited, since with the sources used approximately one neutron was produced per hundred thousand γ-ray quanta emitted. So far as we are aware, no previous observations of the effect of neutrons on chemical reactions or colloidal stability have been published.

This investigation was begun in the hope of discovering a method of detecting neutrons which would be independent of the usual techniques of inducing radioactivity or the use of electrical counters. Two methods, which possess the great advantage of integrating the effects produced until they are easily measured by standard chemical methods, are indicated above.

The similarity of the effects due to neutron and γ-ray irradiation would seem to indicate that the commonly accepted views on the mode of action of the latter are in need of revision.

A fuller account of this work will be published shortly.

Production of Cosmic Ray Showers at a Considerable Depth below Ground-Level

IN order to find whether showers are produced by the penetrating cosmic rays which reach considerable depths below ground-level, we have performed experiments in Holborn Underground station (by permission of the London Passenger Transport Board) at a depth corresponding to 60 m. of water. The vertical intensity of the radiation at this depth, as measured by the rate of occurrence of coincidences between three counters in a vertical plane, is about one-fifteenth that at ground-level. To count showers we used five counters, arranged in a pentagon formation, so that at least three particles are needed to discharge the five counters simultaneously. The occurrence of coincidences is therefore in itself definite proof of the presence of showers. The quintuple coincidence method is preferable to the triple coincidence method as usually used hitherto, as in the latter case a coincidence can be produced by two particles. The presence of showers can then be proved only by showing that there is an increase in the rate of occurrence of coincidences when a sheet of, say, lead is placed over the counters, the dimensions and disposition of the lead being such that coincidences due to particles originating in it must be due to at least three particles. The detection of showers then entails the establishment of a difference between rates with and without the lead, and these may be nearly equal.

Our preliminary results have shown that (*a*) showers are produced in the earth above the counting apparatus; (*b*) the shower rate is increased several fold when the group of counters is surrounded by lead; (*c*) the thickness of lead for maximum shower production is about 1·6 cm., that is, about the same as at ground-level; (*d*) for this thickness the ratio of the rate of shower production to vertical intensity is not very different from that at ground-level under the same conditions.

These conclusions are not in agreement with those of Auger[1], who has reported the absence of showers under 8 m. of earth; or those of Pickering[2], who has reported a rapid diminution in the ratio of the rate of shower production to intensity at depths down to 10 m. of water. The difference seems to be explicable in terms of the counter dispositions used in the various cases, and we shall discuss this point when our results are published in full.

Since there is good reason to believe that protons, owing to their large mass, should produce very few showers, we can conclude from our results that a considerable part of the radiation which penetrates 60 m. of water must consist of positive or negative electrons.

Influence of the Velocity of Slow Neutrons on their Capture by Certain Nuclei

WE have tried to measure the dependence of the cross-section of protons for absorption of neutrons on the relative velocities of these particles. A method which allows of the determination of the absorption of slow neutrons by paraffin wax was used[1]. A source of neutrons (radon + beryllium) was placed in the middle and a silver plate at one end of a cylinder of paraffin wax (4·5 cm. diameter, 18 cm. long). This end could be dipped 5 cm. deep in liquid oxygen. A screen of cadmium could be interposed at different distances between the source and the silver.

The intensity of activation of the silver obtained at room temperature was plotted against the distance between the silver and the absorbing cadmium screen. A curve was obtained, which showed that the diminution of the activity of the silver, due to interposing the cadmium screen, decreased to a half when the distance between the silver and the absorber was increased by 1·6 cm. This shows that, in the given geometrical circumstances, 50 per cent of the slow neutrons, which are absorbable in cadmium, are absorbed or scattered out of the wax cylinder after diffusion through 1·6 cm. of paraffin. Cooling the end of the cylinder to 90° K. increased the activity of the silver, but had no effect on the thickness of the layer of paraffin wax required to reduce the slow neutrons to 50 per cent. This shows that the cross-sections of protons for elastic scattering and for absorption of neutrons are not much increased when the neutrons are slowed down below the velocity they obtain in paraffin wax at room temperature. This seems contradictory to the theory of capture of neutrons by protons[2]. Mr. Francis Perrin and Mr. Walter M. Elsasser, who kindly discussed this result with us, think it compatible with theory for the following reason. The protons in paraffin wax have, in consequence of the total degeneration of the C–H vibration, always a minimum velocity which is large compared with the thermal velocity at room temperature. The relative velocity between a neutron and a proton is therefore changed by a smaller factor than $\sqrt{T_1/T_2}$ when the temperature of the wax is changed from T_2 to T_1. ($\sqrt{T_1/T_2}$ is 1·78 for our case; a change of cross-section of less than 15 per cent would not have been observable.)

Moon and Tillman[3] have shown that neutrons slowed down by paraffin wax are more capable of activating silver and rhodium, when the wax is cooled down to 90° K., but less efficient for iodine. When repeating these experiments, we found the same increase for the activation of silver (28 ± 5 per cent) but an increase of about 10 per cent instead of a decrease for iodine. It might be expected that the cross-section of most nuclei for the capture of slow neutrons would be inversely proportional to the relative velocity between the capturing nucleus and the neutron. In this case, the increase of activation should be 78 per cent for cooling down to 90° K. Moon and Tillman have suggested that not all the neutrons capable of activating silver are already in thermal equilibrium with the protons of the paraffin wax. If the probability for the capture of neutrons by silver be proportional to $1/v$ (v being the velocity of the neutrons relative to the silver atoms), neutrons of energy higher than kT might still give an appreciable contribution to the activation of silver. But cooling the diffusing paraffin would have no big influence on the velocity of these neutrons, and the total activity would therefore be increased by a smaller factor than $\sqrt{T_1/T_2}$.

We observed that the activation of silver by neutrons which had diffused through paraffin was independent of the temperature of the latter when 2 mm. of cadmium was placed directly in front of the silver. It thus seems possible to distinguish at least roughly the neutrons which are still capable of activating silver—although with a small probability—but have a higher energy than kT, from those the energy of which is on the average kT. If the activations above this background, which is independent of the temperature and of the thickness of the cadmium screen in front of the silver, are compared, the activity obtained at 90° K. was 70 per cent higher than that obtained at room temperature. This result indicates that the cross-section for the capture of neutrons by silver nuclei is actually proportional to $1/v$.

For thin cadmium screens a dependence of the absorption coefficient on the velocity of the neutrons was found. These results will be published later.

Redetermination of the Soludility of Chloropentammine Cobaltic Chloride

RECENTLY, I had occasion to describe an improved method for the purification of chloropentammine cobaltic chloride, and to note that the product behaved differently from that obtained by the older method, in that it passed into solution much more rapidly[1]. For this reason, and as previous measurements[2] are not very concordant and may in some cases have been carried out with impure materials, a redetermination of the solubility seemed of interest.

Experiments were carried out at 25·00° and at 0·20°; the salt was violently stirred with water and samples were taken every half-hour or so by means of a pipette fitted with a small sintered-glass filter, until a constant composition was reached. Analyses were carried out by volumetric determination of chloride after decomposition with alkali.

In the experiments at 25°, the influence of the conditions of precipitation was studied by measuring the solubilities of specimens which had: (*a*) been precipitated quickly in the cold from water solution by HCl; (*b*) been heated for some hours under HCl after precipitation in the cold; (*c*) been slowly precipitated on the water-bath from a solution of pure roseo-chloride in presence of excess HCl. No appreciable difference in the final solubilities could be detected.

The solubilities found were, in mols/litre, at 25·00°, 0·0211; and at 0·20°, 0·00925. When plotted (log s against $1/T$) these results are found to agree well with those of Brönsted and Peterson, but not with the other determinations.

Mention should be made of the possible effect of aquotisation in the course of the experiment. This takes place at 25° to the extent of about 0·6 per cent per hour, and means that the saturated solution

contains a little excess chloride ion and a little less purpureo-ion. It is easy to show, however, that if the mass-law may be assumed for the small range concerned, the two corrections mutually cancel, and the *total* (including non-ionisable) chlorine concentration in the solution is constant. In practice, once equilibrium had been attained, no variation with time of the solubility as measured could be detected.

Flame Speeds during the Inflammation of Moist Carbonic Oxide–Oxygen Mixtures

IN 1932[1] we found that the mixture of carbonic oxide and oxygen which gave the maximum speed of flame during the 'uniform movement' was approximately that for combining proportions ($2CO + O_2$), in accordance with the theory advanced earlier[2]. This conclusion is supported by recent experiments carried out at the U.S. Bureau of Standards by Fiock and Roeder[3], using two different methods for measuring the speed of flame, with central ignition (*a*) in a closed sphere and (*b*) in a soap bubble. The concentration of moisture was carefully measured and kept constant in each series (a necessary precaution which we emphasised in our paper), but differed in the two series, being 2·7 and 3·3 per cent.

Fiock and Roeder's results are of further interest in that they show a slight but distinct displacement of the maximum speed towards a mixture containing an excess of carbonic oxide. This effect can be explained as being due to the moisture present in the mixtures taking part in the combustion, so that there are simultaneous reactions:

$$2CO + O_2 \rightarrow 2CO_2$$
$$CO + H_2O \rightarrow CO_2 + H_2,$$

and the displacement should be greater the higher the concentration of water vapour. Fiock and Roeder's experiments indicate that this is so; our own experiments, which gave no evidence of a displacement, were made with mixtures containing only 1·6 per cent of water vapour.

Effect of Adsorbed Water on the Catalytic Decomposition of Hydrocarbons (by a Molecular Beam Method)

BY using true molecular beams of various hydrocarbons projected on to a platinum filament (4 mm.² heated area) of known and controllable temperature, we have studied the primary decompositions instantaneously by pressure variations in the filament chamber, which is large compared with the filament. Similar decompositions at a carbon surface have also been studied, the carbon surface consisting of a thin layer of carbon deposited on platinum by heating a strip of the latter in a hydrocarbon atmosphere. Some preliminary results were briefly reported at the meeting of the American Physical Society in June, 1934[1]. The inhibiting effects then ascribed to hydrogen are actually due to water.

It has been conclusively shown that in both cases —the bright platinum filament and the carbon filament—no dehydrogenation of paraffins, olefines or alcohols takes place unless traces of water are present in the vapours concerned. We postulate that this water is necessary to maintain a monomolecular layer of water molecules on the catalytic surface, and that this layer is the true seat of dehydrogenation. The dehydrogenation is inhibited by an excess of water on the foil in the lower temperature region. Thus the temperature at which the reaction falls off is dependent on the water content of the gas investigated. This phenomenon makes it impossible to follow the uninhibited course of the reaction into lower temperature regions. Traces of air in the presence of traces of water do not affect any of these reactions.

Under favourable conditions, the dehydrogenation is within the limits of experimental error complete over temperature ranges of several hundred degrees centigrade. This must mean that the promoting water layer is adsorbed on the surface in a different manner from the inhibiting layers. Therefore, we can draw interesting conclusions regarding the adsorption of water at high temperatures and the heat of activation of the dehydrogenation process itself. If the filament is heated to about 1550° C., at which temperature all adsorbed vapours are driven off (slight carbon formation on the surface cannot under these conditions be prevented), the pressure in the reaction vessel drops to zero in all cases tested except that of methane. This complete disappearance of all incoming molecules leads to the conclusion that free radicals are formed by rupture of C–C bonds and that the reaction products are readily adsorbed on the walls of the reaction vessel.

The investigation of the decomposition of methane is not yet concluded, but the fact that at temperatures above 1550° C. the pressure in the reaction chamber is only slightly diminished, favours the assumption of a decomposition of methane into the methylene radical and a hydrogen molecule. The assumed decomposition of all other hydrocarbons into free radicals upon collision with a completely degassed surface at high temperatures can likewise be shown to take place at temperatures several hundred degrees lower when the measurement is performed immediately after degassing the foil at temperatures above 1550° C. In these cases the slow covering of the foil first with a dehydrogenation promoting layer followed by further adsorption layers inhibiting all reaction may be easily followed.

The experimental evidence that the dehydrogenation takes place only in the presence of a promoting mono-molecular water layer on the catalyst alters this catalytic problem fundamentally, since from the theoretical point of view both the mode of adsorption of water and the dehydrogenation reaction proper in presence of the adsorbed water layer have to be considered. The latter may very likely be interpreted as an interaction between the carbon-hydrogen bonds of

the hydrocarbon and the activated hydrogen-oxygen bonds in the adsorbed state.

We have experimental evidence that the water may be substituted by certain other molecules having hydrogen bonds with electronegative elements, for example, hydrogen sulphide.

Since then, we have started experiments by a different method to study the effect of water on the reverse process, the hydrogenation of unsaturated hydrocarbons. The outcome of these preliminary experiments apparently shows that the presence of water is equally important for the hydrogenation process. A hypothesis that adsorbed water plays a vital part in the hydrogenation process was advanced by Boswell[2] in 1922, based on the study of the reduction of nickel oxide by hydrogen as well as the catalysis of the hydrogenation by partially reduced nickel oxide. The great difficulties of proving this hypothesis quite conclusively in the case of the hydrogenation seem to have led to it receiving little attention.

The first part of a detailed account of this work containing the experimental method and the results with paraffins will be submitted for publication in the *Proceedings of the Royal Society* at an early date.

Grateful acknowledgement is made to the directors of the Shell Development Company and especially to Dr. E. C. Williams, for their continuous interest in this work and their permission to publish it.

Endocrine Organs of the Blue Whale

As nothing seems to have been published in the literature on the hormone-producing organs in the whale, I submit a short communication of the preliminary results[1] of my investigations on the subject. The endocrine organs were collected by me during a whaling expedition to the Antarctic. They were preserved in a frozen or dried condition or by means of alcohol for four to ten months before examination.

The *anterior lobe of the pituitary gland* in the blue whale weighs about 30 gm. I have been able to demonstrate the presence of the follicle-stimulating, luteinising, thyreotropic and lactogenic hormones.

The *thyroid gland* in the blue whale weighs about 6–8 kgm. In a dry powder prepared from it was found an average iodine content of 2·03 per mille. The powder produces an increase of metabolism.

The *pancreas* of the blue whale weighs about 50–80 kgm. After being preserved in the frozen state for about five months, it will yield by extraction 500 international units of insulin a kilogram.

The *ovary* in the blue whale weighs 4–5 kgm. The quantity of follicular fluid that can be drained from one ovary is about 500 c.c. It contains about 2,000 mouse units of œstrogenous substances a litre.

The *corpus luteum graviditatis* may, in the blue whale, weigh up to 4 kgm. After having been preserved in a frozen state for a year, it still contains considerable quantities of progestin, namely, at least 60 rabbit units a kilogram.

Quantitative investigations have hitherto been carried out only with the pancreas and the ovary.

A complete and detailed description of the experiments and their results will be published later.

Swarming of *Odontosyllis phosphorea*, Moore, and of other Polychæta near Nanaimo, B.C.

IN his very interesting article on the "Possible Bearing of a Luminous Syllid on the question of the Landfall of Columbus" in NATURE of October 5 (p. 559) L. R. Crawshay mentions the swarming of *Odontosyllis phosphorea*, Moore, in this neighbourhood. He refers to the observations made by Potts[1] in 1911, from which it was inferred that there was a periodicity in the appearance of the swarming forms of the species in Departure Bay, and that this could be correlated with the phases of the moon.

As a result of much more extended observations of the actual state of affairs in 1914, it was shown by Fraser[2] that there is no such periodicity, and that swarming forms of both sexes may be taken on any day over a period of between three and four months provided the water is still at sundown, at which time, exclusively, swarming occurs. In more recent years, I have had many opportunities of confirming Fraser's observations, and swarming forms have been taken at dates both earlier and later in the year than recorded by him. It is interesting to find this difference in the behaviour of *O. phosphorea* from that of both *O. enopla*, Verrill, as recorded by Galloway and Welch[3] and of the Bahamian species, as now described by Crawshay.

The swarming form of *O. phosphorea* has not yet been taken at any point in this neighbourhood far distant from that at which it was observed by Potts and Fraser, but there is little doubt that this is due to the lack of sufficiently intensive search, since the area of distribution of the atokous form has now been so extended as to indicate that it is quite general in the Strait of Georgia. The conditions in Departure Bay are, due to its sheltered situation and to the set of the currents into it from around the adjacent islands, particularly favourable to finding epitokous polychætes and, as Fraser points out, these factors are, no doubt, partly responsible for the concentrations of swarming *O. phosphorea* which occur at the entrance to the bay.

It would, perhaps, be of interest in this connexion to record other species the epitokous forms of which have been taken in Departure Bay in recent years. These include *Autolytus prismaticus*, Fabricius, *Syllis elongata*, Johnson, *Syllis armillaris*, Müller, *Syllis borealis*, Malmgren, *Autolytus magnus*, Berkeley, *Nereis virens*, Sars, *Platynereis Dumerilii* (Aud. M-Edwards) var. *Agassizi*, Ehlers, *Nereis pelagica*, L., *Nereis vexillosa*, Grube, *Glycera nana*, Johnson, *Armandia brevis*, Moore. All these have been taken at or near the Station float at various seasons and at various times of day and night.

Records of Fatalities from Falling Meteorites

WITH reference to Mr. M. A. R. Khan's letter in NATURE of October 12, p. 607, on the above subject, I would point out that Col. G. H. Saxton's letter[1] regarding the Nedagolla meteorite of January 23, 1870, states that of the people in the village, who were greatly alarmed, "some received violent shocks and a man near to whom it fell, was stunned". Apparently the man was not hit, but was stunned by the air pressure.

In the original account[2] of the Mhow meteorite, also referred to by Mr. Khan, it is stated that the largest fragment weighed three pounds, and fragments were picked up four or five miles apart; "one broke a tree, and another wounded a man severely in the arm". However, the authority for the statement is not given and in default of substantiation, it is best, like "The Writer of the Review", to accept Prof. Heide's statement.

Mr. Khan should refer to my account[3] of the Naoki meteoric shower of September 29, 1928, to which his[4] is supplementary.

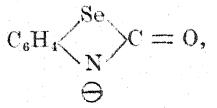
Absorption Spectra of Tautomeric Selenazoles

THE ultra-violet absorption curve of 1-hydroxyl benzselenazole in methyl alcohol is almost identical with that of 1-keto-2-methyl-1 : 2-dihydrobenzselenazole, and quite distinct from that of the *o*-methyl ether. In aqueous sodium hydroxide solution, the curve of the hydroxyselenazole is shifted to the left (deformation), and there is a decrease in maximum due to the production of the ion



on which tautomeric change depends.

1-Thiolbenzselenazole also shows a striking similarity to thiazole analogues in the ultra-violet region, the curve in methyl alcohol being closely similar to that of 1-thio-2-methyl-1 : 2-dihydrobenzselenazole. The absorption curve for the thiolselenazole in aqueous sodium hydroxide belongs to the same family, but shows a slight shift towards the region of shorter wave-length, and an appreciable drop at the first maximum on account of the removal of mobile hydrogen.

Points from Foregoing Letters

TAKING as variables the "preparedness for war", "defence coefficients", "fatigue and expense coefficients", and "dissatisfaction with treaties", Dr. L. F. Richardson expresses by means of differential equations the tendency towards war or peace. He deduces that the international system is unstable if the product of the two defence coefficients exceeds the product of the two fatigue coefficients and may drift either towards war or co-operation, according to the value of the different constants in the equations.

The effect of gamma-rays and of neutrons upon colloidal dispersions (gold and silver, arsenic and cadmium sulphides, vanadium pentoxide, ferric hydroxide) and upon chemical reactions (oxidation of potassium metabisulphite and decomposition of hydrogen peroxide) has been investigated by Prof. F. L. Hopwood and J. T. Phillips, with the view of obtaining a method for the detection of neutrons, not dependent on the formation of radioactive substances, which are variable with time. They have detected an effect upon the chemical reactions and also changes in the stability of the colloidal dispersions.

Experiments carried out below ground at a depth equivalent to 60 m. of water, by D. H. Follett and J. D. Crawshaw, show that cosmic rays which penetrate to this depth have, proportionately, the same ability to produce electron showers as those at the earth's surface, thus indicating that they consist of positive or negative electrons. These findings are not in agreement with those of previous investigators, who have reported rapid diminution of the ratio of shower production, or even complete absence of showers, at lesser depths.

The radioactivation of silver by neutrons at different temperatures and after traversing different thicknesses of paraffin (with a cadmium shield interposed at various distances) has been investigated by Drs. P. Preiswerk and H. von Halban, Jun. They find, in accordance with Fermi's theory, that for silver nuclei the chance of capture varies inversely as the relative velocity of nucleus and neutron, when account is taken of the velocity of thermal neutrons; this result does not hold for collisions of neutrons with the hydrogens of paraffin wax. The authors further find, unlike Moon and Tillman, that cooling the paraffin wax to 90° K. increases by 10 per cent the radioactivity induced in iodine.

The catalytic dehydrogenation of alcohols, paraffins and olefines at a hot platinum or hot carbon surface has been studied by O. Beeck by means of a molecular beam technique. He finds that a monomolecular layer of water is necessary in order to render the surface catalytically active, and that for all cases except methane the primary reaction is a splitting into free radicles (methane splits to free methylene and molecular hydrogen). At lower temperatures an excess of water inhibits the reaction. Water is, apparently, also necessary for the reverse (hydrogenation) reaction.

The presence of various hormones in the thyroid and pituitary glands, pancreas, ovary and corpus luteum of the blue whale has been ascertained by Dr. A. P. Jacobsen.

In connexion with Crawshay's recent suggestion that a phosphorescent syllid may have been responsible for the light "like the flame of a small candle" observed by Columbus after sunset on approaching the American shores, E. Berkeley gives further particulars of the swarming habits of *Odontosyllis phosphorea* at Departure Bay, B.C.

Research Items

Gallo-Roman Official in Early Britain

A RECENT accession to the British Museum (Bloomsbury) collections has enriched the Museum with a closely dated inscription of an interesting historical figure, and made possible a restoration of one of the most important sepulchral monuments surviving from the Roman Province of Britain. For more than eighty years, the Museum has possessed two stones from what must have been one of the most imposing sepulchral monuments of London, which had been dated tentatively as late first century or early second century of our era. One is a 'bolster' with imbricated leaves and central binding; the other bears the beginning of an inscription and is 2 ft. 6 in. in height and more than five feet long as found. Owing to the rarity of the name 'Classicianus' appearing in the mutilated inscription, some reserve was shown in attempting any solution of the problems of meaning and purpose. These stones had been found in 1852 built into one of the semi-circular bastions added in later Roman times to the walls of the city of London. They were found in Trinity Square, Minories. A small portion of the bastion survived until June 1935, when it was brought to light by the enlargement of the Minories Sub-station. An inscribed stone was then discovered upside down in the lowest course of masonry. This has now been presented to the Museum and identified as part of the Classicianus monument. In a description by Mr. C. F. C. Hawkes (*Brit. Mus. Quarterly*, 10, 2) it is pointed out that the stone had already been re-used before it was built into the bastion. It is suggested that the mortuary inscription, so far as now restored, points to this Classicianus being identical with the official of that name mentioned by Tacitus as taking over the procuratorship of Britain on the death of Catus Decianus in A.D. 61, the year of Boudicca's rebellion, and that his names indicate that he was probably a native of Gallia Comata—an interesting example of the tendency noted by Tacitus for natives of Gaul to occupy office even at this early date.

African Bark Canoes

MR. JAMES HORNELL describes and figures in *Man* of December a bark canoe which he saw on the shore in the native quarter of Mozambique in 1926, comparing it with a similar canoe recently described from the Pungwe River in Northern Rhodesia. The Mozambique example represents a great advance upon the Pungwe design. Instead of being made from a continuous length of bark stripped from one tree and sewn into shape without any internal framework, its construction was rather on the model of a sea-going Irish curragh, except that it was sharp at both ends, whale-boat fashion. The bottom was rounded and the sides had a distinct tumble-home form. The framework consisted of a large number of closely set transverse frames made of bamboo poles, bent into a wide U-shape. They were held in position and stiffened by two pairs of stout bamboo poles running longitudinally on the floor, each pair lashed about nine inches on either side of the median line; while another pair on each side formed a rude, but efficient, gunwale. A single lighter bamboo was made fast to the ribs on each side, four or five inches below the gunwale. Five stout plank thwarts strengthened the framework transversely. Their ends were inserted beneath and hidden by the gunwale bamboos, to which they were fastened by stout cord passed through two holes made in each thwart end. A median hole in the midships thwart, and a hole in a short wooden bar on the floor below, showed that the canoe could be used for sail. The bark skin was sewn together in long thick sheets by palm-fibre cord. Where the bark sheets met at each end, they were sewn together at a considerable distance from the edges, the free ends acting as a fender and protecting the sewing. The sides were made of several lengths of bark, with an overlap. The bark skin was sewn to the gunwale by double stitches at short intervals with a single connecting cord running along the outside. The canoe was about fourteen feet in length with an extreme beam of four feet.

An Interesting Habitat for Copepods

IN a paper entitled "A New and Important Copepod Habitat" (*Smithsonian Misc. Coll.*, 94, No. 7, 1935), C. B. Wilson discusses the occurrence of copepods in the spaces between the sand grains of beaches, which he terms "terraqueous", and compares them with free-swimming, commensal and parasitic copepods. Such copepods, he states, are widely distributed in quartz sand, but are seldom found in coral sand and never in 'sand' composed of shell fragments, in which the interstices may be greatly reduced or absent. They occur, however, in mud, where the surface layers are more or less flocculent. They show a wide distribution within any given area of sand, occurring from high to low water and even below low water. Individual species usually show a restricted distribution within a given area, and species change not only from one bay or sand-bank to the next, but also with change in level from high-water downwards. Owing to the nature of the habitat, copepods inhabiting such a region are of minute size, seldom attaining a length greater than 0·5 mm. (in sand), and are usually many times longer than broad, the elongate shape being a necessary modification due to the habitat. This elongation is accompanied by increased flexibility, essential for movement in such surroundings. There is a large development of sensory setæ on the antennules. At the same time, as Remane has pointed out (*Wiss. Meeresuntersuch.*, Kiel, 21, Pt. 2, 1933), there may be a reduction in the development of the eyes, analogous to that of the fauna of caves. These features may both be correlated with the habitat. It is interesting to note that members of the three chief groups of copepods are represented in this fauna, even Calanoids, though the majority appear to belong to the Harpacticoida, and all show the same type of modification in body structure. Owing to its inaccessibility by ordinary dredging methods, this fauna has remained undiscovered until the last few years, during which a large number of new genera and species of copepods and other animals has been described by W. Klie (*Zool. Jahrb. Syst.*, 57, 1929), C. B. Wilson (*U.S. Nat. Mus. Bull.*, 158, 1932) and others.

Structure of *Ctenoplana*

DR. TAKU KOMAI (*Mem. Coll. Sci., Kyoto Imp. Univ.*, B, **9**, No. 4, Art. 6; 1934) describes a specimen of *Ctenoplana* found with a second individual attached to drift seaweed near the Misaki Marine Biological Station. This peculiar creeping ctenophore is very rare and extremely interesting. It is closely related to *Cœloplana*, sharing with it the creeping sole, pigment, branching canals, compact testes, spermiducts, processes of polar plates and the absence of pharyngeal canals. It differs, however, in being much smaller, the ribs persisting, the musculature far less developed and the finger-like processes of the polar plates better differentiated than in *Cœloplana*. These differences are apparently correlated with the swimming and creeping habit, whilst *Cœloplana* is limited to creeping life in the adult stage. There is a close resemblance between *Ctenoplana* and the larvæ of *Cœloplana* which has been already pointed out by Dawydoff. There are, however, differences in the gastro-vascular system, which is far better differentiated in *Ctenoplana*, and in the disposition of the tentacular apparatus—vertical in *Cœloplana* larvæ and horizontal in *Ctenoplana*.

Cultivation of the Walnut

DR. JOYCE B. HAMOND, of the East Malling Research Station, contributes a paper on "Recent Developments in Walnut Growing in England" to the *Journal of the Royal Horticultural Society* for November. This account brings together the results of many original investigations. It may be claimed that the present satisfactory state of walnut culture in Great Britain is largely due to the efforts of research workers whose interest was primarily academic. Ten years ago, the walnuts of this country were poor in taste, unpleasing in colour, often covered by a gaping shell, and altogether unattractive. Then Mr. Howard Spence determined to improve the nut. His own work and wider stimulation laid the foundations for the investigation of methods of propagation by Mr. A. W. Witt, the study of graft diseases and methods of storage of nuts by Miss Hamond, and the control of bacterial blight by Dr. H. Wormald. These aspects are described with detail in the paper under review. Four nursery firms have now taken over the stock of improved trees raised by the East Malling Research Station. These are grafted upon standardised rootstocks, produce well-flavoured fruit of good taste, and are phenologically adapted to the English climate. Grafting of walnut trees is discussed, and bush specimens of this crop may be obtained by merely removing the tips of any shoots which tend to increase in length too vigorously. Miss Hamond shows how the nuts may be bleached and stored in coco-nut fibre mixed with salt. The would-be grower is provided with full information for production of nuts of the highest quality, and the account should go far to popularise the improved walnut as a crop, and extend its cultivation.

Stripe Disease of Daffodils

A DISEASE of daffodils where the leaves become mottled with yellow patches has attained rather serious proportions of late years. Various causes, ranging from 'inherent weakness' to the effects of soil and climate, have been propounded in the past, but it is now realised that a virus is responsible for the malady. Mr. N. K. Gould (*J. Roy. Hort. Soc.*, Nov.) describes a number of experiments upon the incidence, transmission and control of the disease. The Poetaz and Tazetta sections of the Narcissæ are completely free from stripe or mottling, but the other groups can be kept free from the trouble only by the strict removal of infected plants. Treatment with hot water for three hours—the normal precaution against eel-worm—has no effect, either in transmitting or inactivating the causal agent. The virus is quite unaffected by treatment with fourteen disinfectants mentioned in the paper, and has not been transmitted from diseased to healthy plants by grafting or by needle inoculations.

Sooty Mould Fungi

MISS LILIAN FRASER, Linnean Macleay fellow of the Linnean Society of New South Wales, is making a detailed study of the peculiar aggregations of fungi known as sooty moulds. These usually consist of a member of the Capnodiaceæ, a species of *Atichia*, and a third organism belonging to Fungi Imperfecti. Three new papers have been contributed to the *Proceedings of the Linnean Society of New South Wales* (60) during the present year, and represent the third, fourth and fifth of the whole series. Part 3 (pp. 97–118, May 1935) describes "The Life Histories and Systematic Positions of *Aithaloderma* and *Capnodium*, together with Descriptions of New Species". Life-histories of four fungi are considered in detail, and three which are described for the first time are *Capnodium salicinum*, Mont., var. *uniseptatum*, *Aithaloderma ferruginea* and *A. viridis*. Much technical discussion of the systematic position of these fungi is included, and it is held that the Capnodiaceæ, as represented by *Capnodium* and *Aithaloderma*, should be included in the Dothideales. "Species of the Eucapnodieæ" is the title of the fourth part (pp. 159–178, Sept. 1935), which adds six new species and varieties. Amended descriptions of the incompletely known species *Capnodium Walteri*, *C. fuliginodes*, *C. anonæ* and *C. mucronatum* are given, and *Scorias philippinensis* is now recorded from Australia for the first time. Part 5 (pp. 280–290, Sept. 1935) is entitled "Species of the Chætothyriaceæ", and therein eight new species of this subsection of the Capnodiaceæ are described in detail. The taxonomic conclusions of all three papers are based upon adequate culture experiments, and the series should go far towards an elucidation of the complexities of the commonly occurring sooty moulds.

New Current-Measuring Apparatus

FOR the last ten years or more, there have been in existence various types of continuous current meters for the direct measurement and automatic recording of the speed and direction of water flow past lightships and other moored vessels. Such meters are mainly fine-precision instruments, and therefore quite unsuitable for use in exposed positions during periods of severe storm. This has been a very serious drawback, for data relating to bad weather conditions are highly important from the biological point of view. In order that such data may in future become available for fishery research workers and others, Dr. J. N. Carruthers, of the Fisheries Laboratory, Lowestoft, has recently devised a simple, cheap and very sturdy current-measuring apparatus to which he has given the name 'Vertical Log' (*J. Con. Internat. Explor. Mer*, 10, No. 2, 151–168 (1935)). The instrument, it is claimed, will

work continuously in very exacting conditions indeed. It is, however, not automatic in point of direction recording, but requires fleeting attention—often not more than a glance—every now and again. As experience in its use is acquired, it often becomes possible to leave the apparatus unread for several hours on end; at other times it will call for brief inspection every quarter-hour or so. It can be worked equally well from both wooden and steel ships and at all depths. The makers, Messrs. Elliott and Garrood, of Beccles, Suffolk, estimate that, after the first few instruments have been supplied, they will be able to make further 'logs' of this type at a cost of about £12 each. We hope that this new current meter will fully justify the high hopes of its inventor.

Noise Limitation in Valve Amplifiers

IT is now well recognised that the chief factor which limits the amplification obtainable by means of thermionic valves is the electrical noise generated within the amplifier itself. It is not practicable to amplify any electrical signal unless the input voltage of this signal is greater than the electrical noise voltage developed in the early stages of the amplifier. The fundamental limiting sources of this noise are two, namely, thermal agitation of electricity in the input circuits and the voltage fluctuations within the valves themselves. The first of these, thermal agitation, is now fairly well understood and is actually used as a source of calibrating voltage in certain types of receiving and field measuring equipment. The second noise arises from the fact that the space current in a valve is not smooth, but is subject to rapid and irregular fluctuations in magnitude. This matter is discussed in an article by G. L. Pearson entitled "Quiet Amplifier Tubes" published in the October issue of the *Bell Laboratories Record*. The output noise of a valve amplifier due to the intermittent nature of the electron current has been measured for a variety of valves and over a wide range of frequencies. In order to reduce the noise to a minimum under conditions of high signal amplification, it was found that, in general, the valve cathode must be operated at as high a temperature as possible, without impairing the life of the valve. Also the negative bias of the control grid must be reduced to as near zero as possible without causing excessive grid current, while the anode and screen voltages must be reduced below the values normally recommended. Expressing this electrical noise as an equivalent input voltage, the value was found to vary between limits of about 0·7 and 1·5 microvolts for a selection of fifteen American valves. In general, the triodes gave a lower value than the multi-grid valves. At low audio frequencies, this noise is inversely proportional to the frequency, but it remains approximately constant for frequencies above one or two thousand cycles per second.

Toxicity of Cod Liver Oil

THE use of synthetic diets composed of the individual nutrient constituents in purified form has contributed largely to our modern knowledge of nutrition. Purified diets for Herbivora present special problems in that these animals normally consume rations containing large amounts of cellulose, and studies have been conducted on this subject by L. L. Madsen, C. M. McCay, and L. A. Maynard (Cornell University Agricultural Experiment Station, Memoir 178, 1935). After trials, a regenerated cellulose known as washed 'Sylphrap' was adopted as the cellulose constituent, and the diet devised which proved successful in maintaining an adult goat over an extended period consisted, in percentages, of cellulose 30, corn starch 30, casein 15, sucrose 10, yeast 7, salt mixture 5 and lard 3, with the addition of about 1·6 per cent of cod liver oil. Sheep thus reared from weaning were successfully maintained for 480 days, similarly goats though not quite so satisfactorily, and less success was achieved with guinea pigs and rabbits. In the last-named, and to some extent with goats, eventual failure was due to the development of paralysis dependent upon muscular degeneration. It was demonstrated that the cod liver oil was the essential agent causing this lesion, which ensued unless the cod liver oil ration was kept below 0·1 gm. per kilo of live weight. As the authors are careful to state, the results, while furnishing no evidence applicable to the human species, should serve to direct further attention to the reports of Agduhr and others describing similar lesions in infants as being caused by cod liver oil.

New British Standard Glue Tests

THE British Standards Institution has just issued a series of British standard methods for the testing of bone, skin and fish glues. The tests laid down include methods for the determination of moisture content, jelly strength, viscosity, melting point, foam, water absorption, keeping quality, joint strength in shear, reaction, grease, ash, sulphur dioxide and chlorides. The relative importance of the tests described must necessarily depend largely on the purposes for which the glue is intended. The joinery trade is particularly interested in strength and spread, the gummed paper manufacturer in tackiness and foam, etc. It will be seen therefore that it is not necessary for any one particular trade to utilise all the tests laid down. Apart from the industry itself, these methods of test should prove particularly interesting to all those concerned with the examination of glues, both in the laboratory and in the workshop. Copies of this British standard (B.S. No. 647–1935) may be obtained from the Publications Department, British Standards Institution, 28 Victoria Street, London, S.W.1, price 3*s*. 8*d*., including postage.

Maximum Error of Observations

THE statistical properties of the mean of a set of N observations are well known. E. J. Gumbel (*Ann. l'Institut Henri Poincaré*, 5, 115; 1935) discusses the properties of the greatest and least observations of a set, a problem of importance when it is desired to estimate the maximum error of observations. If the distribution of the original observations is normal, or, more generally, what is called of exponential type, the distribution of the extreme values is doubly exponential. Similar conclusions hold for the second greatest and second least, and so on. The work is related to that of Prof. R. A. Fisher, but treated from a different point of view. M. Gumbel remarks that the theory has been applied to the determination of the greatest deviation of artillery fire, the intervals between radioactive emissions, the extreme duration of human life and the intelligence of a racial minority in a certain country of central Europe.

Mechanism of Salt Absorption by Plant Cells

By Dr. W. J. V. Osterhout, Rockefeller Institute for Medical Research, New York

TO solve the problem of the mechanism of the absorption of electrolytes by the plant cell, we need accurate knowledge of what goes on inside the cell. This cannot be obtained with cells of ordinary size. We have therefore studied very large multinucleate plant cells, especially those of *Valonia*[1]. Since this work has called forth comments[2], due to misunderstanding, a brief statement of facts is submitted, although this statement is naturally far from being complete.

(1) *Injury*. A great advantage of *Valonia* is the ease with which injury can be detected. In our laboratory especial care has always been used to avoid working on injured cells. Dr. Steward concludes that our experiments with ammonium chloride were made with injured cells. Working at the high temperatures of Tortugas in the summer, he found that *Valonia* was easily injured by ammonium chloride.

This may happen also in Bermuda in summer, but in winter cells are obtainable which benefit by concentrations of ammonium chloride up to 0·005 *M*. They behave as plants usually do when given an optimum amount of nitrogen. In such experiments certain precautions are necessary, as we have gradually learned during several years of work. The proper handling of these cells requires considerable experience. When the internal concentration of NH_4^+ approaches 0·3 *M* injury may result. This was not the case here.

The following evidences of injury are cited by Dr. Steward:

(*a*) Sodium entered more rapidly than in the controls. This is not significant in view of the fact that in other experiments the rate of entrance in the controls was very variable and was sometimes greater than in this case.

(*b*) Potassium went out 'with the gradient'. It may be misleading to speak of the passage of a cation 'with' or 'against' a gradient without considering the accompanying anion and the product of the ions, which is proportional to the chemical potential. To call this injury is to misunderstand the situation. For injury always causes an escape of potassium chloride which, though much more concentrated inside the cell than outside, is normally retained because the protoplasm is only slightly permeable to it. Injury quickly increases the permeability, and in consequence potassium chloride comes out and growth ceases.

Our experiments present a picture in no way resembling this. No chloride escaped. On the contrary, it continued to enter as usual 'against a gradient', a conclusive proof that the cell was not injured. (During this period the gain in moles of chloride was 14·1 per cent; the loss of potassium was about 15·8 per cent. Presumably potassium went out as potassium hydroxide, to which the protoplasm is normally very permeable.) At the same time ammonium entered ('against a gradient') and became more than a hundred times as concentrated inside as outside. This could not happen if the cell were injured.

Moreover, the cells were better than the controls in growth, in photosynthesis (unpublished work) and in general appearance. They lived indefinitely. In experiments lasting a month a few cells died, but the death rate was no higher than in the controls. The expression "corrected volume" applied to these cells has nothing to do with the death of cells. (All volumes were multiplied by the same factor.)

(*c*) A misunderstanding must be responsible for the following statement. "Considerable prominence has been given to the fact that an external *p*H of 5·5 which causes irreversible injury and death also produces loss of potassium ions." In our work the lowest external *p*H was 6·8, at which there was no sign of injury. According to Steward, 7 is optimal for absorption.

(2) *Metabolism*. Dr. Steward concludes that the study of *Valonia* must be misleading because its metabolism is less than that of storage tissues (for example, potato) the chemical activity of which has been abnormally raised by being cut into thin slices and placed in well-aerated solutions. (Cutting increases abnormally the output of carbon dioxide.)

This involves the relation of metabolism to the absorption of electrolytes. In *Valonia*, the production of carbon dioxide (and of other organic acids) keeps the chemical potential of potassium hydroxide less inside than outside: hence potassium hydroxide continues to enter. The metabolism of *Valonia* is ample for this purpose. The *p*H of the sap is about 5·8 as compared with 8·0 to 8·2 of the sea-water. In a cell 1 cm. in diameter the volume of the protoplasm is less than one per cent of the total. Hence a correct estimate of metabolism, based on the amount of protoplasm, will be more than a hundred times as great as one based on the volume of the cell. In the laboratory the growth in volume under favourable conditions is 0·5–2 per cent per day.

Other aspects of metabolism may be important: if so, it should eventually be possible to demonstrate their roles as clearly as that of carbon dioxide in *Valonia* (and in models).

(3) *Theoretical*. (*a*) When we increase the external *p*H, potassium goes in more rapidly. Its entrance decreases the activity of water inside and raises the osmotic pressure, so that water enters more rapidly: in consequence, the internal concentration of potassium remains approximately constant. Hence the only way to find out how fast potassium enters is to measure the increase of moles of potassium in the cell.

(*b*) If potassium enters chiefly as potassium hydroxide, its rate of entrance will increase with increasing *p*H until secondary changes begin to interfere. Such secondary changes become striking at high *p*H values and undoubtedly begin much lower. It is therefore impossible on theoretical grounds to predict the optimum *p*H. If it should turn out to be 7 in any given case, it would not invalidate the hypothesis.

(*c*) Since *Valonia* is able to accumulate electrolytes without the complications of storage tissues —for example, the presence of intercellular spaces and of injured or altered cells in the sliced tissues, the fact that the cells are placed under abnormal

conditions, and the impossibility of obtaining the cell sap without contamination and chemical change—we must perforce congratulate ourselves on finding such a satisfactory organism for study.

Certain principles which appear to govern accumulation in *Valonia* are so simple that they have been embodied in models in which potassium chloride enters until its chemical potential inside becomes several times as great as outside. (This depends on the bubbling of carbon dioxide through the artificial sap to imitate its production by the living cell.) Such increase in chemical potential involves an expenditure of energy, which comes from chemical reactions (as it does in the cell).

Some of these principles play an important role in other organisms. Future research must reveal the extent of their application.

[1] Osterhout, W. J. V., *Ergebnisse der Physiol.*, **35**, 967; 1935.
[2] Steward, F. C., NATURE, **135**, 553; 1935.

By Dr. F. C. Steward, Birkbeck College, University of London

ONLY minor comments are necessary to the reply of Dr. Osterhout, which is devoted mainly to the question of injury to *V. macrophysa* by ammonium chloride.

Even if the ammonia experiments are free from the suspicion of injury, the fact still remains that the subsequent movements of *potassium* and *sodium* neither necessitate a distinction between ions and molecules nor are they in the direction usually associated with accumulation.

In order to evade the unfortunate implications of the results with respect to sodium, Dr. Osterhout implies that a difference between the 'control' and 'ammonia' groups which, on the data given, is clearly significant, is after all not real. This difference, whether due to injury or not, is certainly in a direction not in accord with the theory and cannot be dismissed, because of the behaviour of cells (unpublished) which were not strict controls for this experiment[1].

Since injury "in the summer time", even at Bermuda, to *V. macrophysa* by ammonium chloride is now acknowledged, readers will scrutinise even more carefully any crucial experiments which involve this salt, and, no doubt, demand more precise designation than the vague terms 'summer' and 'winter', of the seasonal variations which can be tolerated and the limits of internal concentration which differentiate an 'injurious' from a 'beneficial' effect (it is stated[2] that injury occurs in the Bermuda material at a concentration "less than 0·3M".)

However, the major problem is not the applicability of the theory to the absorption of ammonia, or even its ability to explain the secondary effects which this substance produces on the distribution of potassium and sodium, but rather its generalisation to embrace the initial accumulation of all electrolytes, even the alkali halides.

To the discussion of the effects of external reaction, in so far as they test the theory, Dr. Osterhout contributes two observations although he does not answer the more searching criticisms. One denies that the theory derived any of its support from its undoubted ability to explain qualitatively the behaviour of cells in a medium equally acid as the sap, and the second insists that vague, unspecified "secondary" effects obscure the direct effects of external hydroxyl ion concentration which the theory demands. A theory which, already heavily weighted with hypothesis, fails to satisfy a direct test and can only be retained by resort to such vague assumptions would be better abandoned.

Clearly, one cannot conclude from the work on *Valonia* that the simple mechanism suggested will explain adequately the general facts of salt accumulation by cells[3]. Dr. Osterhout may dismiss the metabolic processes which accompany rapid salt accumulation in storage tissue by regarding them as abnormal chemical activity; but if so, he must also be prepared to eliminate as "abnormal" some of the most fundamental attributes of actively growing cells which, in roots and developing leaves (aquatic and otherwise), are now known to be as intimately concerned with salt accumulation as in the cut storage tissues. The theory of "thermodynamic potentials of free base" and its subsidiary hypotheses is completely inadequate as an explanation of the behaviour of any or all of these systems.

If this discussion emphasises that the problem is still an open one, it may not have been in vain.

Progress of Building Research*

THE work of the Building Research Board embraces the products of such a wide range of industries and touches so closely upon the lives of the people that any description of its work is not only of scientific value but is also of importance to the industries directly and indirectly concerned, while at the same time the record is a serious contribution to the material side of social improvement. In this last connexion, it is interesting to note in the annual report for 1934, recently issued, that the Board's resources for research and inquiry have been placed at the disposal of a departmental committee appointed by the Ministry of Health to report on materials and methods of construction suitable for working-class flats.

In the search for fire-proof materials, officers of the Building Research Station have worked in close co-operation with the Fire Offices Committee in the design of the laboratory for fire resistance tests at Elstree (NATURE, Dec. 21, p. 996). The need for data on the transmission of sound through the fabric of a building has led to the provision at the Research Station, in conjunction with the National Physical Laboratory, of facilities for full-scale tests on floors and to the setting up of a special Sub-Committee on Sound Transmission. The problem of impact noises

*Department of Scientific and Industrial Research. Report of the Building Research Board, with the Report of the Director of Building Research, for the Year 1934. Pp. x+174+14 plates. (London: H.M. Stationery Office, 1935.) 3s. 6d. net.

—the cause of considerable anxiety in certain types of construction—is also under examination.

On the subject of damage to buildings by vibration from traffic, machinery, pile-driving and other sources, the investigations, started some years ago and discontinued, are now being resumed, and a preliminary programme of research has been outlined. While it would appear from the report that vibration stresses are, in general, below the estimated fatigue strength of brickwork and concrete even after allowing for considerable stress amplification due to resonance, they are, however, above the compressive fatigue strength of lime mortar, which is therefore liable to gradual disintegration. For the more thorough investigation of this most complex question, special vibrators are being designed for use both on the structures and on the ground, and dynamic extensometers are to be used in the measurement of strains.

The determination of Young's modulus for various building materials, including stone, brick, concrete tiles and asbestos sheeting, has been effected by measuring the frequency of vibration of a specimen in a special apparatus which is described. The error in the observed value of the frequency can be limited to $\pm 0{\cdot}5$ per cent, and the modulus is derived from the formula $E=4l^2n^2\rho$.

Wind-pressure measurements made on the Severn Bridge during a gale in January are discussed, and further tests on the shielding effect of one building on another have yielded certain general conclusions. To carry this investigation further, a model of a portion of London is being made for tests in a wind tunnel.

The general research work of the Station has included the important problem of the weathering qualities of natural building stones, and the report claims that by applying simple tests the value of Portland stone samples can now be determined with confidence. Certain common terms in specifications are held to be needlessly restrictive of choice and tend to exclude material of the best weathering quality. The information available points to the prime importance of careful selection of the stone, and suggests considerable doubt as to the value of preservatives. The effects of atmospheric pollution and of various physical factors influencing weathering are also discussed, and a lengthy investigation on the relation of micro-organisms to the decay of stone is stated to have shown that these are not directly responsible in any considerable degree for the processes of decay—nor, as yet, have they been found to exert any indirect influence. Many other building materials have been under review, and the notes on these give valuable information as to their properties.

It is, however, with structures and the strength of materials that the major part of the report deals, and in this section the results of the investigations are set out in detail. Concrete beams, piles and road slabs have been the subjects of large-scale experiments, and in the case of beams comparative tests were made for the Ministry of Transport to ascertain the behaviour under load of ordinary reinforced concrete, of Ritchie type and of modified Ritchie type continuous girders. Photographs, diagrams and tables give a clear picture of the results obtained, and these show that the ultimate loads carried by the Ritchie and modified Ritchie beams are about 15 per cent higher than those carried by the ordinary type. If, however, the point of failure be taken as that at which the rate of increase of deflection with load begins to become excessive, the conclusion is that there is little to choose between the three types, which each carry, at this point, about three times the working load.

From these brief notes of the subject matter of the report, it will be gathered that this is a volume which should receive close attention from those who are engaged in research in this or cognate fields, or associated professionally or industrially with modern problems of building. J. A. C.

Increasing Aridity in West Africa

BEFORE Section E (Geography) of the British Association meeting at Norwich, Prof. E. P. Stebbing returned to the subject of "The Encroaching Sahara", on which he read a very important paper to the Royal Geographical Society in March of this year (see *Geog. J.*, 85, 506, June 1935). Leaving on one side the difficult and still disputed question of secular desiccation, it is clear that the activities of man have resulted in assisting the spread of desert and semi-desert conditions—"the eastern Sahara Desert is advancing south and threatening the future prosperity of considerable stretches of West Africa".

As a forester, Prof. Stebbing naturally attributes this to the removal of forest, but it would be nearer the truth to say that the removal of any natural vegetation cover, whether by man-made fire and the plough or through grazing by man's domestic animals, conduces to soil erosion and so to deterioration and apparent desiccation. This has happened in the middle western States of America through the ploughing of prairie grassland, and is now being actively combatted; it is happening in West Africa through the shifting cultivation and increasing herds of a semi-civilised population, and is not yet being arrested.

Prof. Stebbing's suggestion for West Africa is to preserve against human occupation and grazing two continuous east to west belts of forest—one, with a minimum width of 7½ miles, of dry forest in the latitude of Lake Chad; the other a belt 30–50 miles wide in the moister savannah forests farther south. It is not a question of planting forest belts as has been suggested for the United States, but is one of preserving strips of the natural vegetation.

Such a suggestion seems simple, but it is directly opposed to British Government policy in West Africa. The laudable aim of the British has been to interfere as little as possible with the habits of the people, and so shifting cultivation and indiscriminate grazing are permissible. Indeed, under the peaceful conditions of the British regime the people, their herds and flocks have all multiplied, and the evil has been intensified at an ever-increasing pace. It is essential that the state of affairs should be widely known amongst those concerned with education in West Africa—part of the remedy lies in their hands. L. D. S.

Recent Aeronautical Research

THE annual report for 1934–35 of the Aeronautical Research Committee* summarises the progress made in the investigation of scientific questions and the dissemination of the knowledge made available during that period. The report takes the usual form of a general survey of the whole field with fourteen detailed supplements upon various divisions.

The outstanding technical achievement of the year is considered to be the designing of the *D H* Comet, which flew and won the race from Mildenhall to Melbourne, a distance of 11,300 miles, in less than three days. This performance was not due to any particular discovery made during that year, but simply to having put into practice principles that scientific research has gradually established over a period of many years. Among these are the necessity for clean design, avoidance of mutual interference of parts, use of variable pitched airscrews and retractable undercarriages, the application of reduced speed landing devices, engine-cooling with minimum drag, etc.

The report visualises further possible increases in aircraft performance due to the steadily maintained improvement in aero-engines, progress in engine cooling, fuller appreciation of the aerodynamic causes and effects of skin friction and the development of lighter methods of construction. When this increased efficiency is directed towards higher speeds, the possibilities of flutter of certain parts developing is increased, and it is suggested that a criterion for stiffness to limit this must rank of equal importance with that for structural strength. Also, high speeds necessitate the use of speed-reducing devices, such as flaps and slots, for landing, and while these are successfully used in an empirical manner, a more detailed knowledge of the flow of air over wings at slow speeds is needed before their behaviour can be understood and forecast.

Investigations into the meteorological conditions affecting aircraft, particularly the measurements of accelerations in gusts, have confirmed that, for average flying speeds of to-day, an additional loading equivalent to not more than twice the aircraft weight is the maximum likely to be met. Design strength regulations at present in use cover these cases sufficiently. Work is continuing on the design of instruments to be attached to high masts in order that a more comprehensive investigation into the velocity gradients extant upon the borders of large atmospheric disturbances can be completed.

The introduction of new research apparatus at the Royal Aircraft Establishment and the National Physical Laboratory appears to have resulted in a notable, although perhaps indirect, advance in knowledge. The explaining of certain apparent phenomena has led to a fuller investigation of the physical conditions of the experiments, which is reflected in the better co-ordination of the experimental results with actual practice.

Progress in certain directions has been made with regard to silencing of aircraft. Well-silenced engine exhausts, and the use of slow-running airscrews, has now reduced those sources of noise to an amount less than that due to the motion of the machine through the air. Thus the principal remaining cause of noise, air disturbances, will probably be reduced in time, as the efforts of designers towards aerodynamical efficiency result in machines that set up less disturbance in flight.

Investigations into the possibilities of large aircraft for civil aviation have led the Committee to the conclusion that there is no inherent difficulty in the construction of machines up to weights of two hundred tons. The flying boat or seaplane with six or eight engines appears to offer the most promising lines of development. Practical difficulties in the installation of such a large engine-power are to be expected, and the aerodynamic efficiency of a number of airscrews distributed along the wings will need investigation.

The most outstanding work in the engine section is that of reducing fuel consumption in flight by the perfection of an automatic mixture control functioning with altitude changes. Trials of this over extended periods have shown reductions up to thirty per cent in consumption. Apart from actual monetary saving, this will give greater air endurance for a given tankage, and relieve the pilot from the necessity of adjusting this control constantly, as is now necessary.

It has been discovered that ice formation in the carburettor can be prevented by the addition of alcohol to the petrol. A device has been produced for detecting automatically the need for, and supplying the necessary proportion of alcohol. There has been progress with compression-ignition engines, particularly with one of sleeve valve form, but as contemporary progress in the petrol engine more than keeps pace with this, there appears to be no immediate prospect of the adoption of this type, when the most important consideration is efficiency.

The supplements to the report deal with these and many other problems in greater detail.

The work of the Committee during the past year, as summarised in this report, has leaned towards consolidation and elaboration of detail, rather than anything leading towards new lines of thought.

Mathematical Sciences in France a Century Ago

AT the annual public meeting of the Paris Academy of Sciences held on December 28, 1835, the president, Baron Charles Dupin, delivered a discourse on "Some Advance which the Mathematical Sciences have made in France since the Year 1830". A translation of this afterwards appeared in the *Magazine of Popular Science*, vol. 2, from which the following notes and extracts have been taken:

Commencing with references to the work of Fourier and Legendre, who had died in 1830 and 1833 respectively, Baron Dupin went on to speak of the researches of Poisson, of Poinsot, "the creator of the theory of couples which has so changed the face of statics and dynamics", of the young geometers Coriolis, Duhamel, Liouville and Sturm; of Prony, Poncelet and Morin, and also of the work of Pontecoulant and other French astronomers.

Turning to "those noble undertakings which are destined to describe mathematically the coasts, the territory and the soil of France", Dupin said: "After having undertaken and completed under the Empire, the hydrography of the coasts of Belgium, and of Holland, and next that of the shores of the ocean from Ushant to Spain, M. Beautemps-Beaupré, our colleague, is now continuing, on the same plan, the

hydrography of the shores of the Channel, and which will be followed by that of the Mediterranean. . . . A word will be sufficient to enable us to appreciate the magnitude of the undertaking. Two hundred thousand pounds, thirty years labour of the hydrographical corps, one half the life of its chief, and four hundred and fifty quarto volumes of observations and calculations, have been necessary to accomplish the hydrographical surveys of the coasts of France, to complete them in their two-fold relation to commerce and the naval interests, and to adapt them to the preparation of the grand atlas of the 'Pilote Français' ".

"The application of the mathematical sciences to those which are designated the natural ones—to the wants of the productive arts—to public works, of which we have presented such fine examples from works over which the Academy presides, forms the most remarkable characteristic in the actual progress of human knowledge. . . . The theory of heat promulgated by Fourier still excites attention. It has been made the subject of a large work by M. Poisson. . . . Effects which the reduction of heat by chemical means cannot produce are now accomplished by mechanical agency. In 1830 the Academy rewarded the gas compressing machine of M. Thilorier. A corresponding member of the Academy, M. Melloni, has communicated to us new facts relating to radiant heat."

From the midst of those philosophers devoted to electricity, "M. Becquerel has opened a path for himself. He has attacked chemistry with weapons of his own preparation, to subdue her to the dominion of mathematical laws. . . . Gifted by nature with extreme delicacy of the organs of sense, and exquisite power of observation, we may justly entitle him the Wollaston of France".

In other branches of investigation, "M. Majendie has borrowed from mechanical laws his explanation of the sounds of the human heart. . . . M. Flourens seeks in the mechanical pressure exercised upon the brain, an explanation of the condition of those persons who undergo the operation of trepanning . . . and M. Dutrochet who has communicated to us so many facts, the fruit of his ingenious observations on the internal dynamics of vegetables, has pushed his investigations into the mechanism of the respiration of insects, both aquatic and aerial".

In concluding his discourse, Baron Dupin said: "I am far from having enumerated all the recent modes in which mathematics have been applied to natural science. I have not even hinted at its application to that of politics, and of social economy, nor to the subject of population. Having individually taken a part in these discussions I shall pass them unnoticed".

"But in this sketch rapid, incomplete, imperfect, I ask with confidence, Do you not recognise the ever-increasing utility of science, the extent of her benefits, the sublimity of her titles, even during the short, embarrassed and turbulent period to which I have confined myself? The sciences must have therefore of necessity, a vital energy peculiar to themselves; a progressive power, superior to the obstacles of time, of things, and of man. Human passions, vulgar ambitions, and party-interests, pass away, but the labours of science, the sacrifices made for her sake, the victories borne off in her name, remain, and contribute to the enlargement of that splendid and profitable heritage on which, at the present day, is based her real grandeur."

Societies and Academies

PARIS

Academy of Sciences, November 25 (*C.R.*, 201, 997–1072). LUCIEN DANIEL: An accidental crossing of the bean. A detailed account of a hybrid bean, the descendants of which do not appear to be in agreement with the Mendel scheme. DIMITRI RIABOUCHINSKY was elected *Correspondant* for the Section of Mechanics in the place of the late M. de Sparre. NICOLAS KRYLOFF and NICOLAS BOGOLIOUBOFF: Some theorems of the general theory of measure. PAUL VINCENSINI: The curvature of congruences of spheres. ENRICE BOMPIANI: A system of curves of a surface invariant by projectivities. D. VAN DANTZIG: The idea of the derivative of a functional. DAVID WOLKOWITSCH: The theoretical problem of balancing rotating parts. ALFRED ROSENBLATT: Certain classes of movements symmetrical with respect to an axis of an incompressible viscous liquid. ANDRÉ AURIC: A cosmogonic hypothesis. CHARLES VALLOT: A new map of the Mont Blanc massif by Henri, Joseph and Charles Vallot on the scale of 1 : 20,000. PIERRE MARTI: A gravimetric cruise of the submarine *Fresnel* in the north-west part of the Mediterranean basin in 1933–34. Work done with the Vening-Meinesz apparatus for the determination of g at sea on the coasts of France, Spain, Corsica and the Balearic Islands. An outline of the results, with a chart, is given: a full account of the results will be published elsewhere. REZA RADMANECHE: The action of the ultra-violet rays on the electrical conductivity of quartz. The experimental results are summarised in a diagram. MAURICE LAMBREY: A system of transformation with logarithmic argument for continuous current. JEAN LAGRULA: An error in photographic photometry. Discussion of the effect of the inequality of the surfaces of the photographic plates and means of avoiding the errors thus produced. LOUIS D'OR: The absorption spectra of sulphur vapour. The author concludes from his experiments that sulphur vapour contains at least four species of molecules, excluding S_1. The spectrum described by Graham, Dobbie and Fox, and by Rosen is not due to S_8 (Graham) or S_2 (Rosen) but to an intermediate molecule, probably S_4. JEAN TERRIEN: The rotation structure of the D and E systems of bands of cuprous chloride. MICHEL KANTZER: The influence of pressure and of foreign gases on the optical absorption of chromyl chloride. A. VILA and F. TESSON: The measurement of the mechanical properties of plastic films. JACQUES BANCELIN and YVES CRIMAIL: Substances inhibiting the corrosion of iron by acids. A comparison of the effects produced by the addition of rhodamine and of thiourea to the acid solution showed that whilst the anti-corrosion effect of rhodamine increased with the concentration, there was a certain concentration of thiourea for which the corrosion of the iron was a minimum. O. BINDER: The decomposition of pentahydrated copper sulphate by heat. Crystallised copper sulphate heated to 650° C. gives a basic sulphate $2CuO.SO_3$, proved by chemical analysis and by a study of the X-ray spectrum to be a definite compound. EMILE CARRIÈRE and MLLE. LUCY FAYSSE: The comparative action on sodium thiosulphate of oxygen compounds of chlorine and of the corresponding oxygen compounds of iodine. JOSEPH MAGROU: Attempts at the culture of mycorrhizal fungi. ANTOINE DE CUGNAC: Remarks

on the meaning of certain polymorph species in the Gramineæ. PH. JOYET-LAVERGNE: The relations between vitamin A and the plastids. The author concludes that vitamin A is an essential constituent of the chondriome, and this is verified for plastids in the course of their evolution. MLLE. GILBERTE MOUROT: Nitrogenous metabolism in protein starvation. DAVID BROUN and HERMANN SCHEINER: The physico-chemical state of acetylcholine in the blood. E. LÉVY-SOLAL and M. SUREAU: Graphical study of the work of accouchement. RAYMOND HAMET: A new true sympathicolytic: Koepfli's rauvolfine. BERNARD TROUVELOT and GRISON: Variations of fertility of *Leptinotarsa decemlineata* with the tuber producing *Solanum* consumed by the insect. Experiments with six species of *Solanum* showed that the fertility of the insect varied considerably with the species of plant. ETIENNE WOLFF: The experimental transformation of genetic females into intersexuals, produced by the injection of male hormone into fowl embryos. Intersexuality can be obtained regularly in the embryo of the fowl by androsterone injection of genetically female individuals. A. GUILLAUME and G. TANRET: The hydrolysis of the glucosides and of some organic compounds by ultra-violet rays. The ultra-violet rays possess a clear hydrolysing action, especially marked with glucosides and esters. ROBERT BONNET and MLLE. BERTHE NATAF: The destruction of certain hydrolysing diastases in the course of their action. Seven diastases were studied, and all showed decreased activity with time. It is concluded that there is a real autodestruction of the enzyme. ANDRÉ PAILLOT: A new ultra-virus parasite of *Agrostis segetum* causing a proliferation of the infected tissues. AUGUSTE TRILLAT: Attempts at vaccination for fowl cholera. MAURICE LEMOIGNE, PIERRE MONGUILLON and ROBERT DESVEAUX: The characterisation of hydroxylamine in autolysed green leaves.

CAPE TOWN

Royal Society of South Africa, October 16. W. J. COPENHAGEN: Variation in the phytoplankton of Table Bay, October 1934–October 1935, with a note on the chemical analysis of *Chaetoceras*. The quantitative catch was estimated in terms of 'colour units' (plant pigments): Harvey's method. It would appear that *Chaetoceras* was dominant on over more than seventy per cent of the occasions when catches were obtained. A suggestion is tentatively made that the available energy of a cubic metre of sea-water be expressed in terms of calories. D. B. HODGES and B. F. J. SCHONLAND: Relation between thunderstorms and atmospherics in South Africa. A short description was given of the cathode ray direction finder, as installed at the University of Cape Town. The results obtained with the instrument during part of September and October 1935 have been compared with meteorological maps for the same period. The results show close agreement between the bearings of thunderstorms within a distance of about 1,000 miles as recorded on the maps, and directions of arrival of signals at the apparatus at corresponding times. Variations in the amplitude of atmospherics with distance, and with time of day or night, have been studied. A satisfactory correlation of atmospherics from sources over the sea with depressions in the same areas has been made, particularly in the case of depressions off the south-west coast. The experiments indicate the value of this device both for meteorological forecasting and for information on disturbed weather areas for aircraft. B. F. J. SCHONLAND, D. J. MALAN and H. COLLENS: Recent progress in the study of the lightning discharge. The leader – return stroke sequence is present in practically every case. The effective velocity of the stepped leader is that to be expected from electron-avalanche drift in the critical field for breakdown (2×10^7 cm./sec.). It is suggested that an actual pilot streamer, carrying too small a current to be photographed, provides the necessary ionisation for the luminous heavy-current step which follows it with a velocity of about 5×10^9 cm./sec. The latter catches up the pilot streamer, and the absence of further ionisation ahead of the step then causes a pause in which the high conductivity leader streamer is reorganised and during which the pilot forges ahead. D. J. MALAN: Intensity variations in the main return lightning stroke. The variation in intensity in return lightning strokes was determined by examining photographs obtained with a Boys camera by means of a recording microphotometer. The main stroke intensity fluctuates in such a manner as to cause the return channel luminosity to be divisible into a series of component discharges, all apparently passing upwards from the ground. A maximum of six such component discharges comprising a complete return stroke has been observed (see NATURE, Nov. 23, p. 831). J. L. B. SMITH: Several new Gobioid and fresh-water fishes from South Africa. Five new species are described and figured. A. V. DUTHIE and S. GARSIDE: Studies in South African Ricciaceæ. (1) Three annual species. This paper is the first of a proposed series dealing with South African Ricciaceæ. It includes a discussion of the taxonomic history of the family, and a detailed account of three annual species which are common in the Cape and Stellenbosch Divisions, but have hitherto been confused. One of the above, *R. crystallina*, is cosmopolitan, another, *R. Curtisii*, is fairly abundant in parts of America, but has not previously been known to occur in South Africa, while the third, *R. cupulifera*, is here described as new.

GENEVA

Society of Physics and Natural History, November 7. E. BRINER, B. SUSZ and E. ROD: The maximum concentration of ozone and of nitric oxide at high temperatures of endothermic bodies. Calculations based on the most exact data have given for the maximum concentrations: ozone $2{\cdot}2 \times 10^{-5}$ per cent at 3,500° C., nitric oxide 5·9 per cent at 3,500° C. These are lower values than those previously obtained. J. and L. DESHUSSES: The presence of *Ceratitis capitata* (fruit fly) at Geneva. J. and L. DESHUSSES: The noxious insects of Switzerland: statistics. Considering only as noxious well-known insects which have caused important economic losses, it is shown that 35 per cent of these parasites are Coleoptera, 25·9 per cent Lepidoptera, 14·1 per cent Hymenoptera, 12·1 per cent Hemiptera, 11·8 per cent Diptera and 1·1 per cent Orthoptera. The proportion of the insects enumerated in the various types of cultivation depends on the state of our knowledge, and may not be exact. P. ROSSIER: The analytical representation of the chromatic sensibility of ordinary photographic plates. The author compares a certain function with the sensibilities observed. The sensibility curves obtained for a given plate by different methods differ between themselves

more than the differences between the results of calculation and observation. VUAREMBON: The influence of ethyl alcohol on maltase.

November 21. A. AMSTUTZ: Preliminary note on the structure of the Pennides to the south of Aosta. E. PAREJAS: The organism of B. de Joukowsky and Favre. DON ZIMMET: A nickel-nitroprusside reaction for reduced glutathione. B. SUSZ and PERROTTET: The Raman spectra for the eugenol and estragol groups.

LENINGRAD

Academy of Sciences (*C.R.*, 3, No. 5; 1935). I. VINOGRADOV: New calculations of the Weyl sums. S. A. TCHOUNIKHIN: Some problems of the group theory. B. V. NUMEROV: The photographic meridian circle. L. S. LEIBENSON: The flexual centre of closed thin-walled sections. A. V. MITKEVITCH: The separation of magnetic viscosity and eddy current lag. N. A. and V. A. PREDBRAZHENSKIJ: Alkaloids of the leaves of jaborandi (*Pilocarpus*). (7) The splitting up of the unstable ethyl-paraconic acid (racemic pilopic acid) into optical isomers. A. E. FERSMAN: The geochemical characteristics of protocrystallisation. V. T. MALYSHEK and A. A. MALIANG: Sulphur bacteria in the 'pink' waters of the Surukhani oil-fields and their significance in the geochemistry of water. B. A. RUBIN and V. E. TRUPP: (1) Variations in keeping qualities of different varieties of vegetables, and the reasons for them. (2) Characteristics of the amylase of cabbage. N. ANNENKOVA: On *Dyspohetus pygmæus*, Levinsen, and *Euzonus arcticus*, Griebe (Polychæta). S. S. SMIRNOV: The occurrence of *Acartia tonsa* (Copepoda) in the Bay of Finland.

ROME

Royal National Academy of the Lincei, June 16. TH. MOTZKIN: Some characteristic properties of limited, non-convex ensembles. V. BERNSTEIN: Observations on a theorem of Fabry. F. CONFORTO: The calculation of a particular functional for the functions which render it stationary. G. POMPILI: Algebraic surfaces with plane hyper-elliptic sections of the species $p \geq 2$. L. TOSCANO: Permutable operators with the power of a special linear operator. MARIA PASTORI: Tensors linked to a system of geodetics. G. BOZZA: Decantation of crystalline suspensions (3). Continuous cylindrical decantors. L. MAZZA: Magnetic susceptibility of mixed oxides of the rare earths: mixtures of neodymium with praseodymium or samarium (1). With mixtures of Nd_2O_3 and Sm_2O_3, the magnetic susceptibility varies linearly with the composition. With $Pr_6O_{11}-Nd_2O_3$, however, the susceptibility is greater than that calculated additively for 0–25 per cent of Pr_6O_{11} and less for higher proportions. G. DEVOTO: The structure of antipyrin in aqueous solution. The results of measurements of the dielectric constants of antipyrin and pyramidon in aqueous solutions are not in accord with amphoteric polar formulæ for these compounds, and do not confirm the classical formulæ with double linkings. V. FAMIANI: The action of bromine on the growth and metamorphosis of the larvæ of *Bufo vulgaris*. Suitable small proportions of bromine cause the metamorphosis to begin earlier; but also render it distinctly out of adjustment. Indeed, if no corrective is applied, the life of the animal may be endangered.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Sunday, December 29

BRITISH MUSEUM (NATURAL HISTORY), at 3 and 4.30.—M. A. Phillips: "Fossil Reptiles".*

Monday, December 30

BRITISH MUSEUM (NATURAL HISTORY), at 11.30.—M. Burton: "Microscopic Animals and Man".*

Tuesday, December 31

BRITISH PSYCHOLOGICAL SOCIETY (EDUCATION SECTION), at 2.30.—(at University College, Gower Street, W.C.).—Sir Philip Hartog: "Some Aspects of the Validity and Reliability of Examinations".

Wednesday, January 1

ROYAL SOCIETY OF ARTS, at 3.—Prof. David Katz: "Animal Intelligence" (Dr. Mann Juvenile Lectures. Succeeding lecture on January 8).

GEOGRAPHICAL ASSOCIATION, January 1–3. Annual Conference to be held at the London School of Economics, Houghton Street, Aldwych, London, W.C.2.

J. Fairgrieve: "Can We Teach Geography Better?" (Presidential Address).

SCIENCE MASTERS' ASSOCIATION, January 1–4. Thirty-sixth annual meeting to be held in the Chemistry Department, Imperial College of Science and Technology, South Kensington, London, S.W.7.

Sir William Bragg: "School Science after School" (Presidential Address).

Society of Biological Chemists, India. Influence of Light on some Biochemical Processes. By Dr. N. R. Dhar. Pp. iv+73. (Bangalore: Indian Institute of Science.) 1 rupee. [912

Beiträge zur Erforschung der baulichen Struktur der Backenzähne des Hausrindes (*Bos taurus* L.): Die Prämolar- und Molarentwicklung auf Grund röntgenologischer, histogenetischer und morphologischer Untersuchungen: Die gegenseitigen Beziehungen der einzelnen Gebisskonstituenten und ihre Heranzichung zur physiologischen Leistung. Von Max Küpfer. (Denkschriften der Schweizerischen Naturforschenden Gesellschaft, Band 70, Abh. 1.) Pp. ix+218+78 plates. (Zürich: Gebrüder Fretz A.-G.) [912

The Academy of Natural Sciences of Philadelphia. Monographs, No. 1: The Scrophulariaceæ of Eastern Temperate North America. By Francis W. Pennell. Pp. xiv+650. (Philadelphia: Academy of Natural Sciences.) [1212

The Rockefeller Foundation: International Health Division. Annual Report, 1934. Pp. iv+235. (New York: The Rockefeller Foundation.) [1212

Ministry of Agriculture, Egypt: Technical and Scientific Service. Bulletin No. 161: Sugar Cane Breeding in Egypt; a Progress Report. By Arthur H. Rosenfeld. Pp. 21+3 plates. (Cairo: Government Press.) 3 P.T. [1212

The Nucleus of the Atom and its Structure. (Sigma XI Symposium, Ohio State University.) Pp. 104. (Columbus, Ohio: Ohio State University). 1 dollar. [1212

Thalès: recueil annuel des travaux de l'Institut d'Histoire des Sciences et des Techniques de l'Université de Paris. Année 1, 1934. Pp. xix+184. (Paris: Félix Alcan.) 30 francs. [1212

Recent Scientific and Technical Books

Volumes marked with an asterisk (*) have been received at "NATURE" Office

Mathematics : Mechanics : Physics

Aourriol, J. B. Chaleur. 8vo. Pp. 304. (Paris : Gauthier-Villars, 1935.) 35 francs.

Ballard, P. B., and **Hamilton, E. R.** Fundamental Geometry. Cr. 8vo. First Series, Pupil's Book 3. Pp. 48. Paper, 8*d.*; cloth, 10*d.* First Series, Books 1, 2 and 3, Teacher's Book. Pp. 94. 2*s.* 9*d.* (London : University of London Press, Ltd., 1935.)

Bate, W. G. Everyday Life Arithmetic. Imp. 16mo. Book 2. Pp. vi +74 +24. 1*s.* 9*d.* net. Book 3. Pp. v + 82 +21. 2*s.* net. (London : Sir Isaac Pitman and Sons, Ltd., 1935.)

Carathéodory, Constantin. Variationsrechnung und partielle Differentialgleichungen Erster Ordnung. Med. 8vo. Pp. xi +407. (Leipzig und Berlin : B. G. Teubner, 1935.) 22 gold marks.*

Department of Scientific and Industrial Research: Illumination Research. Technical Paper No. 1 : The Terminology of Illumination and Vision. Second edition, revised. Roy. 8vo. Pp. iv +24. (London : H.M. Stationery Office, 1935.) 6*d.* net.*

Ebner, F. Technische Mathematik : Differential- und Integralrechnung. Unter Mitarbeit von L. Roth. (Teubners H.T.L.-Bücherei, Band 154.) Roy. 8vo. Pp. 167. (Leipzig und Berlin : B. G. Teubner, 1935.) 4 gold marks.

Faraday. Faraday's Diary : being the various Philosophical Notes of Experimental Investigation made by Michael Faraday, D.C.L., F.R.S., during the Years 1820–1862 and bequeathed by him to the Royal Institution of Great Britain, Now, by order of the Managers, printed and published for the first time, under the Editorial supervision of Thomas Martin. Vol. 6 : Nov. 11, 1851–Nov. 5, 1855. Roy. 8vo. Pp. xiv +495 +8 plates. (London : G. Bell and Sons, Ltd., 1935.) 7 vols., £12 12*s.* net.*

Flügge, W. Statik und Dynamik der Schalen. 8vo. Pp. 240. (Berlin : Julius Springer, 1934.) 21 gold marks.

Fuchs, R., Hopf, L., und **Seewald, Fr.,** Herausgegeben von. Aerodynamik. Zweite völlig neubearbeitete und erganzte Auflage der "Aerodynamik" von R. Fuchs und L. Hopf. 3 Bände. Roy. 8vo. Band 1 : Mechanik des Flugzeugs. Pp. 339. (Berlin : Julius Springer, 1934.) 30 gold marks.

Fulford, R. J. Revision and Mental Tests in Arithmetic, Trigonometry and Algebra. Cr. 8vo. Pp. viii +91. (London : University Tutorial Press, Ltd., 1935.) 1*s.*

Knoblauch, O., und **Koch, W.** Technisch-physikalisches Praktikum. Roy. 8vo. Pp. 167. (Berlin : Julius Springer, 1934.) 13.50 gold marks.

Lilliman, A. J. Tests in Mental Mathematics, Fcap. 8vo. Pupil's Book 3. Pp. iv +60. 10*d.* Teacher's Book 3. Pp. xii +76. 1*s.* 6*d.* (London, Bombay and Sydney : George G. Harrap and Co., Ltd., 1935.)

Lodge, Sir Oliver. My Philosophy : Representing My Views on the Many Functions of the Ether of Space. Cheap edition. Roy. 8vo. Pp. 318. (London : Ernest Benn, Ltd., 1935.) 7*s.* 6*d.* net.

Magie, William Francis. A Source Book in Physics. (Source Books in the History of the Sciences.) Med. 8vo. Pp. xiv +620. (New York and London : McGraw-Hill Book Co., Inc., 1935.) 30*s.* net.*

Marsh, M. C. Controlled Humidity in Industry. Roy. 8vo. Pp. 123. (London : Charles Griffin and Co., Ltd., 1935.) 6*s.* net.

Meissner, K. W. Spektroskopie. (Sammlung Göschen, Band 1091.) Pott 8vo. Pp. 180. (Berlin und Leipzig : Walter de Gruyter und Co., 1935.) 1.62 gold marks.

Menger, K., Herausgegeben von. Ergebnisse eines mathematischen Kolloquiums. Roy. 8vo. Heft 6 : 1933–34. Pp. 47. (Leipzig und Wien : Franz Deuticke, 1935.) 1.50 gold marks.

Müller, Horst. Führer durch die technische Mechanik. Roy. 8vo. Pp. 118. (Berlin : Julius Springer, 1935.) 8.50 gold marks.

Sitte, K. F. Mehrstufige Rahmenformeln : Flotte Verfahren und bequeme Formeln für Zehntausande von praktisch Fällen nebst der allgemeine Grundformeln, eine Anleitung, Zahlenbeispielen und Quellenangaben. Band 1. 8vo. Pp. 238. (Brünn : Rohrer Verlag, 1934.) 8 gold marks.

Engineering

Aspinall, H. Turner. Worked Examples in Electrotechnics. Part 1. Cr. 8vo. Pp. 156. (London : E. and F. N. Spon, Ltd., 1935.) 5*s.* net.

Bolton, D. J., Honey, Philip C., and **Richardson, N. S.** Electrical Water Heating : with Special Reference to the Domestic Storage Heater. Ex. Cr. 8vo. Pp. viii +192. (London : Chapman and Hall, Ltd., 1935.) 7*s.* 6*d.* net.*

Burrill, L. E. Ship Vibration : Simple Methods of Estimating Critical Frequencies. Roy. 8vo. (London : E. and F. N. Spon, Ltd., 1935.) 2*s.* 6*d.* net.

David, Pierre. Les filtres électriques : théorie, construction, applications. Deuxième édition augmentée d'un complément sur les systèmes sélectifs complexes. 8vo. Pp. 211. (Paris : Gauthier-Villars, 1935.) 50 francs.

De Ville, Eric. Elements of Electrical Engineering. Cr. 8vo. Pp. viii +216. (London, Glasgow and Bombay : Blackie and Son, Ltd., 1935.) 5*s.*

Eweis, M. Reibungs- und Undichtigkeitsverluste an Kolbenringen. (Forschungsheft 371.) Sup. Roy. 8vo. Pp. 23 +3 plates. (Berlin : V.D.I. Verlag G.m.b.H., 1935.) 5 gold marks.

Friedmann, W. Bestimmung der Biegewechselfestigkeit von Drähten : Bau einer entsprechenden Materialprüfmaschine. (Mitteilungen der Wöhlerinstitut, Braunschweig, Heft 32.) 8vo. Pp. 93. (Berlin : N.E.M.-Verlag, 1934.) 4.50 gold marks.

Goldingham, Arthur H. Diesel Engines. Third edition. Demy 8vo. Pp. 263. (London : E. and F. N. Spon, Ltd., 1935.) 10*s.* 6*d.* net.

Goldingham, Arthur H. High Speed Diesel Engines. New impression. Demy 8vo. Pp. 156. (London : E. and F. N. Spon, Ltd., 1935.) 5*s.* net.
